Surgical approaches for renal tumors

33

Joao Luiz Pippi Salle and Roman Jednak

The diagnosis of a renal tumor in children is always accompanied by great apprehension in the family and caregivers. Preoperative management has been extensively described in the previous chapter. The surgeon is an important member of the team managing such patients. A detailed and well-organized surgical plan not only facilitates complete tumor removal without spillage but also ensures accurate staging and improves patient survival. Surgical approaches can differ depending on the suspected diagnosis and patient age.[1] In order to decide on the best surgical strategy, several anatomic and physiologic points should be considered and deserve further discussion.

Anatomic relationships

Adjacent organs

The kidneys are located in the lumbar fossa surrounded by a layer of perinephric fat, which is covered by a thin fascial layer called Gerota's fascia. Organs and structures adjacent to the kidneys are:

- Posteriorly: diaphragm, psoas major, and quadratus lumborum muscles.
- Anteriorly:
  Right kidney: liver, hepatic flexure of the colon, second portion of the duodenum, adrenal gland.
  Left kidney: spleen, body of the pancreas, stomach, splenic flexure of the colon, adrenal gland.

Renal vasculature

The kidney has four vascular segments, termed apical, anterior, posterior, and basilar. A relative avascular plane exists between the junction of the anterior and posterior segments. This is the preferred line of incision whenever parenchymal incisions are necessary.

Arterial blood supply

Each segment is supplied by one or more arterial branches. Ligation of one of these branches results in devascularization of the corresponding renal segment since they are end arteries without collateral circulation. Multiple renal arteries occur unilaterally in 23% and bilaterally in 10% of the population.[2]

The kidney is susceptible to ischemia due to a very active aerobic metabolism. Experimental studies indicate that a warm ischemic time of up to 30 minutes can be sustained without significant functional loss.[3] Renal proximal tubular cells are the most sensitive to ischemia during arterial occlusion and may be damaged transiently or permanently depending on the duration and severity of the injury. When a long surgical period of ischemia is expected, external surface cooling or perfusion of the kidneys with cold solution instilled into the renal artery is required. External surface cooling is the more practical and less invasive of the two methods. It is preferable to keep the entire kidney covered with ice for 10–15 minutes after arterial occlusion. Temperatures of 20–25°C can be maintained using this method and animal and humans studies have shown that hypothermia to this degree allows for complete renal protection from arterial occlusion for up to 3 hours.[4] Generous preoperative and intraoperative hydration and the avoidance of unnecessary renal artery manipulation or traction are additional measures to protect against ischemic renal injury. The administration of mannitol 10–15 minutes prior to arterial occlusion is also beneficial, since it increases renal plasma flow, decreases intrarenal vascular resistance, minimizes cellular edema, and promotes an osmotic diuresis when renal circulation is re-established.[5,6] When renal ischemia is necessary for surgery, it is preferable to occlude the artery alone since the simultaneous occlusion of the artery and

vein seems to produce additional venous congestion and more renal damage.[5]

Venous drainage

Multiple renal veins are less common than multiple renal arteries. The right renal vein is shorter than the left and has no tributaries. The left renal vein is longer and has a thicker muscular layer. Injuries to the right renal vein occur more easily, given its thinner wall. Both renal veins enter the inferior vena cava (IVC) laterally. The left adrenal and gonadal veins are significant branches, draining into the left renal vein, and their presence has important implications for extensive vascular resections. Occlusion of the left renal vein at the level of the IVC will not significantly impair venous drainage of the left kidney, since collateral venous drainage can develop via the tributaries of the left renal vein. Involvement of the IVC by tumor thrombus has variable clinical repercussion, depending on the side as well as the level of involvement. Lower extremity edema, a varicocele, dilated superficial abdominal veins, proteinuria, pulmonary embolism, a right atrial mass or non-function of the involved kidney are all clinical signs suggestive of intravascular tumor extension.[7] Transabdominal color Doppler ultrasonography and magnetic resonance imaging (MRI) are the preferred studies when evaluating for intravascular tumor extension.[8] Tumor thrombus extending to the IVC is variable, and the more cephalad the extension the more difficult the surgical resection will be. Fortunately, the tumor thrombus does not usually invade the wall of the IVC and can be removed with the affected kidney using a simple venotomy. When the thrombus does involve the wall of the IVC, resection of the involved segment is required. Resection of the infrarenal segment of the IVC can usually be done safely, since a rich collateral circulation develops in most cases. With right-sided renal tumors, the suprarenal portion of the IVC can also be safely removed since venous drainage from the left kidney can occur via the gonadal and adrenal tributaries. A similar resection cannot be performed for left renal tumors, since there is no significant collateral venous circulation for the right renal vein once drainage to the IVC is interrupted. Knowledge of these anatomic particularities has great importance when planning the surgical strategy for renal tumors with vascular involvement.

Collecting system

Each renal segment contains one or more major calices draining the corresponding portion of the kidney. In total, 8–10 major calices open into the renal pelvis. An understanding of the caliceal anatomy is required when performing partial nephrectomy if one is to adequately repair the collecting system if it is entered during tumor resection.

Preoperative evaluation

Laboratory investigations

All children should have a preoperative hemoglobin level, a white blood cell (WBC) count with differential, and a platelet count. Acquired von Willebrand's disease can occur in up to 8% of patients, and consideration may be given to performing a bleeding time.[9] Renal function should be assessed with serum electrolytes, along with a serum creatinine and blood urea nitrogen (BUN) level. Liver function testing should include serum aspartate aminotransferase (AST), serum alanine aminotransferase (ALT), total bilirubin, and alkaline phosphatase. The serum calcium level should be checked, since it may be elevated in children with congenital mesoblastic nephroma and rhabdoid tumor of the kidney.[9] Urinalysis and urine culture complete the laboratory investigations. Patients with suspected or proven urinary tract infection should receive 48 hours of antibiotic therapy since severe bacteremia can occur following manipulation of an infected kidney.

Radiologic imaging

The goal of preoperative imaging is to evaluate local extension of the mass, assess for possible contralateral lesions, confirm adequate contralateral renal function, and evaluate for possible vascular invasion. Ultrasonography can confirm the organ of origin and the solid nature of the lesion. Doppler assessment of the renal vein and IVC is essential when evaluating for intravascular tumor extension.[7] Computer tomography (CT) can assess the degree of local involvement and regional extension. The contralateral kidney should also be carefully assessed for additional masses and adequate function. Three-dimensional reconstruction of CT images is important when a partial nephrectomy is planned.[10] MRI is excellent for mapping intravascular tumor extension and can be used when the ultrasound results are inconclusive.[8] Chest radiographs and a chest CT are performed to identify pulmonary lesions.

Certain investigations are necessary only with specific types of tumors. Renal cell carcinoma and clear

cell carcinoma tend to metastasize to bone. Consequently, patients should undergo a bone scan and skeletal survey.[11] Brain metastases can occur with both clear cell sarcoma and rhabdoid tumor of the kidney; therefore, a head MRI or CT scan should be performed in these patients.[12]

The surgical management of Wilms' tumor

Patient preparation

Proper patient preparation and positioning is essential for an optimal surgical outcome. The incision should allow for unhindered access to the tumor mass, enable the surgeon to accurately assess the abdomen for staging purposes, and allow the surgeon to deal appropriately with potential complications should they develop. The typical incision is transverse, extending from the tip of the 12th rib on the affected side to the lateral margin of the opposite rectus muscle. Some surgeons prefer to extend the incision further, by taking it to the tip of the 12th rib on the opposite side.

The placement of intravenous (IV) lines in the lower extremities should be avoided. This is particularly important when tumor thrombus extends into the renal vein or vena cava and surgical management is anticipated. The placement of an arterial line is recommended to accurately measure mean arterial blood pressure. This is especially important in patients with large tumors or vascular involvement.

Most solid renal tumors in children are malignant. The most prevalent diagnosis in younger patients is Wilms' tumor. Renal cell carcinoma occurs more commonly in older children and adolescents. Patient age therefore has potential implications when planning the surgical strategy. Preoperative management, as well as the timing for surgical intervention in children with Wilms' tumor, has been discussed earlier.

Surgical principles

Adequate exposure is essential and is usually achieved via a transabdominal, transperitoneal incision. Prior to nephrectomy, a complete abdominal exploration should be performed and the kidneys palpated and inspected completely to exclude bilateral pathology. The entire abdominal cavity is inspected in order to rule out macroscopic metastatic disease and to provide surgical staging. Gerota's fascia of the contralateral kidney should be opened, and both the anterior and posterior renal surfaces inspected. This must be performed routinely, since preoperative imaging may miss approximately 6% of bilateral Wilms' tumors (although the necessity for contralateral exploration is controversial, as survival rates are not different in those with contralateral metachronous tumor). Most of these missed tumors are <2 cm, and their removal has an excellent outcome.[13,14] Suspicious areas within the kidney parenchyma noted on preoperative imaging should be biopsied. Chemotherapy should be the initial approach when bilateral Wilms' tumor is encountered. Suspected residual tumor is removed following chemotherapy.[15,16] Similarly, areas suspicious for abdominal metastases should be biopsied and marked with small titanium clips. At the time of surgical resection, clipping is recommended to mark areas of possible residual tumor and resection margins. Biopsy of the tumor prior to nephrectomy should be avoided in order to prevent tumor spillage.

Nephrectomy

The left colon is reflected to achieve adequate renal exposure and access to the great vessels. Division of the splenocolic ligament facilitates colonic mobilization and avoids excessive traction and possible splenic injury. On the right side, the colon and duodenum are mobilized in order to get adequate access to the IVC and aorta.

Exposure and ligation of the renal vessels should be attempted, if technically feasible, prior to mobilizing the kidney, in order to reduce the risk of hematogenous tumor dissemination. As previously mentioned, the renal vein is shorter on the right, and care must be taken to avoid injury to the IVC. The right renal artery can be dissected either lateral to the vena cava or between the vena cava and aorta. The latter approach can be helpful with large tumors that extend medially. The renal vein is longer on the left and passes over the aorta. Tributaries of the left renal vein include the gonadal, adrenal, and lumbar veins, and care must be taken to avoid their inadvertent injury. The left renal artery is located by retracting the renal vein. Early ligation of the renal vessels may not be possible with large tumors, and a technically difficult or dangerous dissection should not be attempted.

Biopsies should not be taken prior to tumor resection in order to avoid tumor spillage. Rupture of the renal capsule or tumor spillage into the peritoneum will upgrade the tumor stage. Gerota's fascia should be removed with the kidney, since extension into the perinephic fat can occur and is an important factor

when staging the disease. The adrenal gland may be preserved if it is not adjacent to the tumor mass. The presence of an upper pole tumor usually requires removal of the ipsilateral adrenal gland. Ureteral ligature is performed as distal as convenient, but complete resection of the ureter is not necessary.

Radical resection of involved organs should be undertaken only if complete resection of tumor is possible. If complete resection is not technically possible, a tumor biopsy should be performed. Since tumor often adheres to and compresses surrounding organs without actual invasion, chemotherapy can be used to shrink the tumor and subsequently allow resection with preservation of adjacent structures. Titanium clips should be used to mark suspicious areas, resection margins, and residual tumor in order to guide future radiologic investigation or radiation planning. Clips should not be used for hemostasis, and the number used should be kept to a minimum.

Inoperable tumors

Occasionally a tumor is found involving vital structures and is considered inoperable. It is important to keep in mind that large tumors may give the misleading appearance of extension into adjacent organs. They often compress or adhere to these structures without true invasion and are amenable to complete resection. This notwithstanding, consideration on the part of the surgeon should include the feasibility of safe removal of these large tumors. Intraoperative rupture and peritoneal spillage upstage the disease when they occur and necessitate postoperative radiation. This is usually worse for prognosis than biopsy, chemotherapy, and eventual resection. Unresectable tumors should be considered stage III and treated accordingly.[17]

Lymph node sampling

A formal lymph node dissection is not required.[18] In addition to assessing for hilar lymph node involvement, routine lymph node sampling should be performed from the iliac, para-aortic, and celiac regions. All suspicious lymph nodes require excision.

Intravascular invasion

Careful palpation of the renal vein and IVC can reveal evidence of intravascular invasion. Intracaval tumor extension occurs in 4% of patients.[7] This is particularly important to keep in mind when patients present with lower extremity edema, varicocele, dilated superficial abdominal veins, proteinuria, pulmonary embolism, a right atrial mass, or non-function of the involved kidney.

Intravascular tumor extension should be removed en bloc with the kidney if possible. Left-sided renal tumors with IVC involvement present a greater technical challenge than similar right-sided tumors. The right renal vein lacks significant tributaries to provide collateral venous drainage in the absence of the IVC. Tumor extension above the hepatic veins can be treated with preoperative chemotherapy. Tumor thrombus unresponsive to chemotherapy and involving the vena cava above the hepatic veins should be resected with the assistance of the cardiac surgery team, especially if atrial involvement is present. A midline thoracoabdominal incision is required in such cases. A chevron transabdominal incision is preferred when there is renal vein or infrahepatic vena caval involvement. The renal artery and ureter are ligated and divided, and the entire kidney is mobilized outside Gerota's fascia. The kidney is left attached only by the involved renal vein. It is important to avoid excessive mobilization of the renal vein and IVC in order to avoid displacement of the tumor thrombus. The IVC is dissected and controlled above and below the renal veins and any additional small tributaries are also controlled and ligated. The contralateral renal vein is controlled as well. The anterior surface of the renal vein is incised over the thrombus and the incision is then continued posteriorly beneath the thrombus. In the majority of cases there is no attachment of the thrombus to the wall of the vena cava, and gentle traction on the kidney extracts the thrombus. At this point it is important to release the suprarenal vena cava and apply positive pulmonary pressure. This maneuver ensures that small remaining fragments of the thrombus are flushed from the vena cava, which is then repaired.[2]

When the thrombus is invading the wall of the vena cava, an en bloc resection is mandatory. Resection of the infrarenal portion of the vena cava can usually be performed safely because of the rich collateral circulation that develops in most cases. Resection of the suprarenal portion of the vena cava is also possible, but some important principles must be taken into consideration. For right-sided tumors, this resection can be accomplished provided ligation of the left renal vein is performed adjacent to the vena cava. This allows collateral circulation from the gonadal and adrenal veins to drain the left kidney. For left-sided tumors, a similar resection cannot be performed since right-sided renal venous drainage lacks a similar collateral network.

Tumor spillage and rupture

Peritoneal soiling during resection classifies the patient as stage III. It is important to define whether soiling is diffuse or local. Percutaneous needle biopsy is considered local spillage. An incisional biopsy at the time of surgery is considered local spillage unless the operating surgeon considers peritoneal soiling to have occurred. Tumor spillage is considered when the primary tumor capsule is violated or tumor is cut across during the dissection of adherent organs, lymph nodes, or intravascular tumor thrombus. Tumor rupture disseminates tumor cells throughout the peritoneal cavity. Bloody peritoneal fluid is a sign of major spillage. It is also important to describe if an intraoperative hematoma develops, since the hematogenous spread of tumor cells is presumed to occur in this case and necessitates a stage III classification. Finally, when tumor penetrates the renal capsule such that the free surface communicates with the peritoneum, major spillage is considered. It is very important to describe precisely how spillage occurs and to define it as local or diffuse.

Partial nephrectomy

Partial nephrectomy is not routinely indicated for Wilms' tumor except in the presence of bilateral disease or tumors in a solitary kidney. Partial nephrectomy in these situations is performed following an initial biopsy and course of chemotherapy to reduce tumor size. Partial nephrectomy can also play a role in the management of patients with underlying conditions predisposing to Wilms' tumor such as Beckwith–Wiedemann syndrome or WAGR syndrome.[19] Children with a solitary kidney or renal failure are also candidates.[13] The surgical principles for performing partial nephrectomy are described in detail later.

Pathology specimen

All surgical specimens should be submitted fresh and intact. Fixing the specimen in formalin should be avoided. The specimen should not be bivalved, since the capsule may retract and compromise the accuracy of staging on the basis of capsular invasion (i.e. distinguishing stage I from stage II disease).

Surgical outcome

The surgical outcome following nephrectomy for Wilms' tumor is very good. Despite the resection of large tumors approached primarily without preoperative reductive chemotherapy, the complication rate is 9.8%. Intestinal obstruction is the most common complication and occurs more commonly in patients undergoing preoperative chemotherapy. Not surprisingly, surgeons accustomed to regularly performing nephrectomies generate the lowest complication rates.[20]

Renal cell carcinoma

Wilms' tumor typically presents between 1 and 5 years of age, with 90% of tumors being diagnosed before age 7. Adolescent and adult Wilms' tumor does occur but is uncommon. Renal cell carcinoma (RCC) occurs infrequently in children and presents at a mean age of 9–10 years.[21] Notably, in children between the ages of 10 and 20, the incidence of RCC has been shown to be similar to the incidence of Wilms' tumor.[22]

No consensus has been reached as to the definitive form of therapy for RCC, but radical nephrectomy has been the main surgical approach. Primary treatment with partial nephrectomy has been reported in one pediatric case.[23] The adult form is aggressive and responds poorly to chemotherapy. Some authors have suggested a less aggressive course for the pediatric form of the disease, even when associated with positive lymph nodes. Like the adult form, however, disseminated disease predicts a poor outcome.[21,24]

Nephrectomy

When an RCC is suspected, a subcostal transperitoneal or extraperitoneal flank incision may be considered and does not appear to influence survival rates.[25] Should a Wilms' tumor be encountered, adequate staging including lymph node sampling and perhaps inspection of the contralateral kidney is necessary. A subcostal incision can be easily extended in this case. Certain anatomic variables, such as a narrow subcostal angle, may make a midline transperitoneal approach more appropriate. Certainly, any case potentially requiring vascular access to the superior vena cava or right atrium should be approached via a midline approach, since the incision can be extended as a median sternotomy. A transverse transperitoneal or chevron incision gives good exposure to the lateral and superior aspects of the kidney in addition to the great vessels.[2]

Radical nephrectomy for RCC is performed following the same principles as described for Wilms' tumor. This also applies to the surgical approaches for tumors with vascular invasion. An important difference in the tumor biology of these two lesions has

important implications on the surgical approach to RCC, however. RCC responds poorly to both chemotherapy and external beam radiation. As a consequence, complete surgical resection is mandatory in order to optimize chances for a long-term cure.[26] Quek et al[27] reviewed their experience with 99 adult patients having intravascular tumor extension. The tumor extended to the renal vein in 31 patients, infrahepatic vena cava in 22 patients, intrahepatic vena cava in 34 patients, and right atrium in 12 patients. Overall 2- and 5-year survival rates following extensive resection were 54% and 33%, respectively. They advocated an aggressive surgical approach for those patients with clinically confined tumors with isolated venous tumor thrombus extension.[27] There are no similar studies in pediatric patients.

Partial nephrectomy

The main difference in the initial surgical approach to RCC in comparison to Wilms' tumor lies in the application of partial nephrectomy: partial nephrectomy for Wilms' tumor is deferred until completion of an initial course of chemotherapy, whereas partial nephrectomy for RCC can be used as the primary surgical approach in appropriately selected cases. An adequate resection should leave 1 cm margins of normal parenchyma surrounding the tumor.[2] It is important to remember that data on the success of partial nephrectomy for RCC have been collected from series in adults. Nevertheless the 90–100% cancer-specific survival obtained in adults with lesions of <4 cm is encouraging.[10]

Most cases of partial nephrectomy necessitate transient ischemia to the kidney. Certain points are important to understand before proceeding with the surgery. Renal tolerance to warm ischemia is approximately 30 minutes, as derived from canine studies.[3] Cold ischemia is tolerated for up to 3 hours.[28] Prior to partial nephrectomy, the core temperature of the kidney should therefore be lowered by placing it on ice for 10–15 minutes after clamping the artery.[4] Immediately after renal artery occlusion, there is an accumulation of monophosphate nucleotides produced by ATP degradation within the kidney. Progressive loss of ATP depletes cellular energy reserves, causing dysfunction of the cellular membrane, influx of water and salt, cellular edema, and ultimately cellular death. Proximal tubular cells are the most predisposed to injury during ischemia, whereas glomeruli and blood vessels are more resistant.[29] When the renal artery and vein are occluded simultaneously, renal damage is more pronounced.[30] Solitary kidneys and kidneys with extensive collateral circulation seem to better tolerate longer periods of renal ischemia.[31,32] Experimental studies indicate that manual renal compression to control intraoperative hemorrhage seems to cause more renal injury than simple arterial occlusion.[5] Protective factors that can be used to reduce ischemic damage include adequate hydration, avoiding hypotension, minimizing arterial manipulation, and the administration of mannitol 5–15 minutes prior to arterial occlusion.[6]

Advances in renal imaging can allow for detailed reconstruction of renal anatomy when preparing for partial nephrectomy. Specific indications for partial nephrectomy for RCC include solitary kidney, compromised renal function, the presence of a benign disease that could compromise future renal function, or bilateral tumors.[33] Further studies clarified success of partial nephrectomy in patients with localized disease <4 cm and a normal contralateral kidney.[34,35] The major disadvantage of partial nephrectomy for RCC is the risk of missing multifocal disease predisposing to local tumor recurrence. This can occur in 4–6% of patients.[33,36,37] The technical success rate is excellent, and operative morbidity and mortality is low. Long-term cancer-free survival for low-stage disease is comparable to radical nephrectomy. The overall incidence of local recurrence is low, at 0–10%. For tumors ≤4 cm, local recurrence rates are even less, at 0–3%. The risk of local recurrence depends primarily on the initial local pathologic tumor stage. The reported incidence of multifocal renal cell carcinoma is approximately 15%, but it also depends on tumor size, histology, and stage. The pathologic risk of multifocal disease is <5% when the maximal diameter of the primary tumor is ≤4 cm.[10]

An extraperitoneal flank incision is preferred for partial nephrectomy. Optimal exposure is accomplished without the need to remove a rib in most children. The kidney is mobilized, leaving Gerota's fascia intact. Arterial control is not necessary for small peripheral lesions. Temporary arterial occlusion is recommended for larger lesions. Occlusion of both the renal vein and artery can further minimize bleeding for large lesions or for those that are centrally located. After occluding the renal vessels, the kidney should be surface-cooled in ice slush for 10–15 minutes. It is not advisable to perfuse the renal artery with cold solutions, because of the risk of tumor dissemination.[2] Depending on the characteristics of the lesion, partial nephrectomy can be performed using simple enucleation, polar segmental nephrectomy,

wedge resection, transverse resection, or extracorporeal partial nephrectomy. In every case, regardless of the technique used, it is essential to remove the tumor completely, leaving a small surrounding margin of grossly normal renal parenchyma. Intraoperative ultrasonography can be helpful in delineating tumor margins and enabling a complete safe resection. This is especially helpful in central or poorly defined lesions. As the resection is carried through the renal parenchyma, arterial and venous branches are identified and suture ligated to minimize excessive bleeding following vascular unclamping. The collecting system should be repaired with absorbable sutures if entered. Frozen section biopsies of the tumor bed should be obtained following resection. Further resection is required if tumor is identified in the biopsy specimens.

Segmental polar nephrectomy

Segmental polar nephrectomy is performed in patients with a tumor mass confined to the upper or lower pole of the kidney. The arterial and venous branches supplying the corresponding pole are first ligated and divided. An ischemic line of demarcation generally appears, outlining the limits of the segment to be excised. For obvious reasons it is not possible to spare the renal capsule, as it overlies the tumor area. Simple, interrupted 2–0 or 3–0 chromic sutures are placed in the renal edges and perirenal fat or Oxycel secured within the defect.

Wedge resection

Wedge resections are necessary for non-polar, peripheral lesions. As significant bleeding can occur during

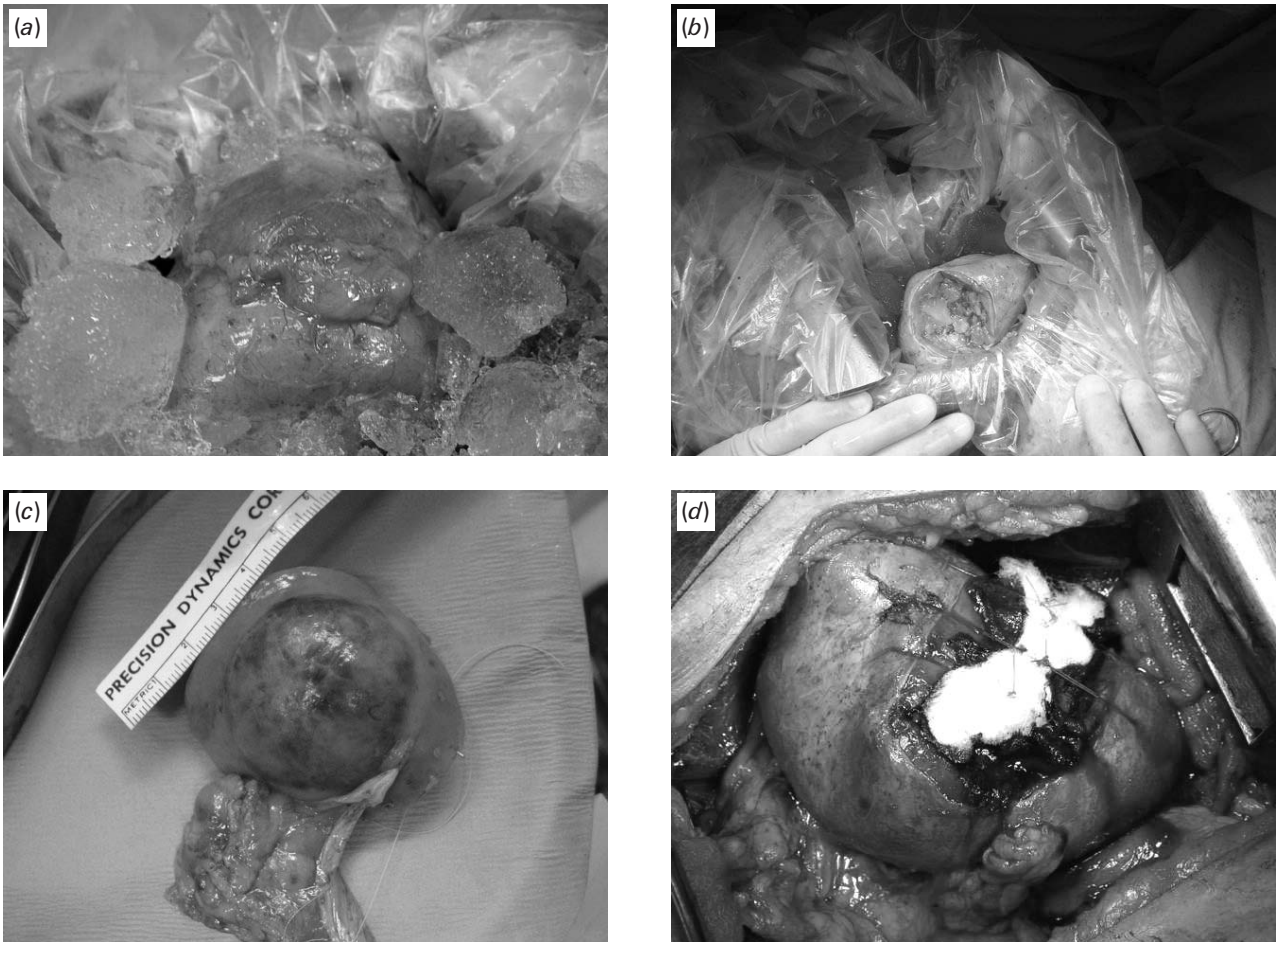

Figure 33.1 (*a*) Renal cell carcinoma in a 12-year-old child with tuberous sclerosis. The renal artery has been temporarily occluded and the kidney cooled with ice slush. Note that perinephric fat is left attached to the tumor. (*b*) A wedge partial nephrectomy performed in the midpole of the kidney. The arterial and venous branches suture ligated during the excision of the tumor. (*c*) The tumor is removed with a margin of normal parenchyma around the periphery of the lesion. (*d*) The renal artery has been unclamped and the kidney revascularized. Oxycel has been placed in the renal defect.

this procedure, it is advisable to control the renal artery with the application of surface hypothermia. The procedure is then carried out in a fashion similar to that described above for segmental nephrectomy (Figure 33.1).

Transverse resection

Transverse resection is used for large tumors involving the upper or lower renal pole. It is important to identify the major arterial and venous branches close to the hilum in this situation. Following ligation and division of the vessels, the ischemic portion of the kidney along with the tumor and a margin of normal tissue are removed.

Central tumors

Central tumors present a technically more challenging problem. Preoperative imaging with three-dimensional CT reconstruction is mandatory to outline the vascular anatomy. The dissection is carried out close to the central renal vessels and, consequently, significant arterial and venous bleeding may occur. Both the renal artery and vein need to be transiently occluded.[2] Only the smaller arterial branches providing blood supply to the tumor area should be clamped and divided. Arteries supplying the normal parenchyma should be carefully spared, since they are end arteries and their division will permanently devascularize the corresponding normal renal segment. Intraoperative ultrasonography can be a valuable tool in identifying central tumors, which are not easily palpable and consequently difficult to localize.

Simple enucleation

Simple enucleation is sometimes indicated in patients having received preoperative chemotherapy for bilateral Wilms' tumor or patients with von Hippel–Lindau disease and multiple low-stage encapsulated tumors.[38–40]

Extracorporeal partial nephrectomy

Extracorporeal partial nephrectomy and renal autotransplantation is a good option for tumors involving the renal hilum. Although this procedure has the advantage of providing a bloodless surgical field and allowing for a precise dissection, the surgical time is increased since a vascular anastomosis is required. It is preferable to leave the ureter attached during surgery if possible, but if necessary it can be divided. Care must be taken to avoid injury to the vascular supply of the ureter and pelvis during removal of tumors close to the hilum or those involving the lower pole.

Complications of partial nephrectomy

Complications of partial nephrectomy include hemorrhage, urinary fistula formation, ureteral obstruction, renal insufficiency, and infection.

Congenital mesoblastic nephroma

Nephrectomy for infants with congenital mesoblastic nephroma (CMN) should be performed with great care to avoid leaving behind residual tumor. This is particularly important for cellular variants of CMN and infants older than 3 months of age. Special attention should be given to the dissection of the renal hilum, which is the most common location for invasion and local recurrence.[41,42]

Douglas A Husmann

Similarities and differences in evaluating pediatric versus adult traumatic injuries

General comments

Whether the incidence of renal injury following blunt abdominal trauma is increased in the pediatric compared with the adult patient population is controversial.[1–4] Hypothetically, the pediatric kidney is believed to be more susceptible to trauma due to a decrease in the physical renal protective mechanisms found in childhood: i.e. a slightly lower renal position in the abdomen, an immature thoracic cage, and weaker abdominal musculature. Statistical evaluations to confirm that children have an increased risk of renal injury have revealed mixed results and the question remains unresolved.[1–5] What is known, however, is that pre-existing congenital renal abnormalities are found 3–5-fold more commonly in pediatric patients undergoing a screening computed tomography (CT) scan for trauma than the adult population.[2–4,6] Classically, patients with a pre-existing genitourinary (GU) abnormality present with a history of hematuria disproportionate to the severity of trauma. In the pediatric population the most common pre-existing GU anomalies found, listed in decreasing frequency, are: ureteropelvic junction (UPJ) obstruction, hydroureteronephrosis secondary to reflux, horseshoe kidney, non-obstructing, non-refluxing hydronephrosis/hydroureteronephrosis, and primary obstructing megaureter.[2–4]

Traumatic induced hematuria

In children, hematuria is unreliable for determining the extent of renal injury; indeed, some studies have failed to find any evidence of either gross or microscopic hematuria in up to 70% of children sustaining grade 2 or higher renal injuries (Table 34.1). In essence, post-traumatic hematuria cannot be used as the sole determinant in deciding whether or not to screen the child for the presence of a GU injury.[7,8]

Indications for imaging the genitourinary tract following trauma

In the adult, radiographic assessment of the GU tract is recommended following all penetrating trauma, as well as blunt trauma, victims that have one of four criteria:

1. A significant deceleration (motor vehicle accident (MVA), fall from >15 feet) or high-velocity injury (strike to the back or flank with a high-velocity foreign object, i.e. football helmet, baseball bat, etc.).
2. Significant external trauma resulting in fractures of thoracic bony structures, spine, pelvis, and femur, bruising of the torso/perineum and/or signs of peritoneal irritation.
3. Gross hematuria.
4. Microscopic hematuria (>50 red blood cells per high-power field (RBCs/HPF)) associated with shock (systolic blood pressure <90 mmHg).[4,9–12]

Clinicians debate about whether the adult screening criteria outlined above apply to children.[7,10,13–17] This controversy is based on three separate concerns. First, hypotension in children is not a reliable indicator of the severity of the injury. Children often have normal blood pressure in spite of significant blood loss. In children, a fall in serial hemoglobin or hematocrit value is a better determinant of blood loss than hypotension.[14] Secondly, there is not a consensus opinion in the literature regarding the definition of an associated injury in the child. For example, does an isolated closed head injury indicate the need for a screening abdominal CT?[7] Finally, there is no standard definition of a deceleration or high-velocity injury with some authors neglecting to include the latter criteria in their list of indications for abdominal three-dimensional imaging.

To help end this controversy, in 2004 Santucci and

associates reviewed all of the previous data regarding traumatic renal injuries in children.[10] In this excellent review article, they found that use of adult screening criteria is highly accurate and applicable in children. We currently recommend the same radiographic screening criteria noted in the first paragraph of this section be used in both children and adults.

Radiographic and endoscopic assessment and treatment of genitourinary injuries

Abdominal and pelvic computed tomography and single-shot intravenous pyelography

The patient's hemodynamic stability determines whether, when, and occasionally what type of imaging studies should be done. In the clinically stable patient, a triphasic abdominal and pelvic CT scan (precontrast study, followed by a study immediately after injection of contrast, and then a 15–20 minute delayed study) is the most sensitive method for diagnosis and classification of GU trauma (see Table 34.1 for classification of renal trauma[4,7,8,10,11,15,16]).

In the clinically unstable patient, a single-phase CT scan is frequently obtained, with the images taken immediately following injection of contrast. In our experience, this test is beneficial in determining renal perfusion and the presence of major renal fractures, but will be unable to accurately determine the presence of urinary extravasation and will miss the majority of the isolated ureteral injuries.[2,18,19] In the unstable patient requiring emergent laparotomy, with no preoperative imaging studies obtained, once the patient is stabilized in the operating room, a single-shot intravenous pyelogram (IVP) (2 ml/kg intravenous bolus of contrast), with the X-ray taken 10–15 minutes following injection of contrast, may be of benefit. In our experience, this study frequently results in a poor imaging of the urinary tract. These unstable patients usually have a history of profound hypotension, associated with poor renal perfusion and subsequently poor excretion and visualization of contrast. The main benefit of a single-shot IVP may be to detect a normally functioning contralateral kidney if unilateral nephrectomy is a consideration. As an alternative to the single-shot IVP, the patient can be resuscitated and a delayed CT evaluation is obtained. If necessary, a definitive surgical repair of any GU injury is subsequently deferred for 12–24 hours.[4,20]

Table 34.1 Grading of renal injuries

Grade of renal injury	Description
1	Renal contusion or subcapsular hematoma
2	Non-expanding perirenal hematoma, <1 cm parenchymal laceration, no urinary extravasation, all renal fragments viable
3	Non-expanding perirenal hematoma, >1 cm parenchymal laceration, no urinary extravasation, renal fragments may be viable or devitalized
4	Laceration extending into the collecting system with urinary extravasation, renal fragments may be viable or devitalized or Injury to the main renal vasculature with contained hemorrhage
5	Completely shattered kidney, by definition multiple major lacerations of >1 cm associated with multiple devitalized fragments or Injury to the main renal vasculature with uncontrolled hemorrhage, renal hilar avulsion

Indications and use of arteriography

Up to 25% of grade 3–4 renal trauma managed by non-operative protocols will require angiography and selective angioinfarction of bleeding vessels for persistent or delayed renal hemorrhage.[21,22] Clinical signs of persistent bleeding are hematuria associated with blood clots in the voided or catheterized bladder and a falling serial hemoglobin. Orthostatic blood pressure alterations are a late finding in the pediatric patient population.[4,21,23–25] Delayed hemorrhage classically develops 10–14 days post injury, but may occur up to 1 month following the traumatic insult. Delayed hemorrhage usually arises from the development of arteriovenous (AV) or pseudoaneurysm malformations.[4,23–25] Unlike AV malformations arising from a renal biopsy, AV malformations following

renal fractures rarely, if ever, resolve spontaneously: nearly all require active intervention.[4,23–25]

Superselective angiographic embolization of isolated renal artery branches for persistent or delayed hemorrhage has a success rate approaching 80%. This is the preferred treatment method for persistent or delayed bleeding. Surgical exploration is reserved for angiographic embolization failure.[4,23–25] Occasionally, angiographic embolization is used to treat persistent urinary fistulas. In this clinical scenario, a functionally transected renal fragment following a grade 3, 4, or 5 renal injury is completely separated from the renal collecting system, and a persistent urinary fistula develops despite management by a double-J stent and/or a percutaneous nephrostomy tube. In these unusual patients, selective angiographic embolization can be performed to resolve the urinary fistula by necrosing the isolated functional renal fragment.[4,26]

Postembolization syndrome (fever, flank pain, and an adynamic ileus) is a well-recognized and self-limiting condition that occurs after angiographic embolization. Symptoms usually resolve by the 5th postembolization day.[4,27–30] Bacterial seeding of either the necrotic renal tissue or the hematoma from the angiographic intervention must be ruled out in patients with postembolization fever. It is therefore mandatory to obtain blood and urine cultures if a febrile response develops postembolization. If the fever persists for ≥5 days following angiographic infarction or if a patient becomes clinically labile, the clinician should consider a repeat CT scan with possible aspiration and culture of the hematoma/urinoma.[4,30]

Indications and use of retrograde pyelography and percutaneous drainage

In patients with a history of trauma, two indications exist for performing retrograde pyelography. First, to rule out the presence of a partial/total ureteral disruption and secondly to aid in placement of a double-J ureteral stent for the management of a symptomatic urinoma.[2–6,18,31] Most post-traumatic urinomas are asymptomatic. Approximately 75% of the urinomas spontaneously resolve.[4,31–34] Occasionally, the urine collection is associated with persistent flank pain, adynamic ileus, and/or low-grade temperature. In these cases we manage these patients with endoscopic intervention with cystoscopy, retrograde pyelography, and placement of a ureteral stent.[31] Although percutaneous drainage and internal stenting are both efficacious, the major advantages to internal drainage include improvements in quality of life during convalescence, specifically avoidance of external catheter care, and the reduced risk of inadvertent tube dislodgment.[4,31,32,35] A disadvantage of internal drainage is that stent placement and removal requires general anesthesia in the child. In addition, smaller ureteral stents (4–5 Fr) placed in young children occasionally become blocked with debris and blood clot from the dissolving hematoma. We recommend placement of percutanous nephrostomy tubes to manage urinomas in one of three situations:

1 Patients who have failed attempts at endoscopic management.
2 Patients who are unstable and therefore not candidates for general anesthesia.
3 Patients with persistent gross hematuria in whom we are afraid that the small-caliber ureteral stent will become occluded.[31,32]

Indications and use of DMSA and follow-up radiographic imaging following renal trauma

We do not recommend follow-up renal imaging for grade 1–2 renal injuries. In patients with grade 3, 4, and 5 renal injuries, a repeat CT scan with delayed images should be obtained 2–3 days after the traumatic insult. This study assesses the extent of the hematoma/urinoma and functions as a baseline evaluation in case delayed hemorrhage occurs.[4,6] Additional repeat CT scans are considered if fever, flank pain, and hematuria persist or increase.[6] A 3-month follow-up CT scan is ordered in all grade 3, 4, and 5 renal injuries. This latter study is used to verify resolution of a perinephric hematoma/urinoma and to define the anatomic configuration of the residual functioning renal parenchyma.[8]

Nuclear renal scanning using technetium 99m dimercaptosuccinic acid (^{99m}Tc DMSA) allows the physician to determine renal cortical function and differential renal function. Serial DMSA scans obtained post trauma have revealed that little if any renal parenchyma recovers function 7 days following injury; therefore, a DMSA scan obtained more than 1 week after the injury provides a valid estimate of subsequent renal function.[36,37] We suggest that all patients with grade 3 injuries with devitalized fragments, all grade 4 and 5 renal injuries, and all patients with persistent post-traumatic hypertension should be evaluated with a quantitative radionuclide scintigraphy, preferably DMSA. The study should be per-

formed at least 1 week after the traumatic insult.[4,36] Provided the serum creatinine is normal, a differential renal function exceeding 30% suggests satisfactory function that would prevent renal failure in the event that the uninjured kidney is lost.[4,34,37]

Effect of etiology on the management of traumatic genitourinary injuries

Blunt versus penetrating genitourinary trauma

The etiology of the traumatic injury plays an important role in determining the management of the patient. In North America, blunt trauma, usually high-velocity, or sudden deceleration injury causes approximately 90% of renal injuries in children. Fewer than 2% of the children with blunt renal trauma will require radiographic or surgical intervention.[4,6,8,33]

Approximately 10% of traumatic pediatric renal injuries result from penetrating trauma. In the presence of penetrating trauma, the physician should immediately triage the patient into one of two groups, depending on the source of the penetrating trauma: either a stab/low-velocity penetrating-wound group or a high-velocity penetrating-wound group.[4,6,8] Although penetrating trauma results in the risk of wound contamination by outside material, several studies have shown that a selective non-operative approach to the management of patients with stab wounds and, in very select cases, low-velocity gunshot wounds, can be safely implemented.[4,23,38] In hemodynamically stable patients with a penetrating wound posterior to the anterior axillary line, intravenous antibiotics are initiated and a screening triphasic abdominal and pelvic CT is obtained. In these patients surgical exploration/laparoscopy is indicated for persistent blood loss, the presence of air in the peritoneum, signs of developing peritonitis, or radiographic findings consistent with a ureteral injury.[4,23,38–41]

Gunshot wounds to the trunk are associated with a GU injury approximately 15% of the time.[39] In patients with GU trauma secondary to a gunshot wound, the kidney is the site of injury in approximately 60% of the patients, the bladder in 20%, the urethra in 5%, the ureter in 2%, and 13% will have two or more GU injuries.[39,42] If a GU structure is traumatically damaged as a result of a gunshot wound, the likelihood of associated organ injury is approximately 90%.[21,39,42] Although the majority of blunt renal trauma and the majority of penetrating renal trauma from stab wounds are amenable to complete radiographic staging and non-operative management, rarely are gunshot wounds to the kidney amenable to non-operative management. In most cases, gunshot wounds to the abdomen result in a hemodynamically unstable patient with multiple associated organ injuries that require urgent laparotomy. The need for emergent surgery excludes the ability to adequately stage the renal injury.[21,22,39] If the patients with a gunshot wound can undergo adequate radiographic staging, isolated grade 1 or 2 renal injuries can be managed successfully with a non-operative approach, with minimal complications[21] (Table 34.2).

Gunshot wounds caused by high-velocity missiles (>350 m/s) deserve special consideration. The kinetic energy of a high-velocity bullet creates a surrounding energy wave 30–40 times the missile diameter. In addition, the missile will frequently yaw or tumble during penetration; the combination of blast injury and missile tumbling results in extensive damage to the surrounding tissues at a large distance from its path.[6] With high-velocity gunshot wounds to the torso, radiographic and/or surgical evaluation at the time of the assault may not reveal the presence of a GU injury. In some patients with a high-velocity injury, the renal pelvis and/or ureter will appear intact or perhaps only slightly contused at the time of the radiographic examination and/or surgical exploration. As the high-velocity blast injury matures, necrosis of the ureter or portions of the renal pelvis may develop, the extent of the GU injury finally coming to attention as urinary extravasation develops as a result of delayed necrosis. Blast injuries to the urinary drainage system may only be apparent 3–5 days after the injury, when an increase in urine output from surgically placed drains is recorded.[4,43,44]

Management of renal trauma

Multiple studies have found that the nephrectomy rate in patients with traumatic renal injuries was higher with surgical exploration than with non-operative management.[34,38,45–47] These reports hypothesize that hemorrhage from the severely injured kidney is tamponaded (controlled) by an intact Gerota's fascia. Surgical exploration would disrupt the fascia, resulting in uncontrollable renal bleeding thereby increasing the need for emergency nephrectomy. This hypothesis is controversial. Current studies using the

Table 34.2 Consensus recommendations for management of renal trauma

Clinical findings and/or grade of renal injury	Recommended treatment
Grade 1 or 2 renal injury, irrespective of traumatic etiology	Non-operative
Isolated grade 3, 4, and hemodynamically stable grade 5 renal injuries	Non-operative
Uncontrollable renal hemorrhage/vascular instability (usually grade 4 vascular or the vast majority of grade 5 injuries)	Absolute requirement for surgical intervention
Persistent or delayed hemorrhage not responding to angiographic embolization	Absolute requirement for surgical intervention
Expanding pulsatile retroperitoneal mass found on surgical exploration for coexisting intra-abdominal injuries	Absolute requirement for surgical intervention (verify contralateral renal function prior to exploration)
Penetrating trauma; inadequate preoperative radiographic staging resulting from vascular instability of patient; retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration strongly recommended (verify contralateral renal function)
Blunt trauma; inadequate preoperative radiographic staging resulting from vascular instability of patient; coexisting intra-abdominal injuries, especially stomach, duodenum, pancreas and colon; retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration recommended (verify contralateral renal function)
Blunt trauma; radiographic screening studies reveal grade 3, grade 4, or 5 renal injury; coexisting intra-abdominal injuries, especially stomach, duodenum, pancreas, and colon	Retroperitoneal (renal) exploration recommended

combination of CT staging of renal injuries combined with the application of trauma-related severity scores, have revealed that emergency nephrectomy during renal exploration for trauma is directly related to the severity of the initial renal injury, and the presence of multiple coexisting injuries, not due to the disruption of Gerota's fascia and the release of a confined tamponade.[4,32,48–51]

Based on the hypothesis that Gerota's fascia would contain renal hemorrhage, three different concepts regarding the management of renal injuries exist:

1 Observation of all grades of renal injury, unless there is an absolute indication for renal exploration.[34,38,52]
2 If a laparotomy is to be performed for a coexisting intra-abdominal injury (especially stomach, duodenal, pancreatic and colonic injuries), renal exploration and renorrhapy of all renal injuries ≥ grade 3 should be simultaneously performed: grades 1 and 2 can be observed. At the time of surgery control of the renal vessels medial to Gerota's fascia should be obtained prior to renal exploration. The surgeon should repair the GU injury and provide drainage of the GU injury separate from the site of the coexisting injuries.[4,6,32,53] In this setting, control of the renal vessels prior to opening Gerota's fascia may prevent life-threatening hemorrhage. It should be noted that with the passage of time, even the need for vascular control before renal exploration has become controversial, with some studies revealing the incidence of nephrectomy being equivalent whether or not prior vascular control is used.[4,6,49,53]
3 In patients with concurrent intra-abdominal injuries, the trauma surgeon should separate the enteric injury from the urinary tract injury with omentum or other alternative tissue and places perioperative drains. All stages of renal injury can be observed if this situation it is hypothesized that the separation of the enteric or pancreatic injury from the GU injury by the omentum, along with the placement of perioperative drains, will prevent breakdown of enteric repairs by leaking urine and/or help prevent the development of urinary tract complications by removal of excess contaminating bacteria or pancreatic enzymes from the site of GU injury.[6,32,48,54,55]

Current recommendations for operative intervention on renal injuries are based on three findings: the hemodynamic stability of the patient, an accurate radiographic staging of the renal trauma, and the presence of associated organ injury.[4,6,21,31,32] Absolute indications for renal exploration include life-threatening hemorrhage from a renal source (usually grade 4 vascular and the vast majority of grade 5 renal injuries), a pulsatile expanding retroperitoneal hematoma found at emergency laparotomy, and persistent or delayed renal bleeding not responding to angioinfarction.[4,6] It is also strongly recommended that patients with penetrating trauma found to have a retroperitoneal hematoma in the absence of adequate preoperative imaging should be explored once contralateral renal function is verified by an intraoperative single-shot IVP.[4,6]

The ideal candidate for non-operative management is the hemodynamically stable patient sustaining either blunt or penetrating trauma, with or without associated intra-abdominal injuries, that has a grade 1–2 renal injury. GU complications in this subset of patients are minimal.[4,6,21] Patients with isolated grade 3, 4 and hemodynamically stable grade 5 renal injuries are also candidates for non-operative treatment. Even identification of a large perinephric hematoma or urinoma is not an absolute indication for operative management, provided the distal ureter is documented to be intact. Angiographic, endoscopic, or percutaneous intervention will eventually be required in up to 55% of the patients. Intervention is necessary for delayed bleeding in approximately 25%, and for symptomatic urinomas in approximately 25%. Surgical exploration to control complications not amenable to non-operative techniques will develop in approximately 5%. In essence, conservative management of isolated grade 3, 4 and hemodynamically stable grade 5 renal injuries will avoid the need for open surgical intervention in approximately 95% of renal injuries.[4,6,8,21,31,32,54,56]

Controversy regarding the management of blunt renal trauma currently involves two different patient populations:

1 Patients with inadequate radiographic staging found to have a non-expanding and non-pulsatile retroperitoneal hematoma found on surgical exploration.
2 Patients with a ≥ grade 3 renal injury undergoing laparotomy for associated intra-abdominal trauma especially if injuries to the stomach and colon are noted. In these situations the urologist should be aware of the relationship between GU morbidity, associated organ injury, and the grade of the renal injury. For example, if a colonic injury and a retroperitoneal hematoma are simultaneously present, approximately 10% of patients will be found to have a grade 1–2 renal injury, and 90% will have a grade 3 or higher renal injury.[4,6,21] In addition, if a colonic or pancreatic injury is concurrently present with devitalized renal tissue, non-operative management of the renal injury is associated with a 3–4-fold higher incidence of complications compared with renal exploration and renorrhaphy. In addition, renal exploration in this latter group of patients does not appear to result in increased risk of nephrectomy.[8,32,48,51] Knowledge of these facts has resulted in the consensus that patients with a known grade 3 or higher renal injury undergoing exploratory laparotomy for multiorgan injury should simultaneously undergo renal exploration with renorrhaphy and the placement of retroperitoneal drains. It is also accepted that patients undergoing emergent laparatomy without adequate preoperative radiographic studies who are found to have stomach, duodenal, colonic or pancreatic injuries and a coexisting retroperitoneal hematoma, should have a single-shot IVP obtained, to verify contralateral renal function, and proceed with renal exploration[4,6,8] (see Table 34.2).

Non-operative therapy for renal trauma

Non-operative therapy consists of bedrest, close monitoring of the vital signs and urine output, serial abdominal examinations, serial hemoglobin/hematocrit determinations, and transfusion as indicated for decreasing hematocrit or hypotension. In the patient with a ≥ grade 3 renal injury, massive blood loss and vascular instability may rapidly appear. The patient managed in this fashion should have blood immediately available.[4,6] Repeat CT imaging of the kidney 2–3 days following trauma is recommended in patients with grade 3, 4, and 5 renal injuries. CT imaging should be pursued earlier if prompted by clinical indications (see earlier section on DMSA and follow-up radiographic imaging following renal trauma). If the child remains hemodynamically stable with or without transfusions, and CT verifies a stable or resolving urinoma and/or hematoma, observation can continue. If the child becomes hemodynamically unstable or continues to have a falling hemoglobin/hematocrit despite transfusions, renal angiography

with selective angioinfarction of the bleeding site should be performed. Children with a urinoma who complain of chronic or increasing flank pain, or have a persistent low-grade fever and/or a persistent ileus, should be considered for endoscopic or percutaneous management of the urinoma. They should be allowed to walk as soon as gross hematuria has resolved. Resumption of strenuous physical activity is prohibited for 6 weeks.[4,6,8,21,22]

We recommend intravenous broad-spectrum antibiotics in patients with a renal injury secondary to penetrating trauma on a non-operative protocol, due to the high risk of wound contamination from outside material. In renal injuries following blunt trauma, antibiotics may be considered if a large retroperitoneal hematoma or urinary extravasation exist. In this latter situation, the presence of an indwelling urethral catheter and/or multiple intravascular catheters may cause bacteremic colonization of the hematoma or urinoma.[4,6,8,21,22]

Operative intervention for renal trauma

Renal salvage by renorrhaphy or partial nephrectomy requires complete exposure of the injured kidney, debridement of non-viable tissue, suture ligation of bleeding arterial vessels, and repair of the collecting system injury. Defects in the renal parenchyma may be closed primarily with renal capsule. For larger defects, we prefer the placement of gel foam and Surgicel pack (small pieces of gel foam wrapped in Surgicel) into the parenchymal defect and closure of the renal capsule defect with woven polyglycolic acid mesh. Alternatively, perinephric fat, omentum, or thrombin-soaked gel foam may be used to pack the parenchymal defect. Watertight closure of the collecting system is not always possible, and may be inadvisable. If the renal pelvis or ureter is closed with tension, tissue ischemia and delayed resolution of urinary leakage may occur. If a major violation of the urinary drainage system is present, placement of intraoperative ureteral stents and/or a nephrostomy tube should be considered. Adequate drainage of the perinephric area following repair is vital. In the presence of concurrent stomach, duodenal, pancreatic, and colonic injuries, interposition of omentum or peritoneum between the site of the major renal injury and the site of the coexisting intra-abdominal injury is usually necessary. Nephrectomy should be considered in irreparable grade 4–5 renal injuries and in the hemodynamically unstable patient with multiorgan trauma.[4,6]

Renal vascular injuries

In terms of arterial renal blood flow the kidney is an end organ, and only rarely is collateral blood flow sufficient to maintain renal function if a segmental or main renal artery is damaged. In a patient sustaining renal arterial trauma, the clinical triad of decreased/absent renal arterial blood flow, inadequate collateral blood flow, and warm ischemic time almost invariably results in the loss of renal function.[4,6] Therefore, no attempt to repair injuries to segmental renal vessels should be considered, and repair of the traumatically injured main renal artery is rarely indicated. In essence, reconstruction of the main renal artery following trauma should only be considered in patients that are hemodynamically stable with an injury to a solitary kidney or in patients with bilateral renal injuries; otherwise, nephrectomy is the most expeditious and least-moribund treatment.[4,6] The infrequent exception to this rule is the presence of an incomplete renal arterial injury where perfusion to the kidney has been maintained by flow of blood through either the partially occluded main renal artery or via collateral vessels.[4,6]

Traumatic induced renal vascular hypertension

The most common causes of post-traumatic renal hypertension are

- renal ischemia from segmental arterial occlusion
- main renal artery occlusion with intact peripheral blood flow to the kidney
- a traumatically induced AV malformation or
- on rare occasion, compression of the renal parenchyma by hematoma/fibrosis (the Page kidney model).

The presence of hypertension immediately following the traumatic insult may be secondary to pain; however, persistent hypertension 30 days post injury could result from a renal source and the diagnosis of traumatically induced renal vascular hypertension should be considered. The incidence of traumatically induced hypertension is almost nonexistent after grade 1 and 2 renal injuries and will be found in approximately 5% of patients with ≥ grade 3 renal injuries.[4,6]

Hypertension from renovascular trauma will usually develop within 36 months following the injury.[4,6] If sustained hypertension develops, an evaluation

with a DMSA scan to determine differential renal function and radiographic studies – magnetic resonance imaging (MRI) or CT angiography – to rule out development of an AV fistula as the source of the hypertension should be performed. Hypertension related to an AV malformation should initially be treated with angiographic embolization. If consideration for surgical intervention is entertained, renal vein renin sampling for split renin ratios should be considered. This ratio is especially helpful in the presence of segmental renal scarring where partial nephrectomy is a consideration for surgical management. In this situation, hypertension related to segmental renal ischemia is treated with a partial nephrectomy. The most common clinical finding in post-traumatic-induced hypertension, however, is a small poorly functioning kidney (<30% differential renal function), associated with scarring. Most authorities believe that a differential renal function of <30% would not prevent the onset of renal failure in the event that the uninjured kidney is lost.[4,6,34,37] Nephrectomy or partial nephrectomy is therefore the treatment of choice for post-traumatic hypertension. Rarely is renal revascularization of any benefit, since hypertension is almost invariably the result of increased renin production from intrarenal or subcapsular fibrosis.[4,6] Surgical treatment of hypertension by decortication of subcapsular fibrosis in patients with a Page kidney-induced hypertension has been published; however, the long-term results of this surgical treatment modality are extremely controversial.[4,6]

Ureteropelvic junction disruption

If the screening CT evaluation reveals the presence of medial and perirenal contrast extravasation with no visualization of the ipsilateral distal ureter on delayed images, the diagnosis of either a large laceration of the renal pelvis or avulsion of the UPJ is entertained and further investigation mandated with either a retrograde pyelogram or surgical exploration.[4,6,18] Disruption of the UPJ is most commonly caused by acceleration–deceleration injuries (fall from >15 feet) or by a sudden extreme hyperextension of the trunk (pedestrian MVA, patient thrown from the vehicle during an MVA). The mechanism of injury results from a sudden displacement of the more mobile kidney associated with a relatively fixed ureter, with force vectors from the traumatic impact interacting at the UPJ.[2,3,18]

Although some reports suggest that a large extrarenal pelvis or a congenital UPJ obstruction renders the patient more susceptible to disruptions of the UPJ, this is controversial. The vast majority of patients with a congenital UPJ or congenital hydronephrosis with a traumatic injury will be found to have a rupture of the renal pelvis or a major laceration through a thinned renal cortex, not a UPJ disruption.[2,3,5,18] Generally, a laceration of an enlarged renal pelvis will appear as an isolated renal injury, whereas a UPJ disruption tends to occur in association with life-threatening injuries. The majority of patients sustaining a UPJ disruption will present with vascular instability, requiring emergency laparatomy, with the patient unable to undergo preoperative imaging. Urinalysis on presentation will have some degree of hematuria present in 70% of patients; however, 30% of patients with a UPJ disruption will have a completely normal urinalysis. In patients undergoing exploratory laparatomy for a coexisting intra-abdominal injury, a retroperitoneal hematoma is rarely revealed.[2,3,18,19] Because of the frequent association of this injury with life-threatening trauma, inadequate preoperative radiographic staging studies, and the absence of a retroperitoneal hematoma, the diagnosis of a UPJ disruption is delayed for >36 hours in more than 50% of patients.[18,19] Patients will eventually come to attention, as a result of persistent postoperative fever flank pain, continued ileus, or sepsis.[2,3,18,19]

Three classic findings on a triphasic CT scan are associated with UPJ disruption:

- good renal contrast excretion, with extravasation around the upper ureter into the medial perirenal space
- absence of parenchymal lacerations and intact renal calices
- non-visualization of the ipsilateral ureter.

When a diagnosis of a possible disruption of the UPJ is entertained, careful evaluation of the delayed CT images is necessary. This diagnosis may be difficult, even if suspected. Specifically, the severely injured patient usually has a history of volume depletion; contrast excretion resulting from the coexistence of hypovolemia, acute tubular necrosis, or renal contusion may be minimal. To definitively rule out the presence of a UPJ disruption, it is necessary to confirm the presence of contrast material in both distal ureters. This can be especially difficult in patients where this injury may be associated with a type 3 renal injury where contrast material may be preferentially accu-

mulating in the retroperitoneum. If the results of the CT scan remain inconclusive, a retrograde pyelogram should be performed.[2–4,6,18,19]

Children with pre-existing hydronephosis from a UPJ obstruction frequently have, at the site of injury, a major laceration through the thinned renal cortex (grade 3 renal injury) or laceration of the renal pelvis and not disruption of the UPJ. These patients should have a retrograde pyelogram to confirm continuity of the UPJ and, if not suspicious for disruption, they can be safely managed with either a percutaneous nephrostomy or a double-J stent placement with delayed pyeloplasty performed after stabilization of the patient.[3,5,31,55]

In patients with a disruption of the UPJ, a delay in diagnosis may significantly increase the risk of nephrectomy.[5,18,19] In the clinically stable patient where the diagnosis is made within 5 days after the traumatic insult, we prefer to proceed to surgical repair, with debridement of any devitilized ureteral tissure, spatulation, and reanastomosis of the ureter over a stent, with concurrent placement of an intraoperative nephrostomy tube and retroperitoneal drain. Since the area of ureteral necrosis may extend for 2–3 cm, mobilization and downward displacement of the kidney may be necessary to obtain a tension-free ureteral anastomosis.[18,19] In patients with a delayed diagnosis of a UPJ disruption ≥ 6 days post-traumatic insult, we prefer to place a nephrostomy tube and allow the injury to stabilize for 6–8 weeks. Differential renal function is then obtained via a DMSA renal scan, and the length of the ureteral injury ascertained by a combined antegrade and retrograde pyelogram. The combination of known percent renal function and length of the ureteral defect will allow the surgeon to make the proper surgical planning. Surgical alternatives in this situation include primary ureteroureterostomy, ileal ureter, autotransplantation, and nephrectomy (renal function <30% in the presence of a normal serum creatinine and renal clearance).[4,6,18,19]

Section IV

The Ureter

The ureter

35

Cem Akbal and Martin Kaefer

General

The goal of this chapter is to provide an overview of the embryology, general physiology, and molecular mechanisms responsible for normal ureteral development and function. The pathophysiology of the most common pathologic abnormalities to afflict the ureter is described subsequently. Processes that affect the ureter are ultimately important because of their impact on kidney physiology. The reader is directed to chapters that specifically focus on alterations in renal function secondary to infection, ureteral obstruction, and vesicoureteral reflux (VUR) for more details on this subject.

Embryology and anatomy

During the 4th week of gestation, the development of the ureter begins as an outpouching of the mesonephric duct, termed the ureteric bud (Figure 35.1). The development of this structure is heavily influenced by molecular factors released from the mesodermal tissue mass, which is destined to become the renal parenchyma (i.e. the metanephric blastema). At 28 days, the ureter consists of an epithelial tube surrounded by loose mesenchymal cells. Transient luminal obstruction ensues, with subsequent recanalization during the 7th week of gestation.[1,2] It appears that this recanalization process begins in the midureter and extends in a bidirectional manner both cranially and caudally. It has been suggested that angiotensin exerts its affect through the angiotensin 2 receptor (AT2) and may play a role in this recanalization process.[3] Chwalle's membrane, a two-layered cell structure, transiently divides the early ureteric bud from the urogenital sinus.[4] Subsequent dissolution of this membrane results in unimpeded flow of urine from the kidney into the bladder.

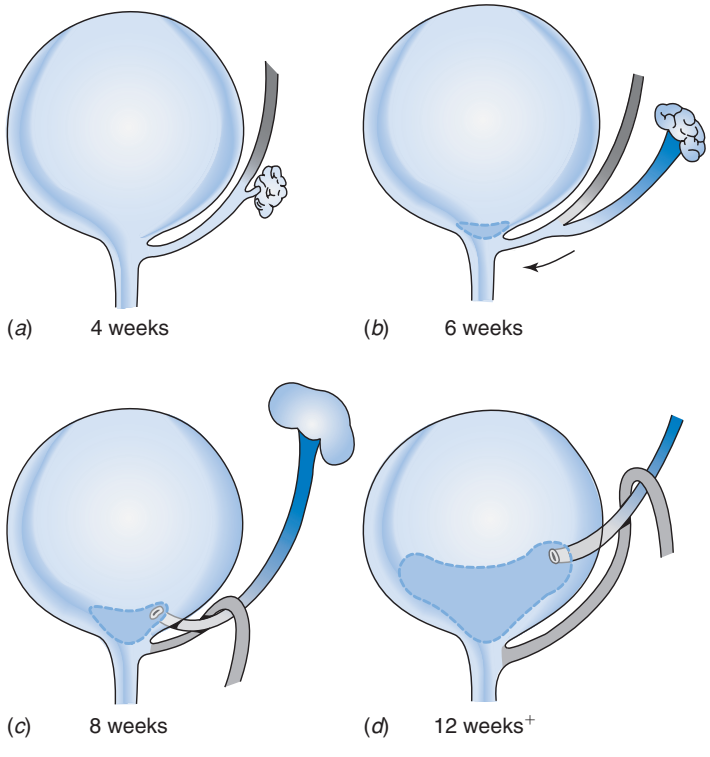

Figure 35.1 Embryology of ureter and trigone. The ureteral bud develops into the ureter and induces the metanephric blastema to differentiate and become the kidney. The common excretory duct (segment of mesonephric duct caudal to the ureteric bud) is absorbed into the bladder and becomes the deep trigone.

The first signs of ureteral muscularization are seen at 12 weeks of gestation. Smooth muscle differentiation is first noted at the ureterovesical junction (UVJ) and then ascends cranially toward the upper collecting system.[5] With time, these fibers, which are initially randomly arranged in the wall of the ureter, become more numerous and assume a more specific orientation.[6] The epithelium attains a transitional configuration by 14 weeks. Once fully developed, the muscular wall of the ureter is characterized as having an inner longitudinal, middle circular, and outer longitudinal layer. As the ureter penetrates the bladder, its muscular layers disperse. The outer layer melds into the detrusor in the upper part of the hiatus to form Waldeyer's sheath, which attaches the ureter to the bladder and is in continuity with the deep trigone.[7] As the ureter makes its transition to an intramural location, the muscle fibers take on a primarily longitudinal orientation.[8] The longitudinal muscle fibers spread out to form the borders of the superficial trigone.

Proper development and spatial orientation of the ureter as it combines with the bladder are dependent on a number of molecular factors. The renin–angiotensin system appears to play a major role in ureteral development. AT2 is expressed in high concentration by the mesenchymal cells that are positioned adjacent to the ureteric bud at early developmental stages. The fact that expression of this receptor markedly decreases after birth supports the contention that AT2 might play an important role in ureteral development.[9] Mice in whom the AT2 gene has been knocked-out demonstrate a high incidence of congenital anomalies of the urinary tract, including VUR, UVJ obstruction, and megaureter.[10] These structural anomalies may result from delayed apoptosis of the mesenchymal cells surrounding the ureteric bud. The clinical relevance of these experimental findings has been underscored by the identification of a select group of patients with mutations at this locus who possess a syndrome that includes uteropelvic junction (UPJ) obstruction and megaureter.[11] Proper spatial orientation of the ureter is probably dependent on genes responsible for cell specification and body segmentation. The *PAX* family of genes has been extensively studied in this regard.[12] These genes appear to play a role in the interplay between the ureter and the developing kidney.[13] *PAX* mutations have been implicated in syndromes with VUR and renal anomalies, and are inherited in an autosomal dominant manner.[14] However, to date, neither mutations in the *PAX* genes nor in other genes involving body segmentation have been demonstrated to any significant degree in patients with familial VUR.[15]

Ureteral physiology

Function of the ureter

The function of the ureter is to effectively transport urine from the renal pelvis to the bladder in a unidirectional fashion. Coordinated antegrade movement of urine is initiated by pacemaker sites located in the renal pelvis and proximal ureter.[16–18] This electrical stimulus propagates caudally and, in so doing, gives rise to peristaltic activity of the ureteral musculature. Under normal conditions peristaltic contractions occur between 2 and 6 times per minute and advance down the ureters at a rate of between 2 and 6 ml/s.[19,20] The following section will describe how events at the cellular level are translated into achieving this goal.

Electrical excitation – muscular contraction

Unlike their skeletal muscle counterparts that receive a discrete stimulus from a motor endplate, smooth muscles cells of the ureter lack discrete neuromuscular junctions and depend on initiation of an action potential from pacemaker cells located in the renal pelvis and upper ureter. The ureter also receives neurologic input from numerous sources. Spontaneous electrical activity initiated by the pacemaker is in itself adequate to propagate electrical activity and induce coordinated peristaltic muscular activity. Evidence to support this contention includes the persistence of peristalsis after renal transplantation or denervation.[21,22] Individual muscle cells allow propagation of electrical activity through tight areas of cell-to-cell contact, termed intermediate junctions.[23–25]

The parasympathetic and sympathetic nervous systems as well as peptidergic substances (e.g. tachykinins, substance P, neurokinin A) and nitric oxide appear to have as their primary role the ability to modify ureteral contraction that has been initiated by the pacemaker unit.[26–28] Neuropeptides influence muscle activity via second messengers, including cAMP, cGMP, Ca^{2+}, inositol 1,4,5-triphosphate (IP_3), and diacylglycerol (DG). Upon binding of the specific effector molecule to the cell receptor, the generation of these second messengers mediates the functional response through a process that frequently involves a cascade of protein phosphorylation. Release of these neurotransmitters is unlikely to exert

the dominant force responsible for peristalsis. Physiologic support for this contention comes from the fact that treatment with specific neuropeptide antagonists (e.g. atropine in the case of the parasympathetic nervous system) often has little or no clinically significant effect on ureteral function.[29]

The smooth muscle cell is the structural element responsible for effective mechanical transport of urine through the ureter. As in skeletal muscle, actin and myosin act as the two primary structural proteins that serve to provide active deformation of the cell during contraction and relaxation. Actin is bound to attachment plaques on the cell surface which serve as an anchor point against which it can exert force on the cell membrane. Any process that results in a significant increase in Ca^{2+} in the region of the contractile proteins favors the development of a contraction. The phosphorylation of myosin is a key step in the contractile process. Phosphorylation of the myosin light chain allows actin to activate myosin Mg^{2+}-ATPase activity, leading to hydrolysis of ATP and the development of smooth muscle tension or shortening.

Function of the ureterovesical junction

The function of the UVJ is to facilitate the unidirectional, antegrade flow of urine from the ureter into the bladder. A number of passive and active factors play a role in maintaining this mechanism.

Facilitation of antegrade flow

After the urine bolus has progressed to the level of the UVJ, it is propelled into the bladder across the intramural ureteral segment. This process is facilitated by retraction of the ureter in a superolateral direction, in keeping with its primarily longitudinally oriented muscle. As a result the resistance at the UVJ is lowered, facilitating antegrade fluid transport.[30]

Prevention of retrograde flow

Sampson was the first to propose a passive valvular mechanism created by the obliquity of the ureter as it courses through the bladder wall, a mechanism which he named 'ureteral lock'.[31] Paquin demonstrated that in normal subjects (i.e. children without VUR), a 5:1 ratio of tunnel length to ureteral diameter existed.[32] In creating reflux by resecting the roof of the submucosal ureter in a pig model, Ransley and Risdon gave further support to the concept that ureteral tunnel length is of importance in maintaining a competent UVJ.[33] In order for this passive mechanism to work successfully, the ureter must have an adequate muscle backing against which it can be compressed during bladder filling. In addition, the distal end of the ureter must be adequately anchored to the base of the bladder, so that with filling it does not migrate laterally and experience a shortening of tunnel length. The importance of adequate muscle backing is supported by the increased incidence of VUR in patients with periureteral diverticuli. The passive mechanism for maintaining unidirectional urine flow across the UVJ is depicted in Figure 35.2.

The traditional concept of the ureterovesical antireflux mechanism was that it consisted solely of this passive flap-valve mechanism. However, a number of investigators have noted sufficient anatomic and physiologic evidence to point to an active sphincteric mechanism.[34] The active valve function of the human ureter is thought to consist of a 'vesicoureteral sphincter', which contracts in response to bladder contraction and relaxes after contraction of the external urethral sphincter.[35] Although an anatomically defined circumferential sphincter has not been identified, it has been postulated that a 'physiologic sphincter' exists.[36,37] During micturition, the longitudinal muscles of the UVJ are postulated to provide this 'active' component by closing the meatus. Alteration

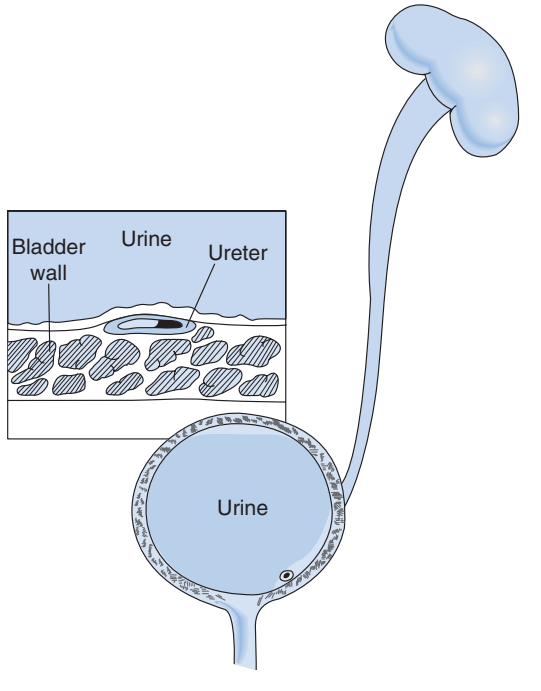

Figure 35.2 Flap-valve mechanism. Urine compresses the ureter between the bladder mucosa and the bladder wall muscle, thus creating a flap-valve mechanism that prevents reflux.

in ureteral jet pattern seen in patients with VUR has been cited by some investigators as evidence for this sphincteric mechanism.[38] Tanagho et al demonstrated that prolonged electrical stimulation or administration of intravenous epinephrine can cause resistance to flow, as contraction of the longitudinal muscle (which makes up part of the trigone) draws the orifice inferomedially.[8] The importance of trigonal attachment in maintaining an active valvular mechanism may vary from species to species. Hannan and Stephens, in excising the muscular component of the canine trigone, failed to demonstrate a significant increase in VUR in their model and concluded that the trigone did not play a major role in the function of the UVJ in this species.[39]

Synopsis of urine transport from renal pelvis to bladder

A graphical representation of the process of urine transport from renal pelvis to bladder, as described by Griffiths and Notschaele, is shown in Figure 35.3.[40] The process begins when the production of urine results in a rise in the renal pelvic pressure. Urine is subsequently propelled into the upper ureter, which is initially in a collapsed state. A contraction wave originates in the most proximal portion of the ureter and moves the bolus of urine in front of it in a caudad direction. For efficient urine transport, the ureteral wall must completely coapt during the propagation of a urine bolus down the ureter.[41] The bolus that is pushed in front of the contraction wave lies almost entirely in a passive, non-contracting part of the ureter.[42] The resting pressure within the ureter, 0–5 cmH_2O, is similar to the intravesical pressure of the non-distended bladder. Peristaltic waves elevate this pressure to between 20 and 80 cmH_2O.[43] If the intraureteral pressure exceeds the intravesical pressure, urine will proceed into the bladder.

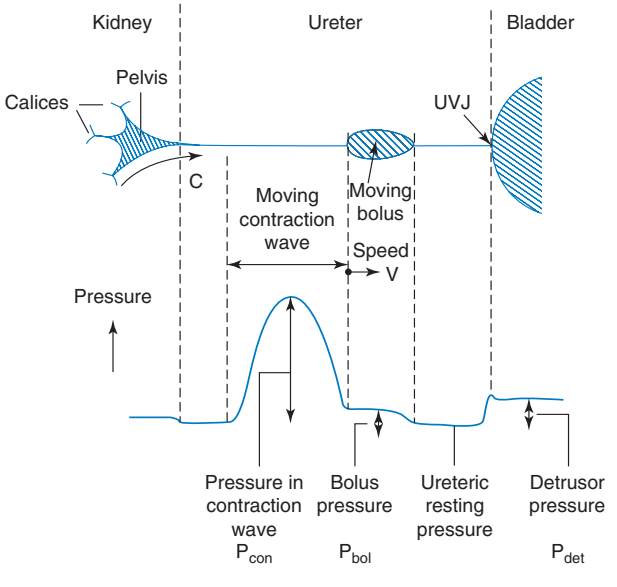

Figure 35.3 Schematic representation of a single bolus of urine in the ureter moving away from the renal pelvis and toward the bladder. Arrow C indicates the direction of bolus transport. The corresponding distribution of pressure within the urinary tract is shown in the lower tracing. UVJ, ureterovesical junction. (Reproduced from Griffiths and Notschaele[40] with permission.)

Factors influencing ureteral function

Many factors affect ureteral function. These factors are typically appreciated in the presence of either ureteral obstruction or VUR, both of which are described in the subsequent section. However, at times, these factors may occur in the absence of these two major maladies: e.g. ureteral dilatation may occur in the absence of obstruction or VUR may be found in patients with high urine output secondary to diabetes insipidus.[44]

Ureteral dilatation

Ureteral dilatation occurs either because of too much fluid entering and/or too little fluid exiting the ureter per unit time. Factors that influence egress of urine from the ureter range from infection to high intravesical pressure to anatomic obstruction of the ureter. An increase in ureteral dimensions adversely affects antegrade urine flow. As described by Laplace's equation, dilatation alters intraluminal pressure:

$$\text{pressure} = \frac{\text{tension} \times \text{wall thickness}}{\text{radius}}$$

By increasing the luminal size (i.e. radius), the intraluminal pressure is diminished, decreasing the force propelling urine in a forward direction.[45]

Urine volume

Hydration status and the ability of the kidney to concentrate urine affect the volume of urine transported per unit time through the ureter. Urinary concentrating ability is the first aspect of renal function to be affected in the presence of obstruction.[46] Evidence also exists that concentrating ability is altered in the

presence of VUR.[47] With increasing urine flow rates, the initial response of the ureter is to increase peristaltic frequency. After the maximal frequency is achieved, further increases in urine transport occur by means of increases in bolus volume.[48,49] Eventually, the boluses coalesce and the ureter becomes filled with a continuous column of fluid.

Infection

Infection within the upper urinary tract may adversely affect urine transport. Experimentally induced pyelonephritis in a primate model has been associated with decreased peristaltic activity.[50] In-vitro studies have shown that bacteria and *Escherichia coli* endotoxin can inhibit ureteral peristaltic activity.[51,52] Other investigators have not been able to suppress ureteral activity with endotoxin but have noted that growth media from *E. coli*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* does inhibit ureteral contractility. These investigators suggested that the inhibition of peristaltic activity is caused by an exotoxin.[53] In humans, irregular peristaltic contractions and alterations in the ureteral jet have been recorded with infection.[38,43] Ureteral dilatation has also been reported to result from retroperitoneal inflammatory processes, which presumably exert their effect via the transudation of bacterial endotoxins or inflammatory mediators.[54]

Ureteral histology

Alterations in ureteral histology are likely to have a significant impact on ureteral function. Lee and colleagues evaluated the histology of obstructed and refluxing megaureters and identified marked differences between the two groups. They found that refluxing megaureters had a twofold increase in the tissue matrix ratio of collagen to smooth muscle when compared with patients with primary obstructed megaureter and controls. This was not only due to an increase in collagen but was also a result of decreased amounts of smooth muscle in the refluxing ureters.[55] The same group of investigators subsequently demonstrated that there was a greater contribution of type III collagen in the refluxing megaureter and felt that this may play a role in the pathophysiology of refluxing megaureters.[56] Because type III collagen is a less distensible fiber, it may cause an intrinsically stiffer ureter and play a role in the lower surgical success in the reimplantation of refluxing megaureters.[57,58] The histology of the refluxing ureter associated with prune belly syndrome likewise exhibits significant histologic alteration. Ureters frequently are found to have a scarcity of muscle bundles among dense connective tissue.[59]

Pathologic processes affecting ureteral function

The two primary pathophysiologic conditions that affect the pediatric ureter are obstruction and VUR. As mentioned previously, infection can itself alter ureteral function. Often two or three of these conditions may coexist in one patient, as for example in the child with posterior urethral valves who suffers from the common combination of bladder dysfunction, VUR, and urinary tract infection.[60]

Ureteral obstruction

Well-known anatomic causes of ureteral obstruction that result in a compromise of the ureteral lumen include ureterocele, ureteral ectopia, and urinary lithiasis. By contrast, the classic example of a functional obstruction is the primary obstructed megaureter in which there exists an adynamic segment of distal ureter with adequate ureteral diameter (Figure 35.4).[61] Apart from anatomic or functional obstruction at the UVJ itself, the relationship between ureteral intraluminal pressure and intravesical pressure is important in determining the efficacy of urine passage across the UVJ into the bladder. The ureter has been shown to decompensate when intravesical pressure approaches 40 cmH_2O.[62]

The effects of ureteral obstruction on renal function are numerous and complex. Molecular mediators, including eisocanoids, nitric oxide, endothelin, and the renin–angiotensin system, dramatically affect blood flow and subsequent urine output.[63–66] After the onset of obstruction, a backup of urine occurs within the urinary collecting system, along with an associated increase in baseline ureteral pressure and an increase in ureteral length and width.[67,68] A transient increase in the amplitude and frequency of the peristaltic contraction waves accompanies these initial dimensional and pressure changes.[69] With time, as the ureter fills with urine, the peristaltic contraction waves become smaller and are unable to coapt the ureteral wall. Urine transport then becomes dependent on hydrostatic forces generated by the kidney.[67] Within a few hours after the onset of obstruction, the

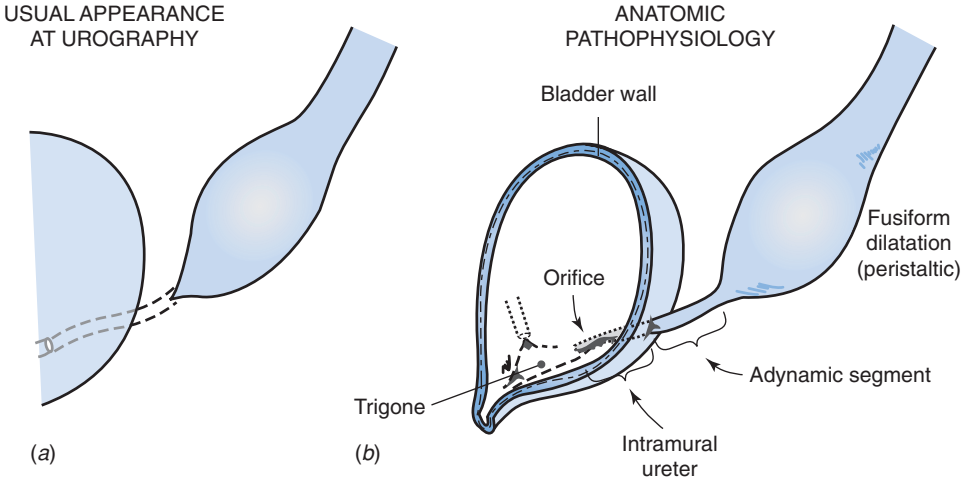

Figure 35.4 (a) Graphic representation of a primary obstructed megaureter. Ureteral dilatation begins above the ureterovesical junction, usually a few millimeters or more above the bladder, just proximal to an adynamic distal segment of ureter. (*b*) Characteristic appearance of the distal portion of a primary obstructed megaureter.

intraluminal baseline ureteral pressure increases substantially. The ureter experiences muscular hypertrophy and a greater ability to generate contractile forces.[70,71] Nevertheless, the simultaneous increase in ureteral diameter decreases the ability of the ureter to generate intraluminal pressure, as predicted by Laplace's law. After ureteral dilatation has occurred, intraureteral pressure declines to a level only slightly higher than the normal baseline pressure. The decrease in ureteral pressure can also be attributed to changes in intrarenal hemodynamics, such as a reduction in renal blood flow, with resultant decreases in the glomerular filtration rate and intratubular hydrostatic pressure.[72,73] Fluid reabsorption into the venous and lymphatic systems (pyelovenous and pyelolymphatic backflow) may also play a role in the reduction in baseline ureteral pressure.[74] Under conditions of obstruction, the hierarchical order of the ureteral pacemakers may also be altered.[75,76] When these alternate pacemakers fire, electrical activity and subsequent peristalsis can propagate both caudally and cranially from the site at which it is initiated. This lack of coordination affects the efficiency of urine transport and contributes to upper tract dilatation.

From a therapeutic standpoint it is important to understand why a tapered megaureter repair may be beneficial once the obstructive element has been removed. The effect of ureteral diameter on the ability to generate effective peristaltic contractions provides the rationale for ureteral tapering in the patient with an increased ureteral size.[77] Relief of distal obstruction usually leads to decompression of the ureter, with spontaneous reduction in diameter and improved peristaltic activity. If the ureteral diameter remains significantly dilated after obstruction has been relieved, then it may be necessary to taper the ureter to achieve a 5:1 ratio of tunnel length to diameter. Although tapering does not alter muscle thickness and the ability of the ureteral fibers to contract, the decrease in radius, according to the Laplace relation, would result in higher intraluminal pressures and a resultant improvement in urine transport.

Vesicoureteral reflux

Vesicoureteral reflux, the retrograde flow of urine across the UVJ, is the most common problem of the ureter treated by the pediatric urologist.[78] The high incidence of sibling VUR supports a genetic basis for this disorder. Factors that have been implicated in the development of VUR include:

- anatomic and functional abnormalities of the UVJ
- inordinately high intravesical pressures
- impaired ureteral function.

Genetics of reflux

Very strong evidence exists to support a genetic component to VUR.[79,80] Although autosomal recessive, X-linked, and polygenic mode of transmission have been supported by various authors in the past, the majority of data suggest an autosomal dominant pattern of inheritance with variable penetrance.[81] Supporting data include an approximate 50% incidence of sibling reflux in the first 2 years of life and the high incidence of parent-to-child transmission.[80,82] Per-

haps most suggestive of autosomal dominant transmission is the incidence of sibling reflux found in multiple-gestation births. Kaefer et al demonstrated reflux in 80% of identical twins and 35% of fraternal twins.[83] The incidence for groups of twins <18 months old was 100% for identical twins and 50% for fraternal twins. Despite such a strong genetic component, it still remains unclear as to which of the factors contributing to reflux is primarily affected (i.e. anatomic properties of UVJ, bladder properties, or impaired ureteral function).

Anatomic abnormalities of the UVJ

As outlined in the previous section on normal ureteral function, unidirectional flow of urine across the UVJ appears to depend on both passive and active components. In comparing the anatomy of children with and without VUR, Paquin demonstrated that there was a significant difference in the ratio of ureteral tunnel length to orifice diameter between the two groups. Whereas the patients with reflux had a ratio of 1.4:1, children not exhibiting reflux had a significantly longer intravesical tunnel, with an average length to width ratio of 5:1.[32] Hutch estimated the average intravesical ureter length to be 0.5 cm in neonates and 1.3 cm in adults.[84] Although the 5:1 ratio sets the standard for reimplantation surgery, many pediatric urologists feel achieving such a long intravesical tunnel may not be absolutely necessary to obviate reflux.

The lateral displacement of the ureteral orifice is a result of the ureteric bud originating on the mesonephric duct at a point more caudal than normal. As a result, the period during which the orifice undergoes migration is prolonged. As predicted by Stephens, the orifice will eventually assume a position on the trigone that is more lateral than usual. The ureter will have a submucosal course that is short and almost perpendicular to the bladder wall, thus failing to meet the anatomic requirements needed for proper functioning of the flap-valve mechanism.[85,86] The degree of reflux correlates with the degree of laterality and inversely with the length of the submucosal ureter (Figure 35.5). Spontaneous resolution of reflux in

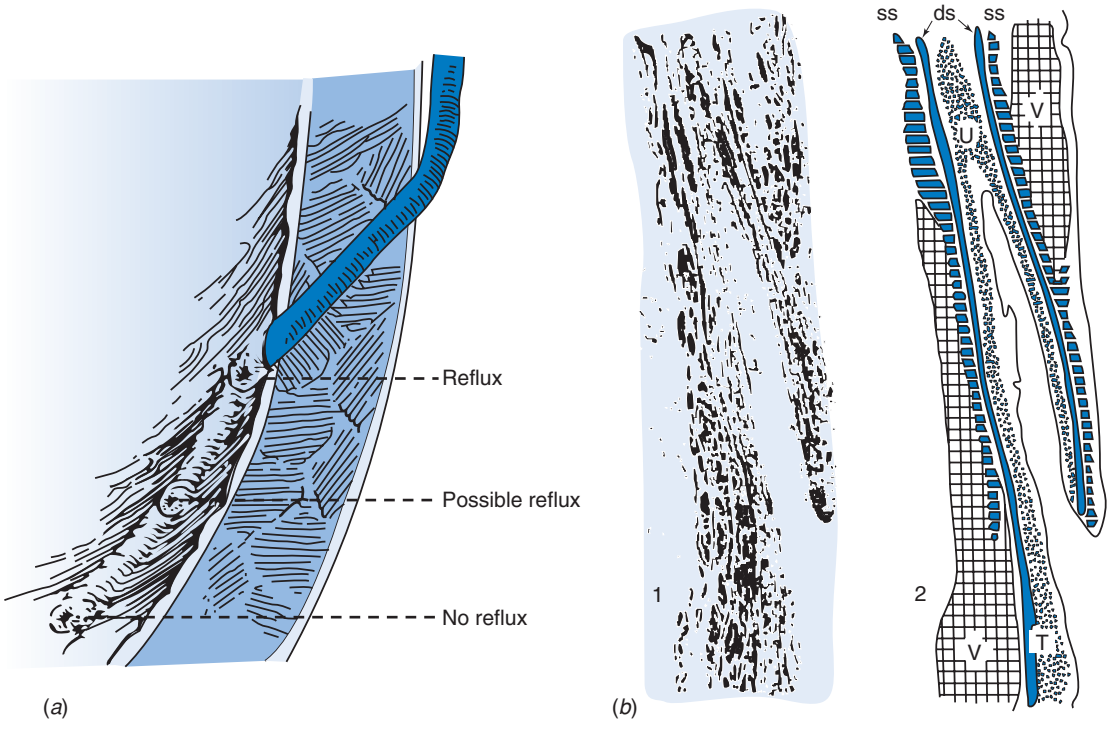

Figure 35.5 (*a*) The refluxing ureterovesical junction has an inadequate length of intravesical submucosal ureter. Some orifices with marginal submucosal tunnels may reflux intermittently. (Reproduced from Glen,[87] with permission.) (*b*) Ureterovesical junction in longitudinal section: 1, photomicrograph; 2, diagrammatic representation. The ureteral muscularis (u) is surrounded by superficial (ss) and deep (ds) periureteral sheaths, which extend in the roof of the submucosal segment and continue beyond the orifice into the trigonal muscle (t). The relationship of superficial sheath to the vesical muscularis (v) is clearly seen. Transverse fascicles in the superior lip of the ureteral orifice belong to the superficial and deep sheaths. No true space separates ureter from bladder. (Reproduced from Elbadawi,[88] with permission.)

children is explained by the growth of the bladder, during which the submucosal tunnel elongates.[85] Proper formation of the trigone is also believed necessary to provide adequate muscular support of the ureters. A more caudal take-off of the ureteric bud from the mesonephric duct results in a shorter common excretory duct. Consequently, its contribution to the development of the trigone is decreased, resulting in poor muscularization. The importance of adequate muscular backing is underscored by the rare female patient with bilateral single-system ectopic ureters. At the time of ureteral reimplantation, special attention must be taken to achieve very long tunnel length due to absent trigonal musculature and poor detrusor muscularization, both of which result in poor posterior support for the reimplanted ureter. If special care is not taken to achieve a greater than normal ureteral tunnel length, these patients are prone to postoperative reflux.[89] A periureteral diverticulum can also contribute to VUR as a result of poor muscle backing and poor attachment of the ureters to the trigonal muscle complex.[90]

Alterations in the active valvular mechanism may also occur and result or contribute to the expression of the reflux phenotype. From an embryologic standpoint, a more caudal take-off of the ureteric bud from the mesonephric duct and the earlier absorption into the bladder would allow less time for the common mesenchyme to accumulate around the developing ureteric bud. One would therefore anticipate that the intramural ureter may be deficient in musculature. As a result, the orifice can be patulous or gaping.

Recent histologic evaluation of the distal ureters in children with VUR has suggested that there may be dysplasia, atrophy, and architectural derangement of smooth muscle fibers.[91] In addition, there appears to be altered extracellular matrix deposition and a decrease in intramural nerve supply.[92] This combination of factors, by affecting the muscle layer of the intramural ureters, may alter the active valvular mechanism deemed by many to contribute to the function of the UVJ. The fact that many children outgrow their VUR suggests that even if histologic alterations of the intravesical ureters are contributing to the presence of VUR, they play only a partial role in the reflux phenotype.

Intravesical pressure

As mentioned earlier in this chapter, intravesical pressure must be lower than the pressure generated by the ureter in order for there to be adequate transport of urine in an antegrade direction. In the presence of increased intravesical pressure, secondary reflux can occur.[62] Failure to maintain a low intravesical pressure also results in an increase in the incidence of VUR, commonly referred to as secondary reflux. The most common anatomic cause of VUR is posterior urethral valves, in which approximately 50% of boys are affected.[93,94] However, functional causes of increased intravesical pressure, including detrusor-sphincter dyssynergia in patients with neuropathic bladder dysfunction secondary to myelomeningocele, are far more common.[95] Transient urodynamic abnormalities have also been identified in neurologically normal children who present with urinary tract infections and reflux in the first year of life. One study identified abnormalities, including detrusor hyperreflexia and elevated filling pressures, in 97% of boys and 77% of girls who presented in infancy with reflux.[96,97] Intravesical pressures in boys were found to be higher than in girls, a finding confirmed by other investigators.[98,99] This finding may account for gender differences in degree of reflux. In older children, bladder dysfunction is apparently an acquired phenomenon, resulting from abnormal voiding patterns in neurologically normal children.[100,101] The normal UVJ is extremely resistant to reflux, even in the face of very high intravesical pressures that occur with normal voiding. However, if intravesical pressures remain chronically elevated, the antireflux mechanism can be overcome. McGuire et al demonstrated that if intravesical pressures exceed 40 cmH_2O, then the chance of reflux and renal injury increase.[62] The development of reflux may further reduce the efficiency of the bladder to empty, and in the case of neuropathic bladder dysfunction may further increase intravesical pressure and further damage the upper urinary tract.[102]

Impaired ureteral function

Although an abnormality of the UVJ is the primary etiologic factor in most cases of reflux, there is evidence that decreased ureteral peristalsis can be a contributory factor. This may explain why a normal ureter may not reflux even when reimplanted into a bladder without a submucosal tunnel or why a defunctionalized refluxing ureter may cease to reflux when a proximal diversion is taken down.[103–105] Tanagho's observation that VUR may temporarily cease after ureteral electric stimulation further supports this possibility.[8] Even the mildest forms of VUR may be associated with a decreased frequency of ureteral

peristalsis.[106] Although this may offer further evidence that decreased peristaltic activity is a possible etiologic factor in the development of reflux, an alternative interpretation is that the decreased peristaltic activity reflects changes in ureteral or renal function resulting from the reflux. Finally, the success rate of antireflux procedures is lower with poorly functioning dilated ureters, and, although this may be related to technical factors, decreased peristaltic activity may be another reason for failure in many instances. Bladder infections and the accompanying inflammation may also contribute to reflux by decreasing compliance of both the bladder and intramural ureter, elevating intravesical pressures, and distorting and weakening the UVJ.[107–109] In some patients reflux appears to only occur during episodes of acute cystitis and resolves once the infection has been adequately treated and the inflammatory response has resolved.[110]

Ureteral development

36

Steven E Lerman, Irene M McAleer, and George W Kaplan

Ureteral development from the ureteral bud is closely associated with the distal end of the mesonephric duct, also known as the wolffian duct. The distal end of the mesonephric duct inferior to the ureteral bud opening forms the common excretory duct. The trigone is formed by integrating the upper portions of the common excretory ducts and a small portion of the mesonephric ducts just superior to the ureteral bud into the bladder base (Figure 36.1). Ultimately, with expansion and absorption of the common excretory duct into the trigone, ureteral and wolffian duct orifices become separated from each other.

The development of ureteral atresia is thought to result from relative or total ischemia that might occur with the migration of the developing kidney as it changes and re-establishes regional blood supply to the ureter. This theory is based on experimental studies on intestinal atresia,[2] and may be extrapolated to explain ureteral stenosis and postnatal involution of multicystic dysplastic kidneys.

Complete or partial ureteral duplication (or triplication) can occur if multiple ureteral buds develop, or if the ureteral bud divides before meeting the metanephrogenic mass. In this instance, if one bud met the center of the metanephrogenic mass and the other a pole of degenerating metanephric tissue, the former would develop normally, whereas the latter might be dysplastic (Figure 36.2) This seems to explain the high association of dysplasia with ureteral ectopia,[3] although these ureters are often also obstructed.

Ureteral ectopy occurs when the orifice is found in a location other than the normal orthotopic corner of the trigone. These orifices can be within the bladder, urethra, vas, or vagina. Ureteral ectopy is four times more common with duplicated systems than with single ureteral systems.

Ureteral obstructions occur primarily at the ureteropelvic and ureterovesical junctions but can also occur in the pelvis where the ureter crosses over the iliac vessels. They are usually intrinsic in nature and the area in question is often of normal caliber but abnormally fibrous histologically, perhaps reflecting a localized vascular accident sometime during development (Figure 36.3).

The imaging of reflux and ureteral disease

37

Jeanne S Chow and David A Diamond

Introduction

This chapter discusses the techniques in evaluating reflux and ureteral diseases. Different imaging modalities are described, with specific clinical scenarios to highlight the uses of each modality. Practice patterns may vary from institution to institution.

Imaging of reflux

Voiding cystourethrography (VCUG), radionuclide cystography (RNC), and sonocystography demonstrate the presence or absence of vesicoureteral reflux (VUR). Whereas VCUG is a fluoroscopic examination and RNC is a nuclear medicine study, they are performed similarly and expose the patient to ionizing radiation. Sonocystography is performed with ultrasound and exposes the child to no ionizing radiation. Sonocystography is an uncommon examination in the United States and will be discussed last in this section.

During a VCUG, dilute water-soluble contrast is instilled into the bladder through a sterile urethral catheter by gravity under fluoroscopic guidance. Spot images of the abdomen, early filling views of the bladder, oblique images of the bladder to view the ureterovesical junctions (UVJs), oblique views of the urethra (especially important in boys), and postvoid images of the abdomen are standard (Figure 37.1). Additional views to show other abnormalities may be necessary.

In infants, a cyclic study is performed, where the bladder is refilled with contrast after the infant voids around the catheter to increase the sensitivity of the study.[1] Otherwise, the bladder is filled to the predicted capacity to maximize likelihood for finding reflux. Bladder capacity is calculated by two equations:[2,3]

<1 year old:

Bladder capacity (ml) = weight in kg × 7

>1 year old:

Bladder capacity (ml) = (age in years + 2) × 30

For RNC, the preparation and catheterization of the patient is identical to that for VCUG. A radiopharmaceutical, technetium 99m (^{99m}Tc) pertechnetate, diluted with water, is instilled into the bladder. A gamma camera continuously records the radioactive emissions from the bladder, ureters, and kidneys for up to 20 minutes.

Comparing VCUG and RNC, VCUG provides higher-resolution images at the expense of a higher dose of radiation to the patient. A VCUG clearly shows the bladder wall, the UVJ (in patients with reflux), the male urethra, intrarenal reflux, and subtle grade 1 reflux much more clearly than an RNC (Figures 37.2 and 37.3).

A traditional VCUG exposes the patient to 100 times the radiation of an RNC. In the past 10 years, low-dose fluoroscopy techniques, including digital fluoroscopy and pulse fluoroscopy, have decreased radiation dose to the patient[4–8] while providing diagnostic quality images.[9–11] Gonadal shielding and careful imaging coning also significantly decrease patient radiation exposure. In our department, modern low-dose fluoroscopic methods reduce the dose of a VCUG to approximately 10 times that of an RNC.

The decision to perform an RNC or a VCUG on a patient suspected of having reflux is complex and depends on the patient and the referring physician. In our department, VCUGs are commonly performed in males and young children or infants with well-documented pyelonephritis, patients with neurogenic bladder, patients with duplex kidneys and dilatation of the upper pole, lower pole (Figure 37.4), or both,

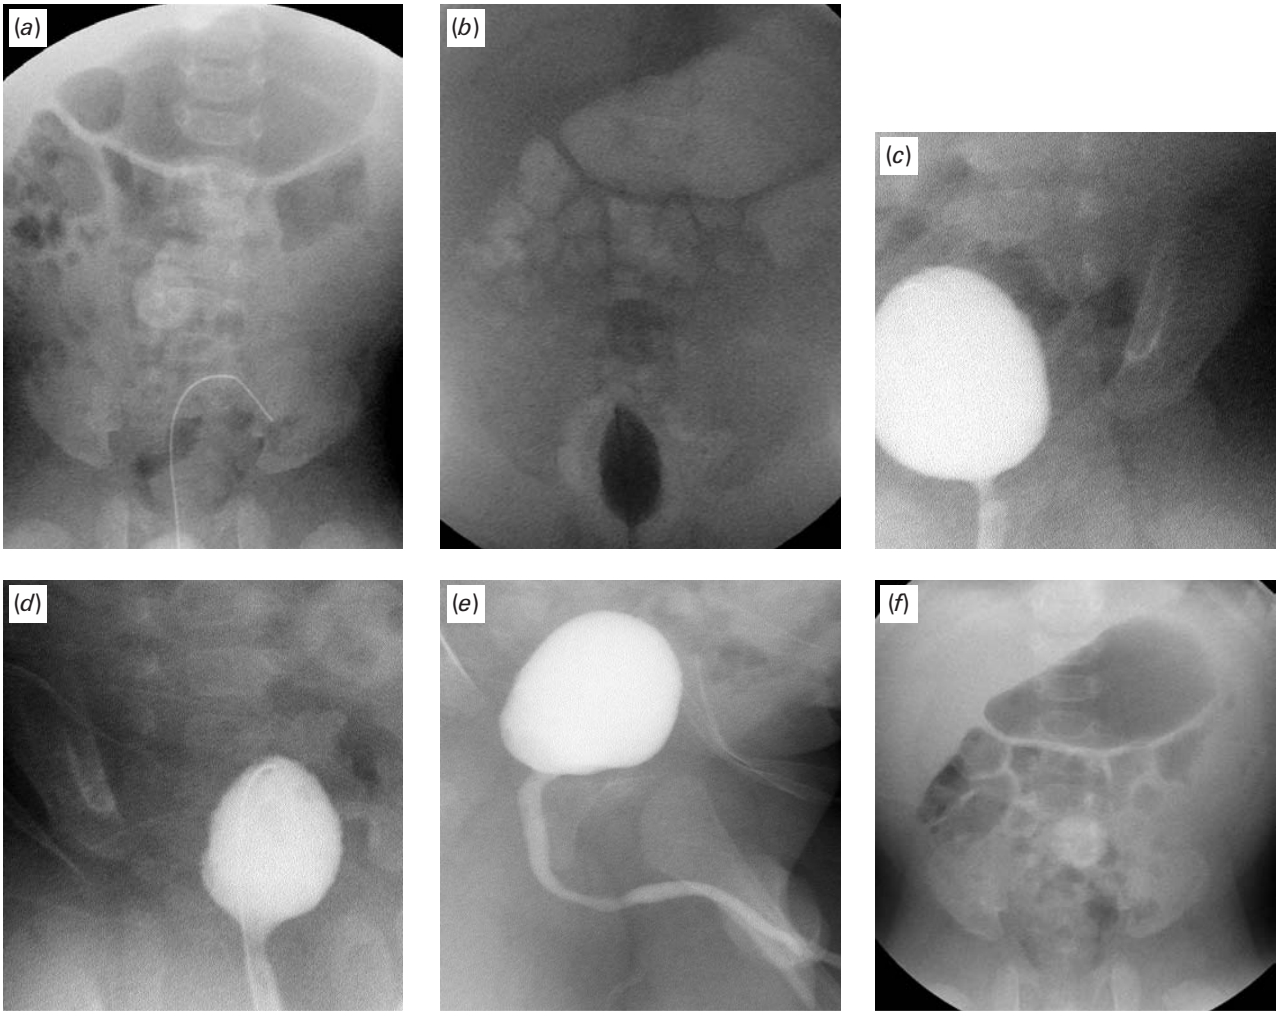

Figure 37.1 Standard images from a normal video cystourethrogram in a boy include: (*a*) a scout film of the abdomen and pelvis; (*b*) early filling view of the bladder; (*c* and *d*) bilateral oblique views to visualize the ureterovesical junctions; (*e*) oblique view of the male urethra; and (*f*) post-procedure image of the abdomen and pelvis.

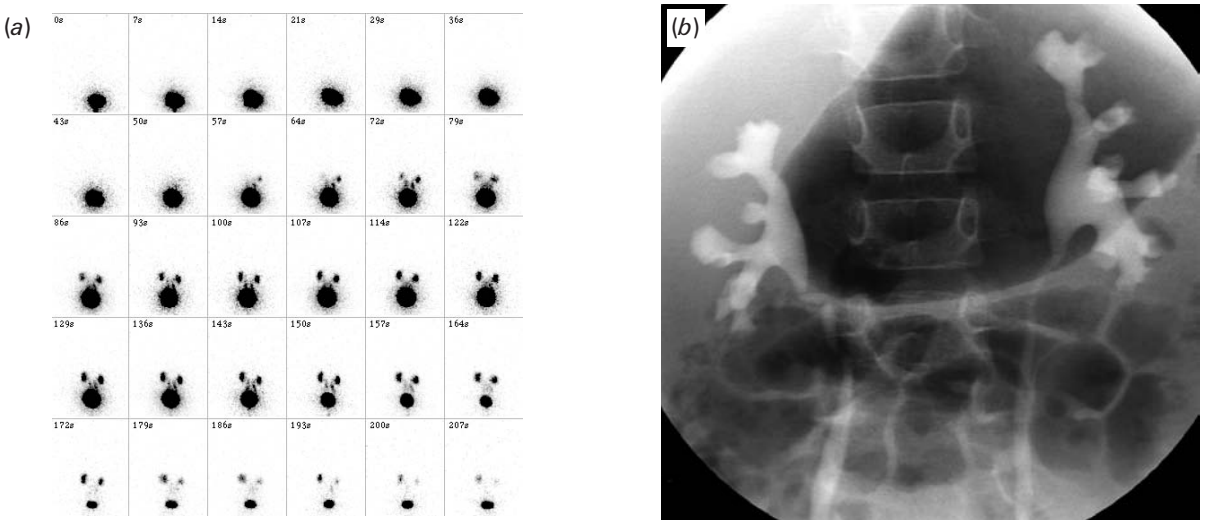

Figure 37.2 (*a*) Multiple images from a radionuclide cystogram demonstrate bilateral grade 2 reflux. (*b*) A single image from a voiding cystourethrogram demonstrates bilateral grade 2–3 reflux.

and patients suspected of having a ureterocele (Figure 37.5). Patients being screened for familial reflux, prior reflux documented by VCUG, or surgically repaired reflux typically have RNCs.

During sonocystography, the bladder is infused with an ultrasound contrast agent, and reflux is assessed by the sonographic appearance of contrast within the kidneys and ureters. The grading system is similar to a VCUG.[12] Sonocystography is sensitive[13] and accurate in detecting reflux[14–16] but does not provide the anatomic detail of the bladder, ureters, and urethra of a VCUG. For this reason, it is indicated in the first-time evaluation of reflux in girls and follow-up reflux after VCUG in boys and girls.[17] Transperineal ultrasound during voiding can detect posterior urethral valves,[18] but is not widely accepted.

These studies for assessing reflux are often stressful for the child and family and are ideally performed by a physician in an environment comfortable for the child, family, and physician. When parents and children are well informed and reassured, no sedation is necessary. Trained technologists and child-life specialists are very helpful in preparing, educating, and

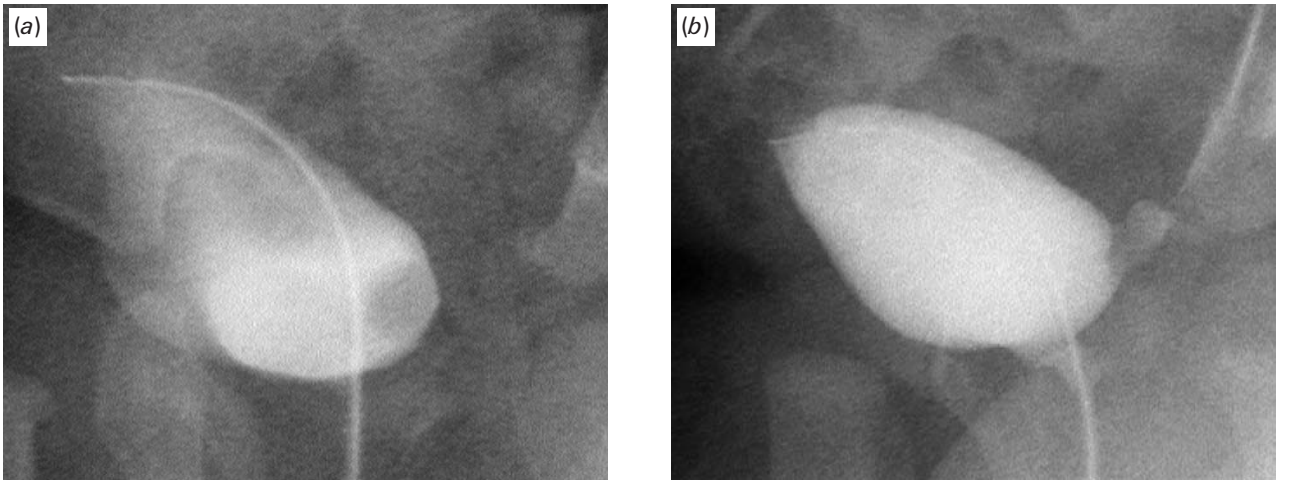

Figure 37.5 Oblique voiding cytourethrograms showing a left ureterocele (*a*) which everts (*b*).

reassuring parents and patients.[19] If sedation is required, midazolam can be used without negative outcome on the results of the examination.[20]

Patients with cardiac disease at risk for bacterial endocarditis need prophylactic antibiotics prior to the procedure. Patients who are suspected of having reflux because of a well-documented case of pyelonephritis, should be on prophylactic antibiotics until the examination, and continued if reflux is found.[21] Use of prophylactic antibiotics for prenatal hydronephrosis or a family history of reflux is controversial. Patients with prior allergies to intravenous contrast do not have allergies to intravesical contrast; thus, no premedication is required.

Imaging of ureteral diseases

Ultrasound

Introduction

Ultrasound is typically the first study selected in evaluating potential ureteral disease in children because it is non-invasive, rarely requires sedation, and emits no ionizing radiation. Whereas the normal-caliber ureter is not visualized on ultrasound, even a mildly dilated ureter is readily imaged with contemporary equipment. This makes ultrasound an ideal modality for following anatomic abnormalities or pathologic processes that result in hydronephrosis and hydroureter. Other than ideally having a bladder fully distended with urine to evaluate the bladder and distal ureters, no patient preparation is necessary.

The diagnostic quality of the ultrasound depends on the ability of the sonographer and sonologist, machinery, and the use of new techniques and software. Imagers trained to work with children often employ special tricks when scanning children, such as prone imaging or scanning while the patient is being cradled by a caretaker, to obtain the best images. The newest ultrasound machines offer compound imaging, harmonic imaging, and three-dimensional and four-dimensional imaging to improve the quality of the images.[22]

The kidneys and bladder are easily visualized by ultrasound. Viewing the kidneys in the supine and prone positions increases the likelihood of visualizing the entire kidney, which can be partially obscured by bowel gas. A normal ureter is usually collapsed, and therefore not typically visualized by ultrasound. A peristalsing ureter containing urine, measuring up to 3.5 mm in diameter, is normal. Dilated ureters are easiest to visualize near the ureteropelvic junction (UPJ) and behind a full bladder near the UVJ. A non-obstructed collecting system may be dilated as a result of a full bladder and should be re-evaluated after the bladder is emptied.

Hydroureter is typically implied by seeing proximal and distal ureteral dilatation. The mid ureter can be visualized, but is often obscured by bowel gas. Hydroureter may be caused by reflux, obstruction, or both. The degree of distal ureteral dilatation in patients with reflux predicts a high grade of reflux.[23] Absence of a ureteral jet or asymmetry in jet frequency seen in the bladder in patients with acute obstruction correlates highly with high-grade ureteral obstruction.[24]

Prenatal hydronephrosis

The finding of hydronephrosis is made on 1 in 200 routine prenatal ultrasounds. Postnatally, ultrasound will confirm the majority of these cases to be mild, without hydroureter, allowing them to be followed sequentially with serial ultrasounds until resolution has been documented. If the postnatal ultrasound demonstrates moderate (characterized by caliceal dilatation) or severe hydronephrosis (characterized by parenchymal thinning), further diagnostic studies are indicated. These would include a VCUG to rule out reflux and an IVP (intravenous pyelogram) or MAG3 (mercaptoacetyltriglycine) renal scan to rule out a UPJ obstruction. Hydroureter with any degree of hydronephrosis would mandate a VCUG (Figure 37.6).

Duplex systems

Duplex collecting systems may also present prenatally if there is associated hydronephrosis. Hydroureteronephrosis of the upper pole moiety and ureter is typically associated with distal ureteral obstruction caused by an ectopic ureter or ectopic ureterocele. Ultrasound views of the bladder enable one to make this distinction, as the ureterocele is visualized as a cystic structure with a fine septum within the bladder (Figure 37.7), or as an ectopic ureter that courses beneath the full thickness of the bladder wall in transverse view. Lower pole hydronephrosis typically results from reflux or UPJ obstruction of the lower pole moiety. Therefore, a VCUG and IVP or MAG3 renal scan would be required for further evaluation of lower pole hydronephrosis.

Postoperative assessment

Whether one performs pyeloplasty for UPJ obstruction or transurethral incision of an obstructing

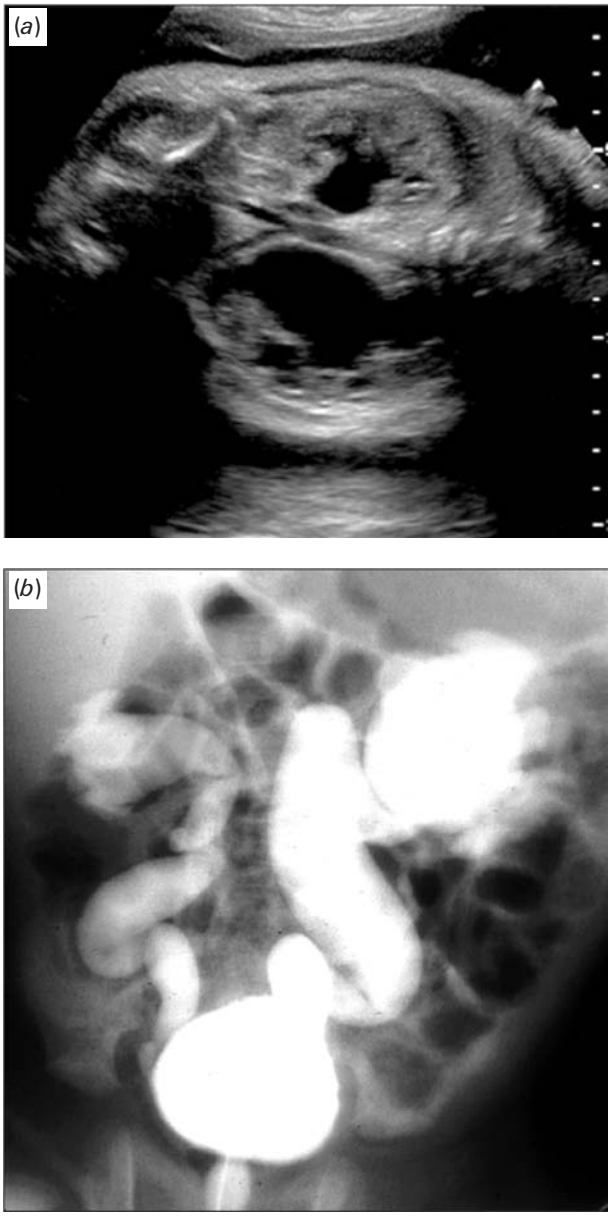

Figure 37.6 (*a*) A prenatal ultrasound shows bilateral hydronephrotic kidneys in the coronal plane. (*b*) A voiding cystourethrogram demonstrates bilateral high-grade vesicoureteral reflux.

ectopic ureterocele, ultrasound is an ideal modality for postoperative assessment of the relief of obstruction. Ultrasound is a non-definitive study for ruling out reflux, as it is known to miss 75% of reflux.

Renal calculi

Ultrasound is an excellent initial study for the assessment of renal colic in the child, possibly secondary to stone disease. Initially, it is important to rule out a congenital obstructive lesion of the ureter either at the UPJ or UVJ. Next, one would attempt to image a

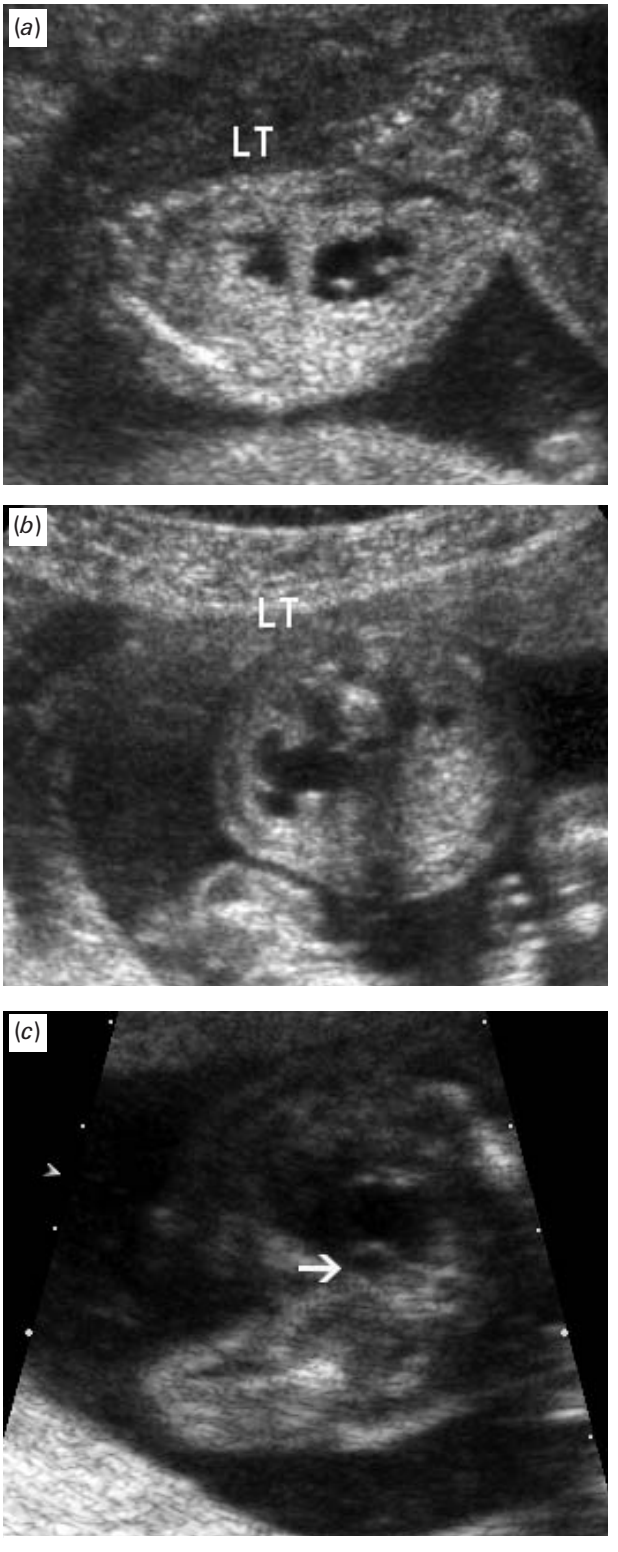

Figure 37.7 Fetal ultrasound, showing sagittal (*a*) and axial (*b*) images of the left kidney, with upper and lower pole hydroureteronephrosis. (*c*) Transverse view of the fetal bladder, showing a ureterocele (arrow). After the patient was born, imaging studies showed a left duplex kidney with an upper pole obstructed ureter ending in a ureterocele and lower pole reflux (imaging studies not shown).

Figure 37.8 A distal ureteral stone. A sagittal ultrasound of the bladder demonstrates a small distal ureteral calculus (arrow), with mild hydroureter and edema at the ureterovesical junction.

stone within the ureter, typically producing distinct shadowing and hydroureteronephrosis proximally (Figure 37.8). Additional calculi may be imaged within the kidney. In some cases, a stone may coexist with a congenital obstructive lesion or alternatively mimic one, if lodged at the UPJ or UVJ. If one is not studying the patient with renal colic compulsively, a stone can be missed. Therefore, the entire course of the renal pelvis and ureter should be followed carefully.

Ultrasound is capable of not only imaging renal and ureteral calculi, but, in the form of extracorporeal shock wave lithotripsy (ESWL) with ultrasound guidance, it can also be used to fragment calculi, thereby allowing them to be cleared naturally by the urinary tract. Effectiveness of any surgical treatment for stone clearance may be accurately assessed by ultrasound. In addition, ultrasound may be used for long-term surveillance of stone formers.

Intravenous pyelogram

Introduction

Historically, the IVP has been the classic imaging modality for the upper urinary tract. Although with advances in imaging technology the indications for IVP have diminished, for a number of clinical situations it remains an extremely valuable study.

The IVP examines the form and function of the kidneys, ureters, and bladder. After a scout film of the abdomen is performed, intravenous contrast is injected. Low-osmolar contrast material has fewer side effects than high-osmolar contrast material and is now used routinely. The IVP technique varies from institution to institution, depending on the clinical question and the risks of radiation dose to the patient balanced with the number of images needed to perform a diagnostic study and personal style. A simple and effective protocol for imaging children is to take supine abdominal radiographs 3 and 15 minutes after contrast injection. At 3 minutes, the kidneys normally show symmetric concentration and excretion of contrast and may show anatomic variants or abnormalities. Abdominal compression with bellows, prone images, fluoroscopy, and delayed images may improve visualization of the ureters.

This study is most commonly used in our institution to assess complex or atypical urinary tract anatomy and to evaluate patients after pyeloplasty and occasionally after other surgeries. IVPs are much less commonly used for the evaluation of nephroureterolithiasis, ureteral strictures, or ureteral masses. Computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine studies are slowly replacing IVP studies. Unlike CT and MRI, IVPs do not require sedation. Compared with CT, the average radiation dose of an IVP is lower.

Ectopic ureter

For the female who is continually wet, a diagnosis of ectopic ureter must be entertained. The IVP remains an excellent modality for making this diagnosis based on indirect findings that point to a (sometimes subtle) poorly functioning upper pole moiety (Figure 37.9). Typically, the lower pole ureter will be laterally displaced from the vertebral column (relative to the normal contralateral ureter) and an upper pole calyx will appear to be missing. In cases where the upper pole moiety is more dilated, one may see tortuousity of the lower pole ureter and an orientation of the lower pole calices toward the ipsilateral (rather than contralateral) shoulder as it approximates a 'drooping lily' sign. In the event that there is function of the upper pole moiety, this may be visualized directly on an IVP.

Primary megaureter versus ectopic ureter

The IVP is no longer routinely performed in all cases of hydroureteronephrosis, as ultrasound and MAG3 renal scan enable one to diagnose and characterize UVJ obstruction. However, IVP may be useful in distinguishing a primary obstructive megaureter (Figure 37.10) – which is usually treated observationally, initially – from a single-system ectopic ureter, which

Figure 37.9 An intravenous pyelogram (IVP) showing a right duplex kidney and with an obstructed ectopic upper pole ureter. (*a*) An image from an IVP demonstrates right upper pole moderate, hydroureteronephrosis. The right lower pole and left kidney and collecting systems appear normal. (*b*) The right upper pole has a low ectopic ureteral insertion, below the bladder neck into the vagina.

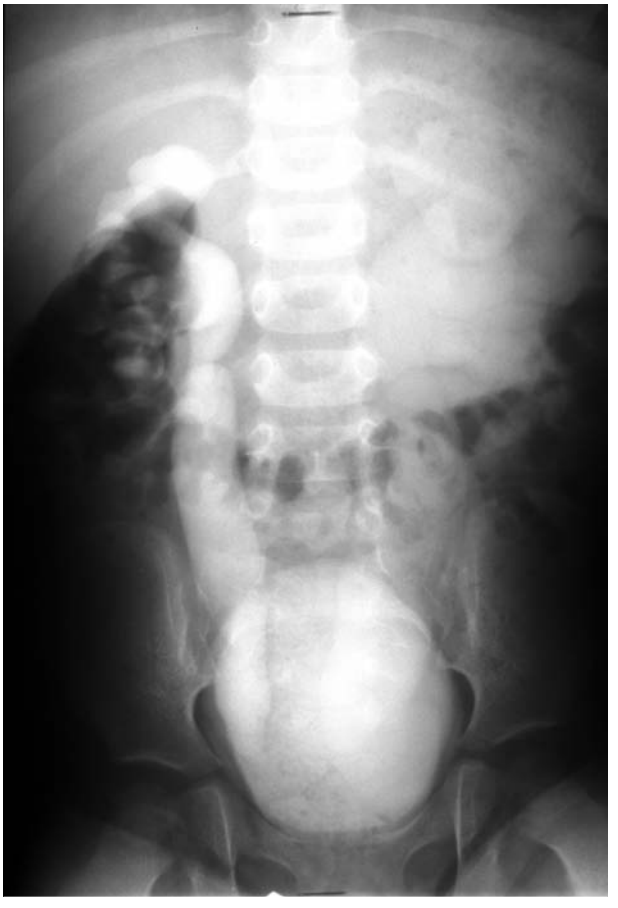

Figure 37.10 A bilateral primary megaureter. An intravenous pyelogram at 2 hours demonstrates left greater than right moderate to severe hydroureteronephrosis. There is marked delayed excretion bilaterally, especially on the left. The sites of ureteral insertion are normal.

should be treated surgically without delay. The IVP with delayed images may allow one to visualize the distal ureter in order to make this important distinction, whereas ultrasound cannot.

Postoperative assessment

For many patients who undergo repair of an UPJ or UVJ obstruction, the hydronephrosis or hydroureteronephrosis does not resolve dramatically on early (1–3 month) postoperative ultrasound imaging. In this setting, an IVP may be invaluable in demonstrating signs of improved excretion and drainage relative to preoperative studies that confirm that a good result is evolving. Alternatively, the IVP is an excellent study for demonstrating a technically poor surgical result, if one fails to see a dependent, funneled anastomosis.

Figure 37.11 An intravenous pyelogram of an 8-year-old boy demonstrating ureteropelvic junction obstruction associated with a crossing lower pole vessel. Note the linear filling defect at the inferior aspect of the renal pelvis.

A setting in which IVP is particularly valuable is in looking for an anterior crossing vessel that may produce intermittent kinking at the UPJ and, as a result, intermittent renal colic. Such a vessel may present as a proximal ureteral filling defect that disappears after surgically transposing the pelvis and ureter anterior to the crossing lower pole artery (Figure 37.11).

MAG3 renal scan

Introduction

During dynamic renal scintigraphy, the activity of intravenously injected ^{99m}Tc MAG is imaged and measured to assess the form and function of the kidney and ureters. ^{99m}Tc DTPA (diethylenetriamine penta-acetic acid) is a less preferred agent. These agents show excellent images of the functioning renal cortex and the collecting system. The time–activity curve, or time for uptake and excretion of the radiotracer, is measured and compared with normal values.

Diuresis renography is performed to distinguish urinary obstruction from a dilated non-obstructed renal collecting system. After initial imaging during a dynamic renal scan, a diuretic, typically furosemide, is injected intravenously. The kidney's ability to drain the radiopharmaceutical over time is measured. In significantly obstructed kidneys, radiotracer fails to be excreted normally.

The Society for Fetal Urology and the Pediatric Nuclear Medicine Council developed the 'well-tempered' diuretic renogram to standardize the evaluation of asymptomatic neonates with hydronephrosis or hydroureteronephrosis.[25] Patients need to be well hydrated prior to the examination. Guidelines are specified within the 'well-tempered' diuretic renogram protocol.

Several patient factors can confound the interpretation of the diuretic renograms. The appearance of refluxed contrast in the collecting system may mimic normal function in a patient with impaired function. Thus, the bladder should be drained by catheter in children with reflux who cannot void spontaneously. Infants, especially those younger than 1 month of age, have functionally immature kidneys, and do not concentrate the radiopharmaceutical into the urine well.[26,27] Studies performed in the first month of life need to interpreted with this in mind. Similarly, kidneys with impaired function may not respond to diuresis. As a result, intravenous urography, renal angiography, and other tests using contrast agents eliminated by the kidneys may have reduced renal uptake and prolong the time for examination.

Hydronephrosis, hydroureteronephrosis, and obstruction

For the assessment of a hydronephrotic kidney or hydroureteronephrotic collecting system the MAG3 renal scan provides quantitative information regarding renal function and drainage of the dilated system. Based on the results of the MAG3 scan, one can determine whether or not relative renal function appears to have been compromised and whether drainage is in the normal, intermediate or obstructive range: clearance time of half of tracer ($T_{1/2}$) <15 minutes is normal, 15–20 minutes intermediate, and >20 minutes obstructive.[28] This information is particularly crucial for the postnatal assessment of prenatal hydronephrosis in healthy, asymptomatic babies. Typically, one waits until 1 month of age prior to performing the MAG3 scan in order to assure adequate renal maturity; then, the severity of an apparent UPJ or UVJ obstruction can be accurately assessed. These functional results, in conjunction with postnatal ultra-

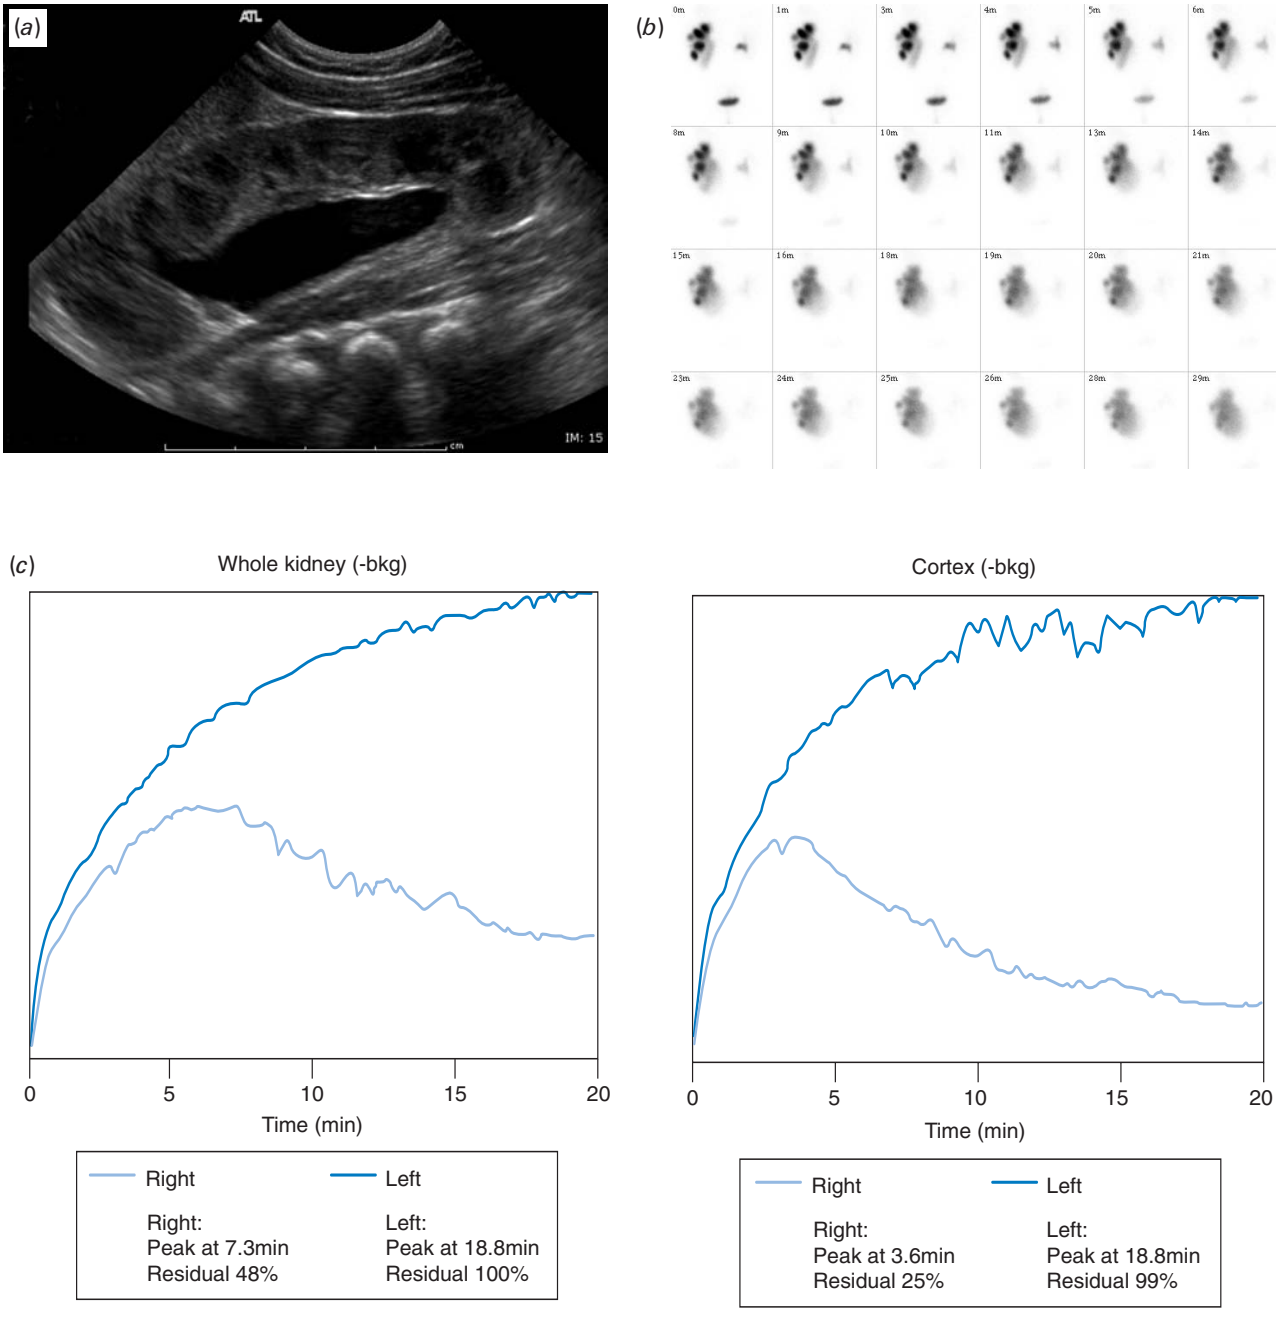

Figure 37.12 A 2-month-old infant with prenatal hydronephrosis. (*a*) Postnatal ultrasound demonstrates unilateral moderate hydronephrosis. (*b* and *c*) Initial MAG3 study with lasix demonstrates delayed drainage of the left kidney as a result of a ureteropelvic junction obstruction. The time–activity curve demonstrates delayed excretion of contrast in the obstructive range. (*d*) Postoperative MAG3 examination demonstrates improvement.

sound findings (Figure 37.12), should enable one to develop a rational management plan – rarely for immediate surgery, and usually for follow-up imaging, entailing serial ultrasound or MAG3 studies, depending upon the initial findings.

Computed tomography/computed axial tomography

Introduction

Computed tomography, also known as computerized axial tomography (CAT), is a widely used modality for pediatric ureteral imaging because of its applicability to stone disease, trauma, and the evaluation of renal masses.

Early CT scans acquired one 'slice' or axial cross section of information at a time. With spiral or helical scanners, X-rays are emitted and detected as the patient moves continuously through the scanner, creating a volume of information. Multislice or multidetector CT (MDCT) scanners have multiple detectors rotating simultaneously around the patient with the effect of increasing spatial resolution and decreasing the time to perform a study over standard spiral scanners.

With a volume of information created, images can be reconstructed in many planes and reformatted to enhance the conspicuity of ureters. The ease and speed of obtaining large quantities of information by CT scan needs to be weighed against the radiation risk and financial cost of the examination. The absorbed radiation dose of a single CT scan of the abdomen is eight times that of an abdominal radiograph. The rapidly growing tissues of children are very susceptible to the deleterious effects of radiation.

Contrast- and non-contrast-enhanced CT scans are used in the evaluation of the ureter. Non-contrast-enhanced CT is used for the evaluation of nephroureterolithiasis and resulting obstruction. Contrast-enhanced CT, especially timed during the excretory phase, is useful for showing the opacified ureters. Multiphase CT scans evaluate the genitourinary system without contrast, then with contrast, timed to the cortical and excretory phases of contrast enhancement. Multiphase CT scans should be used sparingly in children because of their high radiation doses.

Methods used to enhance ureteral opacification after contrast administration include abdominal compression with bellows,[29] intravenous (IV) hydration during the examination,[30] prone and supine imaging,[31] multiplanar reformatting, and virtual endoscopy. The angiographic phase of contrast enhancement is useful in clarifying vascular anatomy in the cases of trauma or UPJ obstruction.[32–34]

Nephroureterolithiasis

The spiral CT scan, without contrast, can rapidly assess the upper tract for a calculus. On the basis of Hounsfield units (Hu), it has the advantage, relative to ultrasound, of distinguishing a stone from an air bubble or intraluminal polyp. Its disadvantage is the ionizing radiation entailed. For patients with VUR, air bubbles may be introduced at the time of a VCUG, producing an upper tract echogenic lesion and mimicking stone on renal ultrasound. Radiolucent filling defects on IVP, which may represent uric acid calculi, can be confirmed as such with CT scan.

Two methods, non-contrast-enhanced CT scan and the combination of ultrasound and plain film, have largely replaced IVP for the initial evaluation of stone disease (Figure 37.13). Non-contrast CT and ultrasound with plain films are more sensitive examinations than IVP,[35–37] have no risk of contrast reaction, and often find alternative diagnoses. Low-dose CT methods for detecting urolithiasis confer approximately double the radiation dose of an IVP.[38]

Although non-contrast CT has greater sensitivity, negative predictive value, and accuracy than the combination of ultrasound and plain films, both methods yield comparable results without causing significant differences in clinical management.[39] Given the often

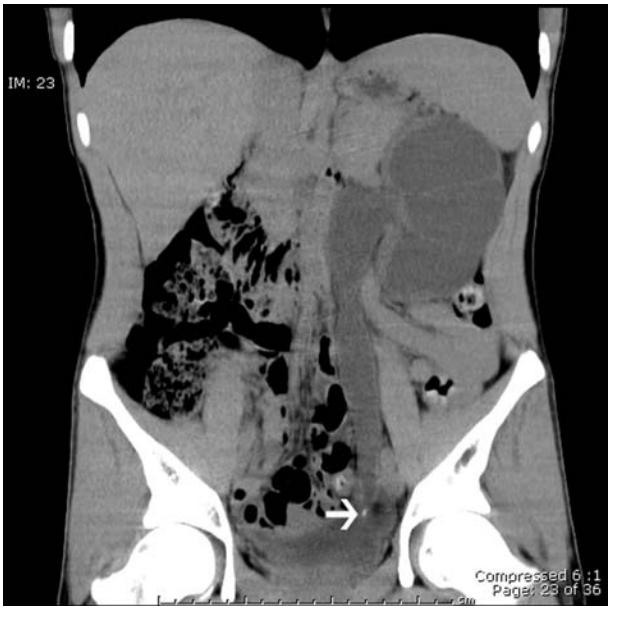

Figure 37.13 Computed tomography with coronal reformatting showing a left ureterovesical junction calculus (arrow) in a patient with a primary megaureter.

lower test cost and absence of ionizing radiation, ultrasound is often the first modality of choice[40] in children.

Ureteral trauma

In the assessment of urologic trauma, the CT scan with contrast is invaluable. Images performed during the excretory phase of contrast enhancement are the best for the evaluation of the ureter.[41–43] Computed tomography is capable of demonstrating extravasation as a result of pelviureteric disruption of the UPJ secondary to hyperextension injuries or ureteral disruption (Figure 37.14) from penetrating trauma. It also affords one the capability of assessing injuries to associated organs such as the spleen or liver.

Other ureteral anomalies

Computed tomography has a wide range of uses, including the assessment of an abnormal course of the ureter such as a retrocaval ureter,[44] ectopic ureteral insertion,[45] or ureteral obstruction. The CT scan with contrast is also valuable in assessing the solid retroperitoneal mass, such as Wilms' tumor or neuroblastoma, and its effect on ureteral anatomy.

Specialized opacification techniques

Introduction

The specialized opacification techniques enable one to visualize the ureter precisely in complex anatomic or operative clinical settings.

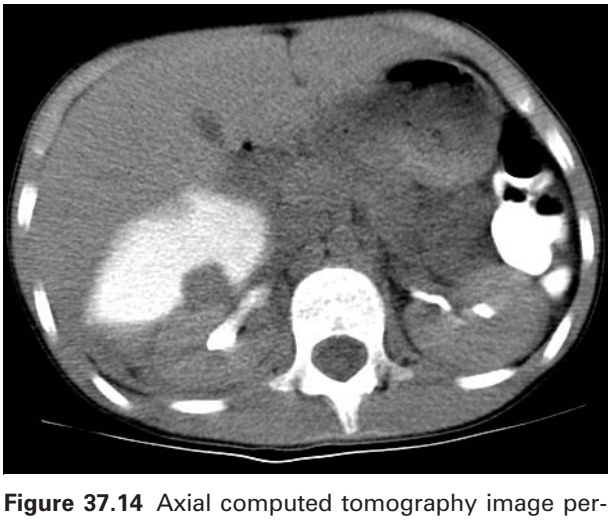

Figure 37.14 Axial computed tomography image performed during the excretory phase of contrast enhancement demonstrates right perinephric contrast extravasation resulting from a ureteral tear at the ureteropelvic junction.

Retrograde ureterography and pyelography

Retrograde ureterography and pyelography is performed cystoscopically in the anesthetized child through a ureteral catheter using one-half strength Cystografin. It is used to opacify the distal ureter prior to pyeloplasty, to ensure normal distal ureteral anatomy, and to confirm the level of ureteral obstruction. It can be invaluable in distinguishing a typical UPJ obstruction from rare lesions such as fibroepithelial polyps of the UPJ and mid-ureteral strictures.[46] Retrograde pyelography is also useful in the assessment of ureteral trauma and evaluation of the stone patient prior to ureteral stone basketing or lithotripsy. In difficult diagnostic situations, such as unusual duplication anomalies or ectopic ureters, retrograde ureterography and pyelography can be extremely valuable in defining the anatomy (Figure 37.15).

Antegrade pyelography and ureterography

Antegrade pyelography and ureterography are uncommon studies, utilized to define unusual anatomy, often in conjunction with the goal of draining a hydronephrotic collecting system. The antegrade study can be extremely valuable in defining postsurgical complications such as obstruction or urinary extravasation. It is particularly useful in defining the anatomy of duplex collecting systems, dilated ureters draining ectopically, and collecting systems associated with poorly functioning kidneys that do not excrete contrast well.

Whitaker test

The Whitaker test is a physiologic study combined with the anatomic benefit of antegrade pyelography that is used to assess upper tract obstruction.[47] The Whitaker test is performed with percutaneous access to the kidney and catheter drainage of the bladder. Pressures within the renal pelvis and bladder are measured during a constant infusion of contrast into the renal pelvis. Pressure differentials between kidney and bladder of <15 cmH_2O are considered normal, whereas pressure differentials >20 cmH_2O are consistent with obstruction. During the course of the study, imaging of the ureter clearly demonstrates the level of obstruction (Figure 37.16). This test is particularly valuable in assessing a postoperative result when hydronephrosis persists and renal function is so impaired that nuclear renography is non-diagnostic.

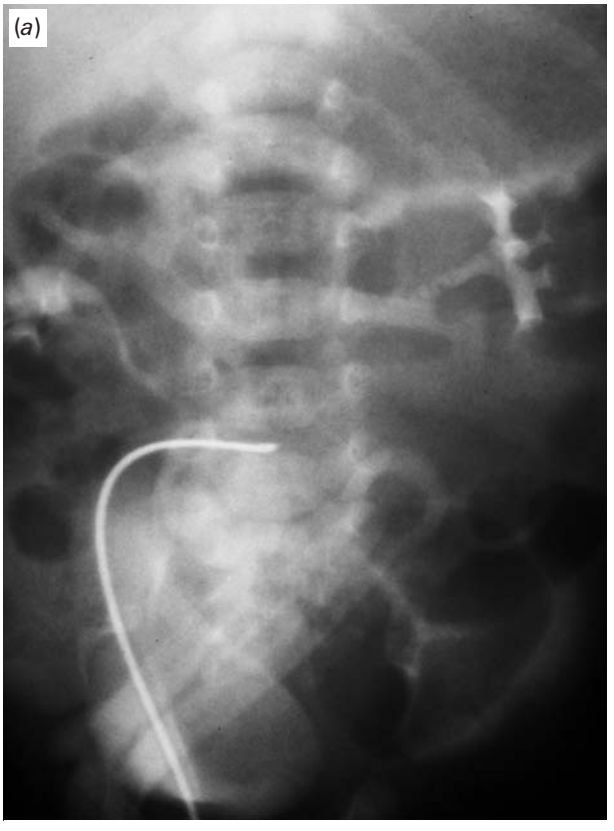

Figure 37.15 An intravenous pyelogram (IVP) and a retrograde ureterogram of a patient with a right upper pole ectopic ureter. (*a*) An IVP of a newborn infant demonstrates lateral deviation of the right lower pole collecting system. The left kidney appears normal. (*b*) A retrograde ureterogram demonstrates the ectopic upper pole ureter and pelvis.

Magnetic resonance urography

Magnetic resonance urography (MRU) offers the combination of high-resolution anatomic imaging and functional information of the genitourinary system without radiation. In children, MRU is used to evaluate urinary tract dilatation[22] and differentiate it from obstruction,[48,49] evaluate complex genitourinary anatomy,[50] and assess the ureters.[51]

MRU is more accurate than ultrasound[52] and IVP[51] in assessing renal anatomy and can provide functional imaging comparable with renal diuretic scintigraphy.[49,53] Unlike IVP and scintigraphy, visualization of the ureters and kidneys is not dependent on renal function. MRU is especially useful in children with poorly functioning kidneys and obstruction (Figure 37.17) or

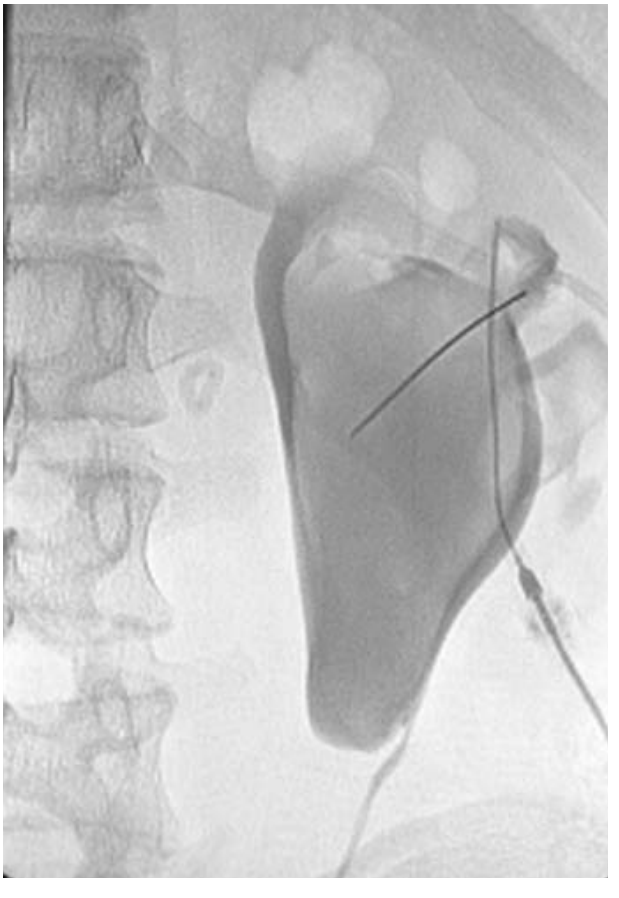

Figure 37.16 Whitaker test in 17-year-old boy following left pyeloplasty, having intermittent flank pain, consistent with slightly high insertion of ureter, but no obstruction.

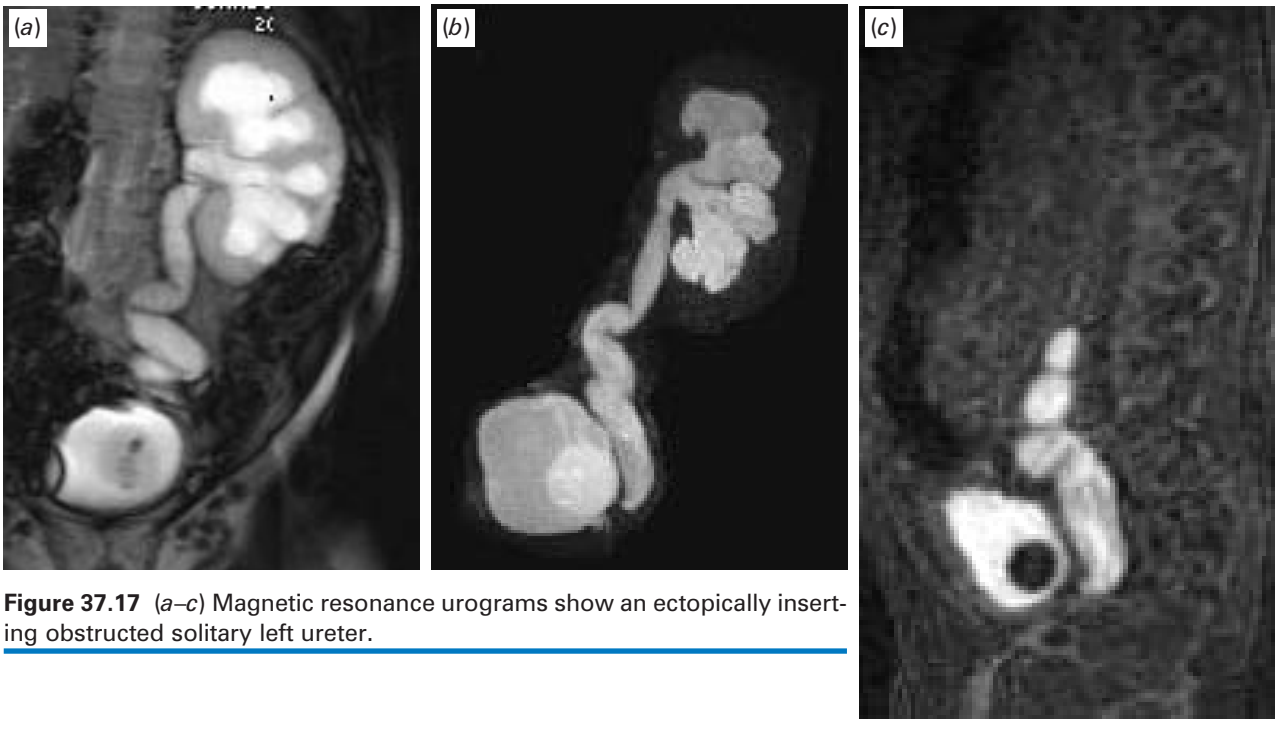

Figure 37.17 (*a–c*) Magnetic resonance urograms show an ectopically inserting obstructed solitary left ureter.

complex anatomy. Some clinicians advocate this method to replace ultrasound and renal diuretic scintigraphy in the evaluation of hydronephrosis.[49]

Many protocols are widely available.[48,49,54–56] Modern MR techniques and improved coils allow for improved spatial and temporal resolution and faster acquisition time. The fast-imaging MR techniques allow evaluation of parenchymal perfusion, glomerular filtration rate,[57] renal excretory function, and urinary drainage.[58] The main limitation of MRU is the relatively long duration of the examination (approximately 30–45 minutes), which often necessitates sedation in young or uncooperative children.

Key points

1 Ultrasound is the initial imaging modality for most forms of ureteral pathology.
2 Nuclear medicine or contrast studies remain essential for the evaluation of VUR.
3 Opacification techniques and MRI are both valuable for imaging of more complex pathology.
4 A CT scan is valuable for stone, trauma, and tumor evaluation.

Ureteral anomalies and their surgical management

38

Christopher S Cooper

Introduction

Aside from ureteropelvic junction (UPJ) or ureterovesical junction (UVJ) obstruction, the pediatric urologist is occasionally confronted with relatively rare causes of ureteral obstruction. These causes include the retrocaval ureter, ureteral strictures or valves, as well as ureteral polyps. The diagnosis of these conditions may follow clinical symptoms of obstruction such as pain, hematuria, or urinary tract infection. Increasingly, the diagnosis of these entities occurs as an incidental finding with anatomic imaging for non-urologic symptoms. This chapter provides a basic description of these rare conditions and management options.

Surgical technique

Ureteral obstruction often dictates operative intervention. Ureteral operations by open or laparoscopic techniques require adherence to certain basic principles. The blood supply to the mid ureter is more tenuous than that of the proximal and distal ureter. The abdominal segment of the ureter receives its blood supply from the renal and gonadal arteries. The pelvic segment of the ureter receives branches from the vesical and middle rectal vessels and, at times, from the common or internal iliac arteries. The adventitia supports multiple blood vessels and nerve fibers. The vessels of the ureter penetrate first through the muscular layers, where they supply the ureter with capillaries, and then form a plexus in the deep aspect of the mucosa.[1] To preserve the adventitia and blood supply, the ureter is usually mobilized with as much surrounding soft tissue as possible. Ischemic injury resulting from indelicate tissue handling will result in ureteral stricture. Delicate handling is, therefore, a requirement for successful ureteral reconstruction and often requires a 'no-touch' technique utilizing ureteral traction sutures.

Critical to the success of ureteral reconstruction is the creation of a tension-free anastomosis. Data from experimental studies demonstrate that accurate tissue approximation without tension optimizes wound healing and decreases the amount of fibrotic tissue. At times, renal mobilization may be necessary to permit additional ureteral length. Since wound contracture constitutes a routine phase of healing, a spatulated anastomosis, when possible, helps maintain an adequate luminal diameter. Absorbable sutures are used in the anastomosis, with the knot tied outside the lumen. Stents are frequently used and serve to promote urinary flow through the ureter and diminish extravasation of urine. Extravasation is thought to result in a localized tissue reaction that inhibits regular ureteral regeneration.[2] Drains placed near the anastomosis are also frequently employed to permit evacuation of any extravasated urine from the site of repair.

Retrocaval ureter

The reported incidence of retrocaval ureter is about 1 in 1000 and occurs three times more frequently in males.[3] The retrocaval ureter almost always involves the right ureter; however, rare cases involving the left side have been reported. The retrocaval ureter is a result of anomalous vascular development and is associated with increased cardiovascular or genitourinary tract abnormalities.[4,5] In the fetus, the supracardinal vein lies dorsal to the ureter and usually forms most of the infrarenal segment of the inferior vena cava. The subcardinal, or posterior cardinal vein lies ventral to the ureter; if the subcardinal vein persists, it becomes the infrarenal segment of the vena cava. In this situation, the ureter must pass around and behind the vena cava – retrocaval ureter.[6] Most patients with

a retrocaval ureter are asymptomatic; however, this anomaly may result in ureteric obstruction, presenting with pain, hematuria, urinary tract infections (UTIs), or stones. In these cases, the retrocaval segment of the ureter is often stenotic. Children are frequently diagnosed after evaluation for UTI.[4]

In the past, most cases of retrocaval ureter were found incidentally on intravenous pyelography (IVP). Two types of retrocaval ureters have been described, based on the radiographic criteria. Type I (low-loop) retrocaval ureter is more common and is associated with moderate or severe hydronephrosis, with significant medial deviation of the ureter toward the midline at the L3 level. This has been described as an S-shape or fishhook deformity (Figure 38.1). Type II (high-loop) retrocaval ureter is seen less frequently, and is associated with mild hydronephrosis and less medial deviation.[6] The widespread use of ultrasonography has resulted in more cases of retrocaval ureter being diagnosed following identification of hydronephrosis. Computed tomography (CT) and magnetic resonance imaging (MRI) scans have also been reported as excellent modalities for confirming the diagnosis.[4,7] A nuclear renal scan provides an estimate of relative renal function as well as the degree of obstruction.

Surgical treatment involves resection of the retrocaval segment and anastomosis anterior to the inferior vena cava (IVC). Frequently, redundant proximal ureter is also excised. The operative approach may be performed through the abdomen or the retroperitoneum using an open incision or via the laparoscope (Figure 38.2).[7–9]

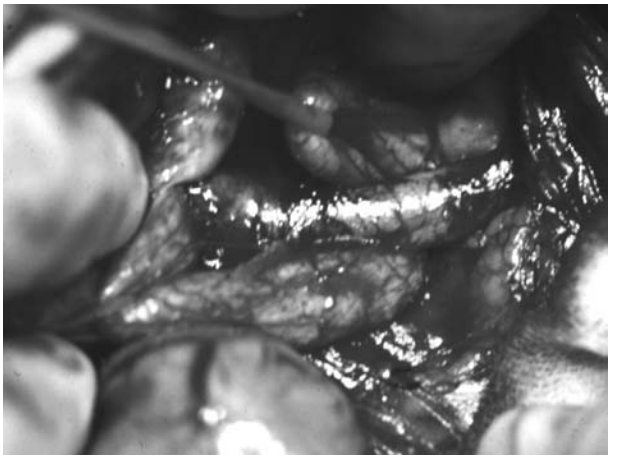

Figure 38.2 Intraoperative view of the retrocaval ureter.

Figure 38.1 Intravenous pyelogram of a patient with a retrocaval ureter, demonstrating dilated proximal ureter with significant medial deviation at the L3 level.

Figure 38.3 A retrograde ureteropyelogram demonstrating a short mid-proximal ureteral stenosis.

Congenital ureteral stenosis and valves

Although ureteral stenosis or strictures most commonly occur in the distal ureter and are associated with megaureters, these segments may also occur in the mid ureter (Figure 38.3). The etiology of congenital ureteral strictures is unknown; however, the location of congenital strictures is predominantly at regions of ureteral development associated with another structure or a change in form such as the junction with the bladder or renal pelvis. In children with a congenital mid ureteral stricture, an association with contralateral renal agenesis or atrophy has been reported, suggesting possible bilateral aberrant ureteral development. Aside from a narrowed lumen lined by the usual transitional epithelium, histologic findings at the site of the stenosis vary from that of thickened muscle to those with a near absence of muscle.[10,11] The symptoms of congenital ureteral strictures are variable and depend upon the degree of obstruction and renal function. The pathologic changes proximal to the stricture are a reflection of the severity and duration of the obstruction. Pyelonephritis, complicating obstruction, may lead to decreased renal function.[12]

With widespread use of prenatal ultrasonography, an increased number of children investigated for antenatal hydronephrosis are found to have congenital mid ureteral strictures. Although asymptomatic, the natural history of these strictures may require a more aggressive approach than other causes of antenatal hydronephrosis.[10] Following the identification of hydronephrosis by renal ultrasonography, a retrograde ureteropyelogram offers the most accurate method of localizing the strictured area and determining the length of the obstruction as well as providing the opportunity to catheterize or stent the ureter. The presentation of a mid ureteral stricture may mimic a classic UPJ obstruction, underscoring the importance of a retrograde ureteropyelogram if the location of the obstruction is in question.

Dilation or endoscopic incision of the ureteral stricture may be considered, but these techniques have a lower chance of success than an ureteroureterostomy or ureteral reimplant. Similar to the retrocaval ureter, treatment may require excision of redundant or kinked segments of the ureter.[12] Mobilization of the kidney may also be required to facilitate a tension-free primary ureteroureterostomy. If the narrowed segment is several centimeters, it may be best to divide the strictured segment in the middle and then spatulate through the narrowed segment in both directions as opposed to performing a complete resection of this segment. This permits use of the entire ureter and may help to avoid tension.[11]

Ureteral valves are also rare and often reported along with ureteral strictures. Valves consist of a transverse fold of tissue lined on both sides by uroepithelium and contains smooth muscle fibers that extend from the wall of the ureter and narrow the ureteral lumen.[11] They have been reported more commonly in boys and on the left side, although others have not demonstrated these associations.[13] During fetal development multiple transverse non-obstructing folds (Ostling's folds) occur and normally disappear with postnatal growth as the ureter loses its tortuosity (Figure 38.4).[12] On occasion, a fold

Figure 38.4 An intravenous pyelogram demonstrating non-obstructive Ostling's folds in the proximal ureter of a 5-month-old infant.

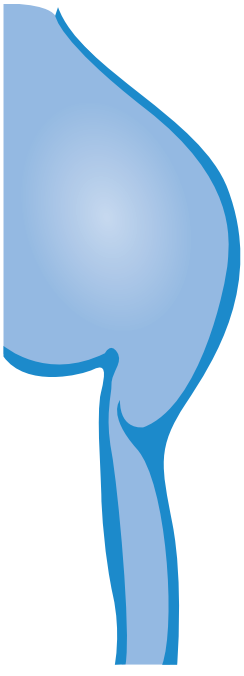

Figure 38.5 Schematic configuration of a ureteral valve with the long axis of the dilated proximal ureteral lumen eccentric to the axis of the non-dilated distal ureter.

remains and there is frequently redundancy and kinking of the ureter proximal to an apparent obstruction.

Two subtypes of ureteral valves have been described: one with ureteral stenosis at and distal to the site of the valve, and one that involves a distal ureter of normal caliber. Both types of valves have the orifice and long axis of the distal ureter eccentrically located with respect to the long axis and lumen of the more proximal dilated ureter (Figure 38.5). This configuration inhibits antegrade flow, but retrograde flow in patients with a normal distal ureter is unimpeded. Whether the ureteral valve is the cause of obstruction or a secondary change that occurs as a result of obstruction with proximal dilation has not been completely resolved. Treatment of the valves depends on location and may involve resection, with subsequent ureteropyelostomy, ureteroureterostomy, or ureteroneocystostomy.

Ureteral polyps

Fibroepithelial polyps are the most common benign neoplasm of the ureter.[14] These lesions occur in all age groups and commonly present with hematuria or flank pain. An intravenous ureteropyelogram usually reveals a cylindrical ureteral filling defect that may prolapse into the bladder (Figure 38.6). Ureteroscopy allows identification of the smooth-surfaced fibroepithelial polyp. Endoscopic resection may permit complete removal of the polyp; however, if it is not completely removed, regrowth may occur.[14] With large polyps, complete endoscopic excision may be facilitated by an antegrade approach via percutaneous nephroureteroscopy. Alternatively, ureterotomy and complete excision of the polyp at its base is curative.

Figure 38.6 Retrograde ureteropyelogram demonstrating a long, smooth filling defect in the distal ureter of a patient with a fibroepithelial polyp.

Megaureter

39

David B Joseph

Introduction

The word megaureter conveys the image of a grossly dilated ureter. The term is non-specific and does not provide insight into the pathophysiology. Our knowledge of the megaureter has changed greatly over the past 15 years, primarily due to fetal sonography, which has allowed us to follow the natural history of the megaureter and gain a better insight into treatment (Figure 39.1).

Historic perspective

Classification

Megaureter is synonymous with a dilated ureter, megaloureter, wide ureter, big ureter, hydroureter – all descriptive terms that lack true meaning.[2] Cussen in 1971 reported on autopsy findings of the urinary system in infants and children. He found a child's ureter consistently measured less than 5 mm.[3] This was supported by the work of Hellstrom and coworkers who reviewed excretory urograms in 100 boys and 94 girls. They directly measured ureteral size from the imaging studies and uniformly found the ureter to be less than 6 mm.[4] By definition, a megaureter equates to a ureter of >8 mm in diameter. In 1977 Smith[5] reported on a classification system developed by a working party of pediatric urologists.[6] The group presented their findings and recommendations at an international pediatric urologic seminar in Philadelphia in 1976. An agreement was made to standardize the nomenclature and classification of the megaureter. The megaureter was classified as primary, referring to a lesion intrinsic to the ureter, and secondary, denoting a reaction of the ureter to a process elsewhere. They went on to create the 'ABC' subclassification, 'A' representing a refluxing megaureter, 'B'

Figure 39.1 An obstructed refluxing megaureter with an unusually long obstructing distal ureterovesical segment. (Reproduced from Joseph,[1] with permission.)

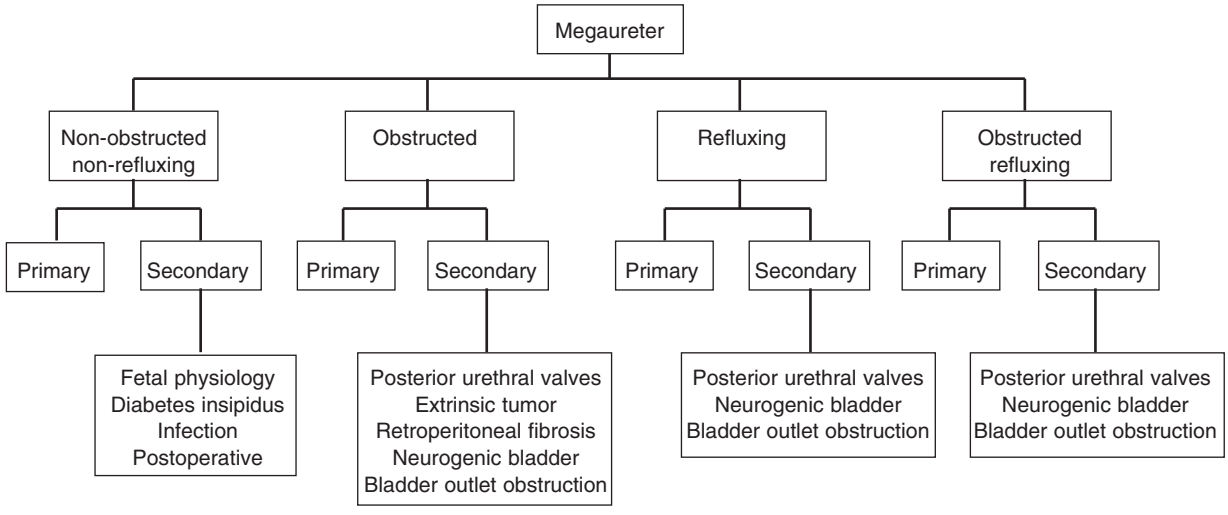

Figure 39.2 Classification of the ureter. (Adapted from King.[7])

an obstructed megaureter, and 'C' a non-refluxing non-obstructed megaureter. King modified this classification in 1980, adding a fourth subclassification consisting of the refluxing obstructed megaureter.[7] King's classification is used most often when describing the megaureter (Figure 39.2).

Anatomy

In order to understand pathophysiology, it is important to have a framework of normal anatomy. The ureter is divided into three distinct regions:

- the ureteropelvic junction
- the middle spindle
- the ureterovesical junction.

The ureterovesical junction is subsequently divided into the juxtavesicoureter and terminal ureter. The terminal ureter then separates into intramural and submucosal segments.[8]

The ureter is enclosed in a loose, ill-defined sheath within the retroperitoneum. This sheath is a protective barrier for the adventitia, particularly when confronted with neoplastic or inflammatory retroperitoneal processes. Proximally, the ureteral sheath and the ureteral adventitia become continuous with the renal pelvis. Distally, the sheath and ureteral adventitia join to form Waldeyer's sheath, which extends into the bladder wall as a portion of the deep trigone.[8]

The ureter consists of three layers: adventitia, muscularis, and mucosa. The adventitia is composed of longitudinally running collagen[9] loosely attached to the underlying muscularis, allowing for free peristaltic activity. The muscularis is made up of smooth muscle cells interspersed with collagen. The inner muscle bundles are arranged longitudinally, the middle circumferentially, and the outer longitudinally.[10] This configuration changes into longitudinally oriented muscle fibers in each layer with sparse collagen as the ureter enters the bladder and intramural region.[11,12] The mucosa consists of multiple layers of transitional epithelium lying directly on the lamina propria.

The ureter is supplied by a rich anastomotic arterial network. The proximal ureter is vascularized predominantly by an artery originating from the renal artery. The middle spindle receives a branch from the aorta and gonadal artery. The distal ureter is supported by arteries from the internal iliac, superior and inferior vesical arteries.[13] A periureteral arterial plexus courses the full extent of the ureter through the adventitia.

The proximal ureter receives neuronal input via the renal and aortic plexus. Unmyelinated nerves travel throughout the adventitial layer.[9] The middle spindle is innervated by the superior hypogastric plexus and the ureterovesical segment by the pelvic plexus.[14] Both adrenergic and cholinergic nerves have been identified within the ureter.[15] It is interesting that ureteral peristalsis is modulated by but not dependent on neuronal input.

Pathophysiology

Obstructed megaureter

The primary obstructed megaureter has generated the greatest interest and investigation. The primary

obstructed megaureter has been reported in approximately 25% of children with obstructive uropathy.[16] It is bilateral in 25% and occurs four times more often in boys.[17] The left ureter is more frequently affected, and the contralateral kidney may be dysplastic or obstructed in 10–15% of children.[2,17] Endoscopically, the obstructed ureteral orifice can have a normal appearance and insert appropriately on the trigone. Caulk[18] and Swensen et al[19] proposed that the obstructed megaureter was similar to the megacolon seen in Hirschsprung's disease. However, this proposition has been refuted based on histologic evidence showing ganglia present in the distal primarily obstructed megaureter in a similar distribution to that of a normal ureter.[20]

Several different histologic abnormalities have been associated with the primary obstructed megaureter, indicating a spectrum of pathologic events. A localized deficiency of muscle fibers within the ureterovesical ureter, with hypertrophy of circular muscle bundles immediately proximal to the deficiency, has been described as an adynamic distal segment resulting in obstruction[21–23] (Figure 39.3). The degree of obstruction may be correlated with the percentage of circular fibers. Gregoir and Debled found three histologic variants of obstructed megaureters:

- dense collagen infiltration of the terminal ureter
- distal circular muscular hypertrophy
- varying degrees of distal muscular dysplasia.[24]

Increase in collagen deposition between the lamina propria and muscle bundles of the distal ureter has been seen with electron microscopy.[25–27] These pathologic changes result in muscular derangement and increased interstitial connective tissue within the ureterovesical junction. The middle spindle and ureteropelvic junction segments are spared.[28]

Dixon and associates assessed the histologic structure of the ectopic obstructed ureter and found the terminal ureter was encircled by an additional thick collar of smooth muscle.[29] Normally oriented muscle layers were also present but had a diminished diameter. They speculate this embryologic malformation does not spontaneously resolve and becomes the subgroup of obstructed megaureter that requires early intervention.

Other clinicians have suggested abnormal acetylcholinesterase activity in the juxtavesical segment, a tonic response to norepinephrine, and increased intracellular calcium as etiologies of the obstructed megaureter.[30,31]

Some forms of the megaureter improve with time.[16,32–36] Spontaneous improvement may result from segmental maturation of the obstructed distal ureter. Nicotina and associates postulate segmental hypoplasia of the inner longitudinal muscle layer and the possible pathogenic involvement of transforming growth factor-β (TGF-β), which has been shown to effect maturation of smooth muscle cells.[32] TGF-β delays muscle cell differentiation and is detectable in the 11–21-week-old fetus but diminishes thereafter. TGF-β has been found in the distal ureters of children >2 years old with obstructive uropathy, but not in children >2 years old who had repair of a nonobstructed megaureter.[32] The spontaneous improvement in the obstructed megaureter may correlate with TGF-β depletion within the first 2 years of life.[32]

Figure 39.3 Obstruction due to an adynamic distal segment. (Reproduced from Joseph,[1] with permission.)

Refluxing megaureter

The refluxing megaureter is endoscopically characterized by a gaping lateral ureteral orifice. Bladder filling and cyclic voiding can transmit pressure into the ureter, resulting in mechanical enlargement (Figure

Figure 39.4 Vesicoureteral reflux in a male neonate with elevated voiding pressure.

Figure 39.5 The gross appearance of the ureter in prune belly syndrome. These ureters are elongated, tortuous, and dilated. There is often ureteral asymmetry, with the distal ureter showing significant ectasia. (Reproduced from Joseph,[39] with permission.)

39.4). Lee and associates have found a twofold increase in the ratio of collagen fibers to smooth muscle fibers in the refluxing megaureter compared with the obstructed megaureter and control ureter.[37,38] They defined collagen fiber types and have shown an increase in collagen types I and III for both obstructed and refluxing megaureters. However, the refluxing megaureter contains a significantly greater percentage of type III collagen than other megaureters. Type III collagen is a less-distensible fiber, raising speculation that this intrinsic characteristic stiffens the ureter. This may play an important role in the failure rate after operative correction of refluxing megaureters compared with the success noted in other forms of megaureters.[37]

The refluxing megaureter associated with prune belly syndrome represents a unique abnormality.[39] In gross appearance, these ureters are elongated, tortuous, and dilated (Figure 39.5). Endoscopically, the ureteral orifices are lateral, golf hole in appearance, and frequently associated with diverticulum. The distal ureter is characterized by asymmetric ectasia and is more often involved than the proximal ureter. Secondary obstruction may occur from kinking and folding of the redundant ureter. Primary obstruction has been reported at the ureterovesical junction in a select group.[39] Histologically, there is an increase in fibrous tissue at the expense of normally developed ureteric muscle. Children with prune belly syndrome and vesicoureteral reflux have been reported to have an increased ratio of collagen to smooth muscle fibers in the muscularis.[40] This may help explain the poor dynamic characteristics of the ureter, resulting in ineffective peristalsis and urinary stagnation.[39] Degeneration of non-myelinated Schwann fibers and a decreased number of nerve plexi may also contribute to decreased ureteral peristalsis.[41] Ureteric abnormalities tend to predominate in the distal portion of the ureter, an important concept to consider during operative intervention.

Non-refluxing non-obstructed megaureter

The non-refluxing non-obstructed megaureter is most often encountered in the neonate with the antenatal diagnosis of hydronephrosis. Whereas the etiology remains in question, fetal renal physiology may play a role. Rapid changes in renal vascular resistance,

glomerular filtration rate (GFR), and urinary concentration result in a 4–6 times increase in urine production prior to birth. This increase in urine output may surpass the dynamic ability of the ureter to transmit the increased volume to the bladder, resulting in transient ureteral dilation.

McLellan et al report resolution of the non-refluxing megaureter in the majority of children, with the time to resolution based on the initial grade of hydronephrosis. Children with grades 1–3 hydronephrosis resolved at a median age of 13, 24, and 35 months, respectively, and children with grade 4 and 5 hydronephrosis resolved at a median age of 48 months.[42]

Refluxing obstructed mgaureter

The refluxing obstructed megaureter results from ectopic insertion of the ureteral orifice in the region of the bladder neck. During bladder filling, the bladder neck is closed, acting as a distal obstruction. With voiding, the bladder neck opens and allows for reflux. A cyclic voiding cystourethrogram may be required for diagnosis in suspected cases.

Diagnosis

The routine use of fetal sonography has dramatically increased the diagnosis of the megaureter. Brown et al delineated the impact that fetal sonography has on identification of the megaureter.[43] Prior to fetal sonography, the diagnosis of a megaureter was preceded by clinically significant symptoms, particularly infection, hematuria, and pain.[2] In the presonography era, clinically significant megaureters accounted for 8% of children found to have hydroureteronephrosis (ureteropelvic junction obstruction was noted in 22%, posterior urethral valves in 19%, and the ectopic ureterocele in 14%).[43] With fetal sonography now routine, the megaureter is noted to occur in 23% of asymptomatic neonates, surpassed only by hydronephrosis, which is seen in 41%.[43] The increased incidence of the megaureter can be explained by a more liberal use of fetal sonography and improved technology.

An unknown percentage of infants identified as having an asymptomatic megaureter will subsequently go on to have clinical symptomatology. This places a greater burden on imaging technology and our ability to assess the true clinical significance of the megaureter's pathologic state.

Evaluation

Ultrasonography

Ultrasonography is the primary imaging modality in the assessment of antenatal hydronephrosis and the initial imaging study obtained for symptomatic genitourinary abnormalities. Sonography plays a key role in the assessment of the megaureter. Evaluating the size, shape, tortuosity, and bulbar appearance of the ureter in conjunction with similar findings of the renal pelvis can often give the impression of an obstructive process. The course of the ureter may be traced from the renal pelvis to its distal insertion. Careful pelvic sonography assists in the differential diagnosis of the megaureter. The ureter may enter an obstructed ureterocele or end in an ectopic location within the bladder neck or posterior urethra. An obstructed distal segment may be recognized when a peristaltic wave of urine abruptly stops a few centimeters from the bladder and rebounds into the dilated proximal ureter (Figure 39.6). The echogenicity of the kidney is a helpful parameter used to distinguish between an obstructive and a non-obstructive process, with increased echogenicity supporting obstruction.[44] A renal resistance index (RI) >0.70 has been suggested to correlate with obstruction. However, the utility of RI in the pediatric population may be limited in the absence of normal standards based on age.[45,46] In addition, sonography lacks the ability to quantify a dynamic process, and the true significance of any abnormal megaureter must be determined by a functional imaging study.

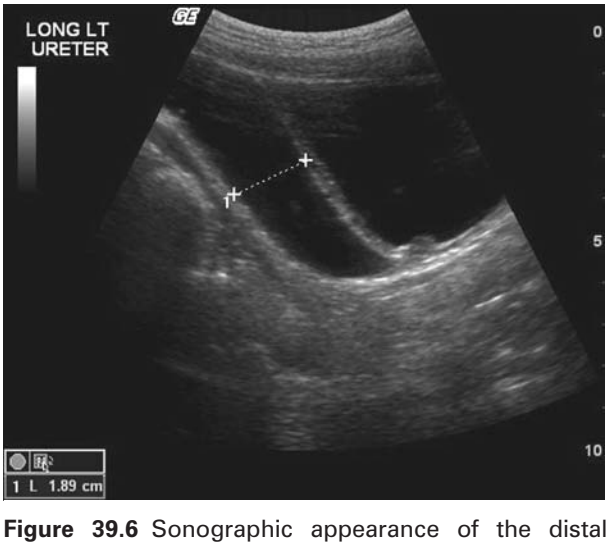

Figure 39.6 Sonographic appearance of the distal megaureter with a diminutive terminal segment.

Voiding cystourethrography

Voiding cystourethrography is essential to rule out vesicoureteral reflux. A conventional fluoroscopic cystogram is preferred over a nuclear cystogram in that the anatomic appearance of the bladder, bladder neck, urethra, and ureters is necessary for precise diagnosis and treatment. The cyclic voiding cystourethrogram is beneficial when an ectopic, sphincteric ureter is suspected. In this scenario, the ureter can be obstructed when the bladder is at rest and refluxes only during the voiding phase. Blickman and Lebowitz characterize the obstructed refluxing megaureter as having a markedly enlarged proximal ureter with a normal-appearing ureterovesical segment.[47]

Excretory urography

Excretory urography is waning as a diagnostic modality in the evaluation of pediatric uropathy. Even with tomography, only limited information is gained. Stool, bowel gas, and immaturity of the neonatal kidney limit its utility. In addition, the degree of hydronephrosis noted does not equate to severity of obstruction. On a rare occasion, excretory uropathy may play a role when anatomic definition is required.[48]

Renography

Diuresis renal scintigraphy provides the greatest quantitative information of functional and dynamic data. The degree of obstruction can be determined by evaluating multiple parameters, including renal uptake, excretion, time to peak activity, and $T_{1/2}$ following lasix washout. Two of the more common radiotracers used to evaluate obstruction are technetium 99m (^{99m}Tc) DTPA (diethylene triamine-penta-acetic acid) and ^{99m}Tc MAG3 (mercapto-acetyltriglycine).[49,50] DTPA is a glomerular agent and provides limited information during the first month of life because of a low neonatal GFR. MAG3 is extracted by the kidney and dependent on effective renal plasma flow not GFR. This results in less background artifact. These factors make MAG3 a more attractive agent during the neonatal period.[49]

Multiple variables affect data acquisition and interpretation. Consequently, renal scintigraphy must be performed in a standardized fashion, using a protocol that optimizes hydration state, administration of diuretic, and acquisition of time–activity curves.[51] It is important to have a separate activity curve generated for the kidney and the ureter when assessing for an obstructive pattern. Isolating simply over the kidney can produce deceiving results that show an acceptable washout of the radiotracer from the kidney only to be washed into an obstructed ureter (Figure 39.7). Obtaining activity curves over the ureter will help confirm distal ureteral obstruction. The timing of diuretic administration can play a role in assessing $T_{1/2}$, with benefits attributed to administration at a standard time either before or after radiopharmaceutical administration.[52] Regardless of the protocol used, it is most important that a consistent methodology is maintained in order to compare successive studies in the same individual.

Magnetic resonance urography

Magnetic resonance urography (MRU) may play a future role in the evaluation of the megaureter. MRU with gadolinium has less nephrotoxic effects than contrast agents used for intravenous urography and conventional computed tomography (CT) imaging. This imaging modality may become the anatomic study of choice, particularly when renal compromise is present.[53–55]

Percutaneous perfusion studies

Upper urinary tract urodynamic assessment can be helpful in difficult cases. The Whitaker test has traditionally been the procedure of choice.[56] However, the Whitaker test has limitations in the pediatric population. It is invasive and requires sedation for placement of a percutaneous renal catheter and bladder catheter. Whitaker described the test using a constant infusion of 10 ml/min, with obstruction defined as an elevation in renal pressure >22 cmH_2O of water pressure over baseline.[56] The rate of infusion accommodated by the normal infant ureter is unknown. Infusing the renal pelvis at a rate of 10 ml/min may overcome the peristaltic flow potential of the normal infant or child's ureter. A constant perfusion of testing medium while recording the renal pelvic pressure may be a more appropriate test.[57,58]

Fung and associates explored ureteral opening pressure as a novel parameter for evaluating the obstructive nature of pediatric hydroureteronephrosis.[58] Renal pelvic pressure was assessed while simultaneously documenting the passage of contrast material from the distal ureter into the bladder. The infusion rate was individually calculated for each patient and maintained within a physiologically relevant range. A pressure increase of 14 cmH_2O within the renal pelvis was deemed consistent with distal ureteral obstruc-

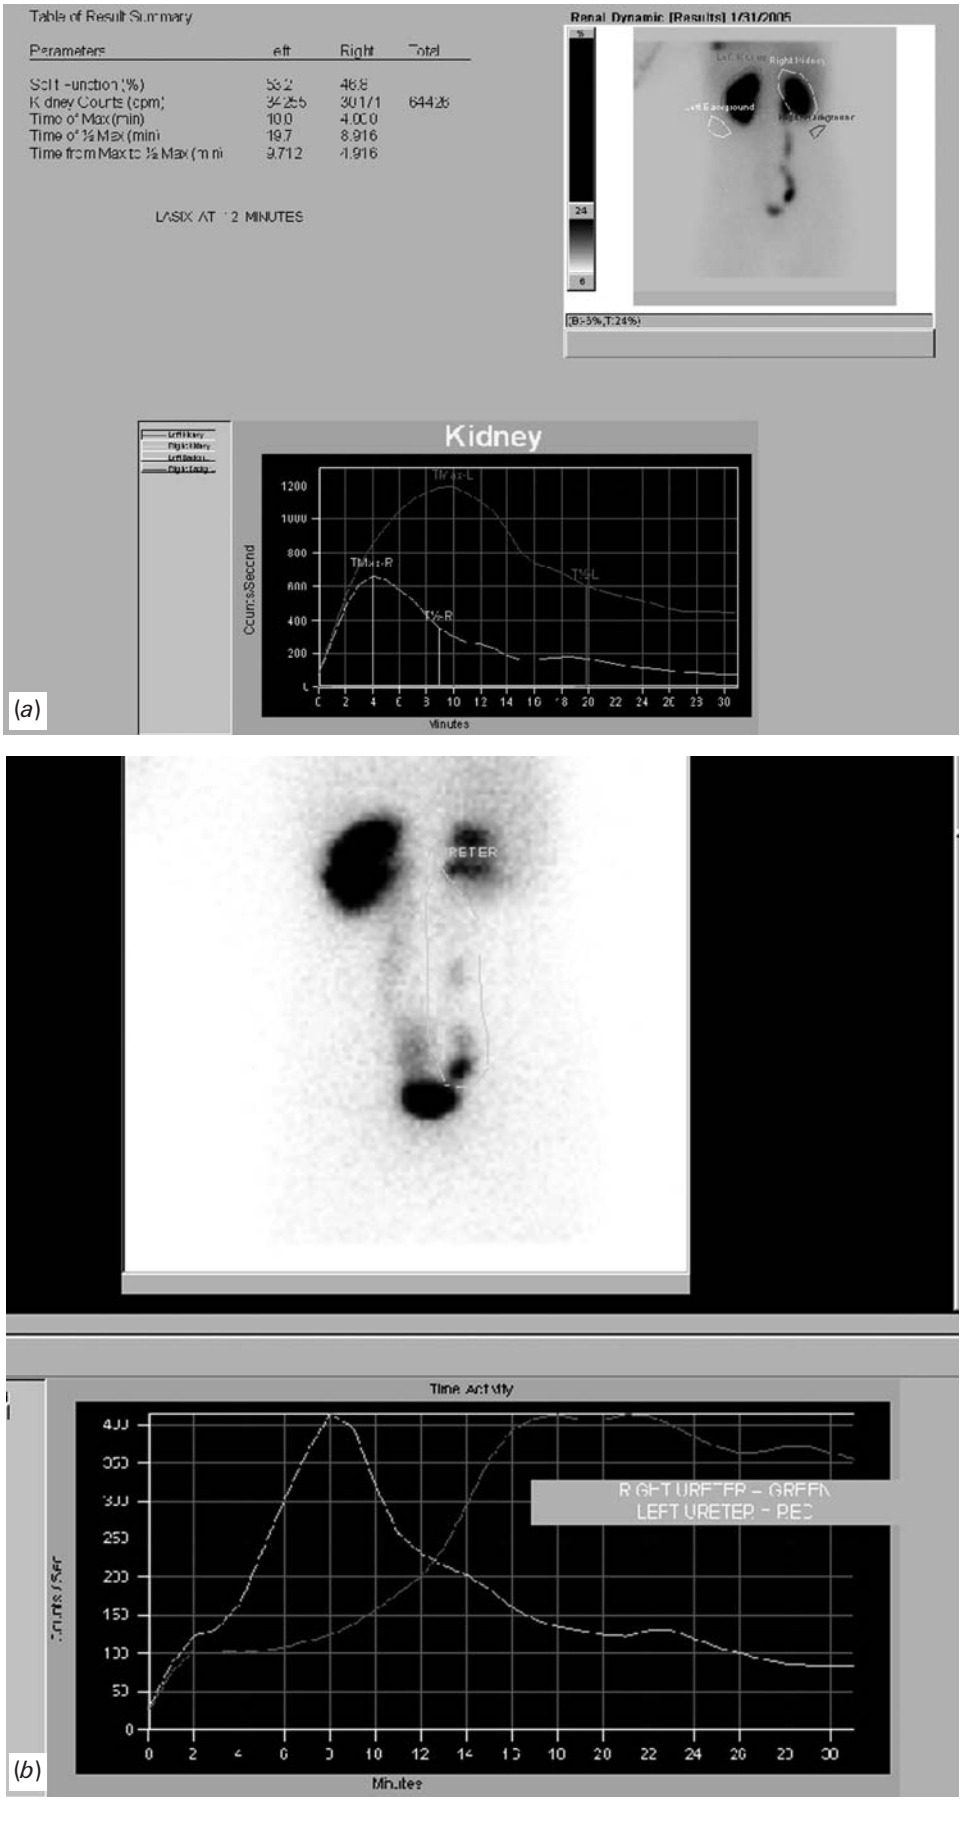

Figure 39.7 (*a*) A MAG3 renal scan, showing a composite pixel image and computer generated kidney washout curve. There is a relatively equal function with a delay in peak activity of the left system with $T_{1/2}$ washout of both kidneys <20 minutes. (*b*) A right ureteral pixel image and curve (**1**), indicating normal time–activity washout. A left ureteral time–activity curve (**2**), shows an obstructive pattern with progressive accumulation and no washout.

tion. Although this approach is invasive, it eliminates the problems of the infusion rate noted in the classic Whitaker study.[58]

Differential treatment

Therapeutic intervention of the megaureter is dependent on accurate classification. Secondary causes of a megaureter justify treatment of the primary problem, whether it is due to a neurogenic bladder, posterior urethral membrane, ureterocele, diabetes insipidus, or a retroperitoneal process. Treatment of those problems is described elsewhere.

Refluxing megaureter

Traditionally, grade IV/V and V/V vesicoureteral reflux (International Study Classification) has prompted operative intervention.[59] That approach may be appropriate for older children presenting with symptomatic urinary infections; however, there is growing evidence that operative intervention is not required in all neonates with refluxing megaureters, especially when identified during the work-up of asymptomatic antenatal hydronephrosis. High-grade vesicoureteral reflux in neonates occurs more often in males than females, and improvement can occur during the first year of life.[59] There is little reason to proceed with early intervention, particularly when an infant has remained symptom-free on prophylactic medical management.

The association of megacystis–megaureter was first described by Williams in 1954[60] and is now well understood.[61] By definition, megacystis–megaureter is a large-capacity, thin-walled bladder with massive primary vesicoureteral reflux.[60,61] Megacystis–megaureter occurs in approximately 80% of boys diagnosed antenatally with bilateral reflux and found to have renal impairment.[62] The etiology of the male predominance is unknown and does not appear to be due to bladder outlet obstruction. It is speculated that higher voiding pressure occurs in the male neonate. Children with megacystis–megaureter show progressive upper tract hydroureteronephrosis and bladder enlargement as a result of recurrent cycling of urine into the upper tract during a detrusor contraction followed by rapid refilling of the bladder upon relaxation of the detrusor after voiding. Over time, this cyclic event continually increases bladder volume and hydroureteronephrosis. Double voiding can temporize this process in children who are toilet trained: 10–15 minutes after the initial void, the child is encouraged to void again, allowing for an overall decrease in volume of retained urine. Positive effects of this technique occur first with stabilization of bladder volume, followed by reduction in bladder size and improvement of hydroureteronephrosis. Intermittent bladder catheterization can be an effective technique of eliminating residual urine in neonates and toddlers who are not toilet trained, allowing the child to reach an age where operative reconstruction would be beneficial. Ultimately, children with a megacystis–megaureter are best served by operative correction of the reflux.[61]

Non-refluxing, non-obstructed megaureter

Approximately 6–10% of neonates diagnosed with fetal sonography will have a non-refluxing non-obstructed megaureter.[63] A functional study is required to confirm adequate ureteral drainage. The initial medical management will be prophylactic antibiotics. Children with a non-refluxing non-obstructed megaureter maintain normal renal function and the megaureter often reverts to normal.

Obstructed refluxing megaureter

The obstructed refluxing megaureter occurs as a result of either a laterally positioned aperistaltic distal segment or ectopic insertion of the ureter into the bladder neck/posterior urethra. Although the condition is not an emergency, operative correction is required in order to diminish the risk of upper urinary tract deterioration and reduce risks of urinary tract infections, particularly those associated with the obstruction component.

Obstructed megaureter

The indication for treatment of the obstructed megaureter prior to fetal sonography was relatively straightforward. Most children presented with a symptomatic urinary tract infection, abdominal pain, nausea, or vomiting and underwent repair.[2] Fetal sonography has identified a substantial number of neonates with an obstructed megaureter, many of whom will not have clinical symptoms. Current management of the obstructed megaureter is controversial.[16,64–67] Medical management, based on prophylactic antibiotics and watchful waiting, allows for potential spontaneous regression of the obstructed megaureter. Renal parenchymal thickness and function must be objectively followed with sonography

and renography in order to identify renal compromise.

Repair of the infant megaureter is technically feasible but remains a challenge even in experienced hands. Secondary operative procedures have been reported as high as 10% when correcting an obstructed megaureter in an infant <8 months of age.[68] It is best to temper the initial urge to repair a megaureter until the child is older than 12 months of age, at which time technical hurdles are not as great.[69]

Occasionally, a neonate with an obstructed megaureter will present with severe renal compromise. In this situation, a distal cutaneous ureterostomy can provide temporary relief,[63] adequately draining the upper urinary tract and decreasing the risk of infection. The decompressed ureter may regain tone and a more normal caliber as the child grows and develops.[63]

Operative approach

Temporary diversion

A percutaneous nephrostomy is helpful when rapid drainage is required. But small nephrostomy tubes are difficult to maintain longer than a few weeks. When prolonged drainage is required, a distal ureterostomy is appropriate. A pyelostomy can be undertaken, but this results in unnecessary proximal diversion when the pathology exists at the bladder level.

A cutaneous ureterostomy is practical for the severely obstructed neonatal megaureter. The procedure carries minimal morbidity, allows for rapid continuous decompression, and can often be performed in the outpatient setting. The ureter is approached through a 2 cm incision placed within an ipsilateral low inguinal skin crease. The muscles are separated and the space of Retzius entered. Identification of the ureter is facilitated when the bladder is partially full and it is usually easily visualized on account of its size. Caution should be taken before opening the ureter, because bowel can be mistaken for a distended ureter, particularly in the infant. When there is doubt, a 21-gauge needle should be used to aspirate the contents and confirm urine. If the ureter is not easily identified, the obliterated umbilical artery provides a suitable landmark for initiating the search. The ureter will often be found just beneath the transected obliterated umbilical artery. Once mobilized, a cutaneous loop ureterostomy provides adequate drainage. The ureter is secured to the anterior rectus fascia with 4–0 or 5–0 absorbable suture and to the skin with the same. The size of the ureter prevents postoperative stenosis.

Definitive reconstruction

The approach to the ureter for definitive urinary reconstruction can be either intravesical, extravesical, or combined. The dilated ureter is redundant and tortuous. Straightening and tapering the ureter without devascularization is required. The functional ability of the ureter to transmit urine into the bladder via peristalsis is inversely related to the size of the megaureter. The ureter is tapered to achieve a ureteral diameter that will allow for a 4–5:1 ratio of tunnel length to ureteral diameter necessary for an antirefluxing repair. Enough ureter is mobilized in order to taper the intravesical ureter and a short portion of extravesical ureter. There should be a gradual transition from the tapered to dilated ureter to prevent a sharp gradient, which can act as a pseudo-obstruction. Multiple tailoring techniques exist for ureteral tapering and include ureteral imbrication and formal ureteral excision.[70–73]

Imbrication

Ureteral imbrication is appropriate for marginally dilated ureters. Two common imbricating techniques are the Starr and Kalicinski plications.[70,71] In the Starr plication, a Lembert technique with 6–0 absorbable suture is used to 'fold in' the redundant ureter over a 10 or 12 Fr catheter[70] (Figure 39.8). Kalicinski established a plication technique that excludes the redundant ureter from the urinary system[71] (Figure 39.9). A 10 or 12 Fr catheter is used for a template and an avascular segment of excess ureter is isolated. A running 5–0 or 6–0 absorbable suture follows the course of the ureter, separating it from the redundant segment. The redundant segment is then folded over the ureter and secured with a second absorbable suture layer (Figure 39.10). Regardless of the imbrication technique, the plicated ureter is brought into the bladder and secured to the floor either in a cross trigonal or a Politano–Leadbetter fashion.

Ureteral stents may be placed for 3–7 days, but are often unnecessary. The advantage of ureteral plication relates to preservation of the blood supply, decreased incidence of devascularization, minimal risk of urinary leak, and infrequent obstruction. When massive ureteral dilation is present, imbrication will add unwanted bulk, making the ureter difficult to reimplant particularly if a bilateral procedure is performed.

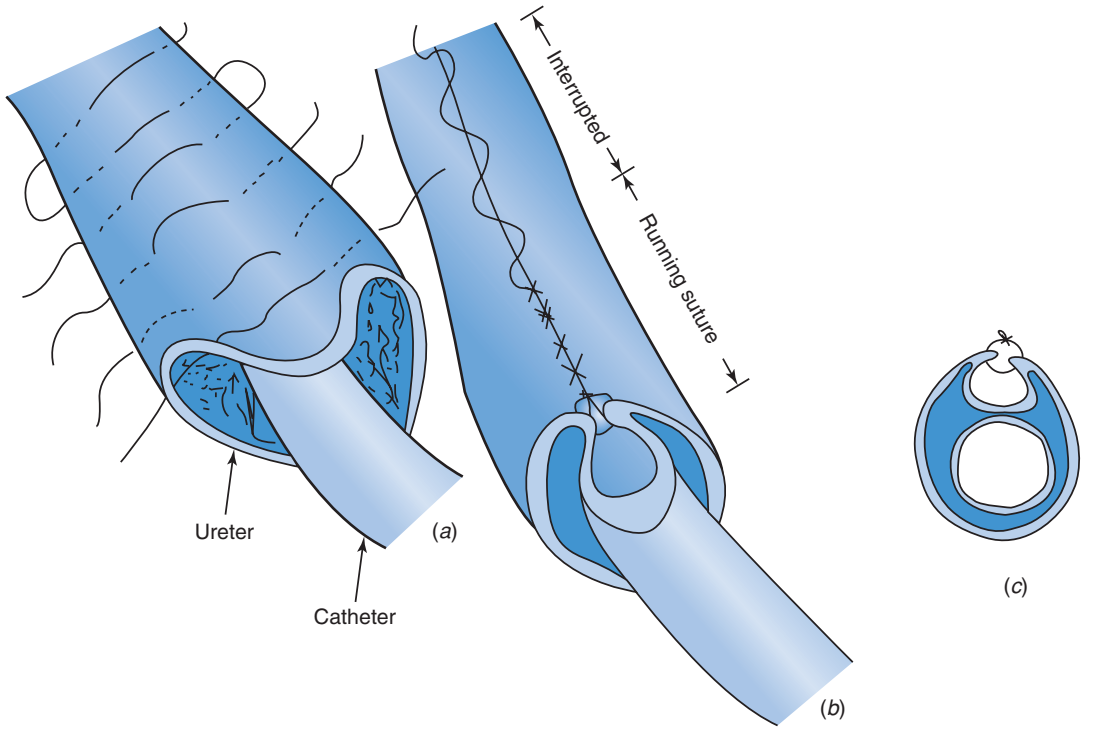

Figure 39.8 Starr technique of ureteral imbrication. (*a*) The ureter is folded inward over a 10 or 12 Fr catheter as a guide. (*b*) The distal portion is secured with interrupted sutures to allow for transection without compromising the running suture line. (c) Cross section of (b).

(*b*) It is then folded over the ureter using a 10 or 12 Fr catheter as a guide. (*c*) The distal portion is secured with interrupted sutures to allow for transection.

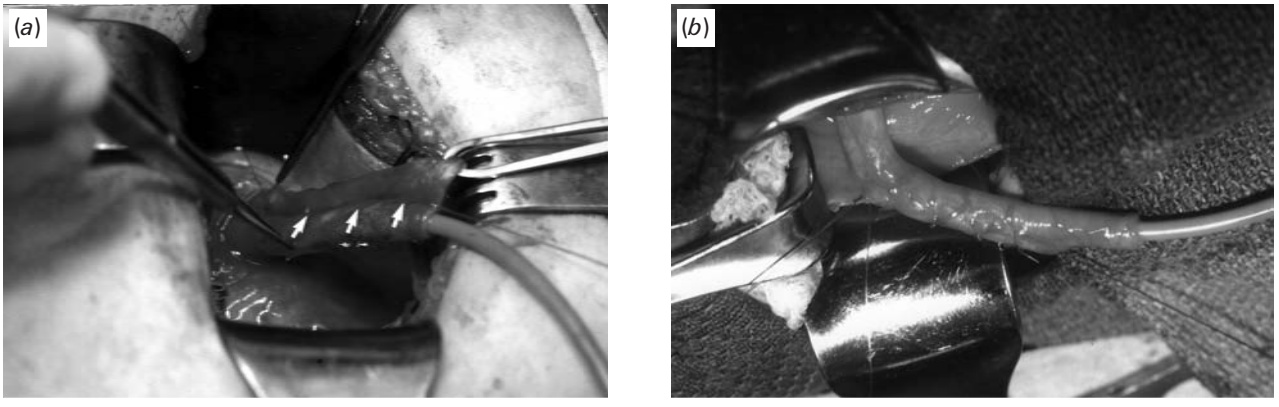

Figure 39.10 (*a*) Kalicinski plication technique isolating the redundant ureter from the distal flow of urine (arrows). (*b*) The excluded segment has been folded and secured to the distal ureter. (Reproduced from Joseph,[1] with permission.)

Excisional tapering

Formal excisional tapering of the ureter is required for extremely bulky ureters or a bilateral process. Hendren pioneered ureteral remodeling and the technique has stood the test of time.[72] The ureter is loosely tapered over a 10 or 12 Fr catheter, depending on the child's age and size. Straight Allis clamps are placed longitudinally along the ureter in a region of least vascularity. Angled Allis clamps are then placed over the ureter, securing the internal 10–12 Fr catheter (Figure 39.11). Care is taken to prevent the temptation of excluding too much redundant ureter, which results in excessive tapering around the catheter. The ureter is closed in two layers: first a running, locking 5–0 or 6–0 absorbable suture directly opposes the mucosa and the muscularis of the ureter – the locking technique limits ureteral reefing and decreases extravasation; a second running adventitial layer of absorbable suture decreases leaking. Both running layers stop a few centimeters from the distal end of the ureter. The very distal portion of the ureter is closed in two layers with interrupted sutures. This allows for excision of the distal ureter, if required, without interruption of the running suture line. A ureteral stent can be placed:

- to decrease urinary extravasation
- to provide a scaffold for the ureter to conform to during the postoperative period
- to prevent kinking
- to bypass the tapered region, which initially may act as an obstruction as a result of postoperative edema.

The ureter may be stented for 7–14 days. The necessity for a Penrose drain is variable, depending on the technique used for ureteral tailoring and the presence of a

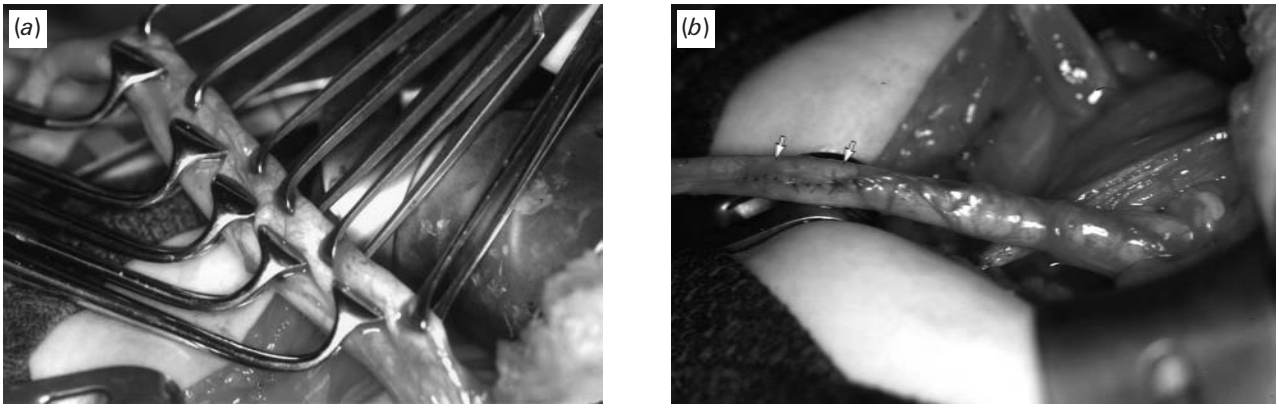

Figure 39.11 (*a*) Angled Hendren clamps placed loosely over a 10 or 12 Fr catheter securing the retained portion of the distal ureter. Straight Allis clamps isolate the segment to be excised. (*b*) A two-layer technique is used to close the ureter, interrupting the distal most portion and allowing for excision, as needed. The arrows indicate the interrupted portion. (Reproduced from Joseph,[1] with permission.)

ureteral stent. A Penrose drain may be helpful when a ureteral stent has not been placed and a substantial portion of tapered distal ureter remains extravesical.

In most situations, only the portion of the distal ureter which is going to be placed within the bladder and 1 or 2 cm beyond needs to be tapered. There should be a gentle transition from the ureteral hiatus at the bladder to the non-tapered ureter. Proximal ureteral tapering is rarely required and limited to children with persisting proximal hydroureteronephrosis, with an obstructed pattern in the face of a patent distal ureter.[73] In complex reconstructive cases, consideration should be given to a transureteroureterostomy and a unilateral tapered reimplant, particularly when there is small bladder.

Postoperative management

Removal of the ureteral stent is dependent on the procedure performed. The stent can be removed 3–7 days after imbrication, and 7–14 days following an excisional repair. Ureterograms at the time of stent removal are not necessarily beneficial. Postoperative edema can limit drainage, giving the appearance of a high-grade obstruction, when, in fact, removal of the stent is all that is required. Administration of a broad-spectrum antibiotic prior to removing a stent decreases the possibility of urosepsis even when the child has been maintained on prophylactic antibiotics.

Postoperative ureteral edema can persist for 6 weeks. Imaging studies, either sonography or renal scintigraphy, should be avoided during that time. The initial images on sonography may show increased hydronephrosis and proximal hydroureter when compared with preoperative sonographic imaging, particularly when repairing a refluxing megaureter (Figure 39.12). This is because of the compliant proximal ureter and relative resistance to flow through the tapered segment. It is important to review the ureteral size on the preoperative cystogram to help determine the significance of postoperative sonographic dilatation. Renal scintigraphy should be used to assess for postoperative obstruction in troublesome cases.

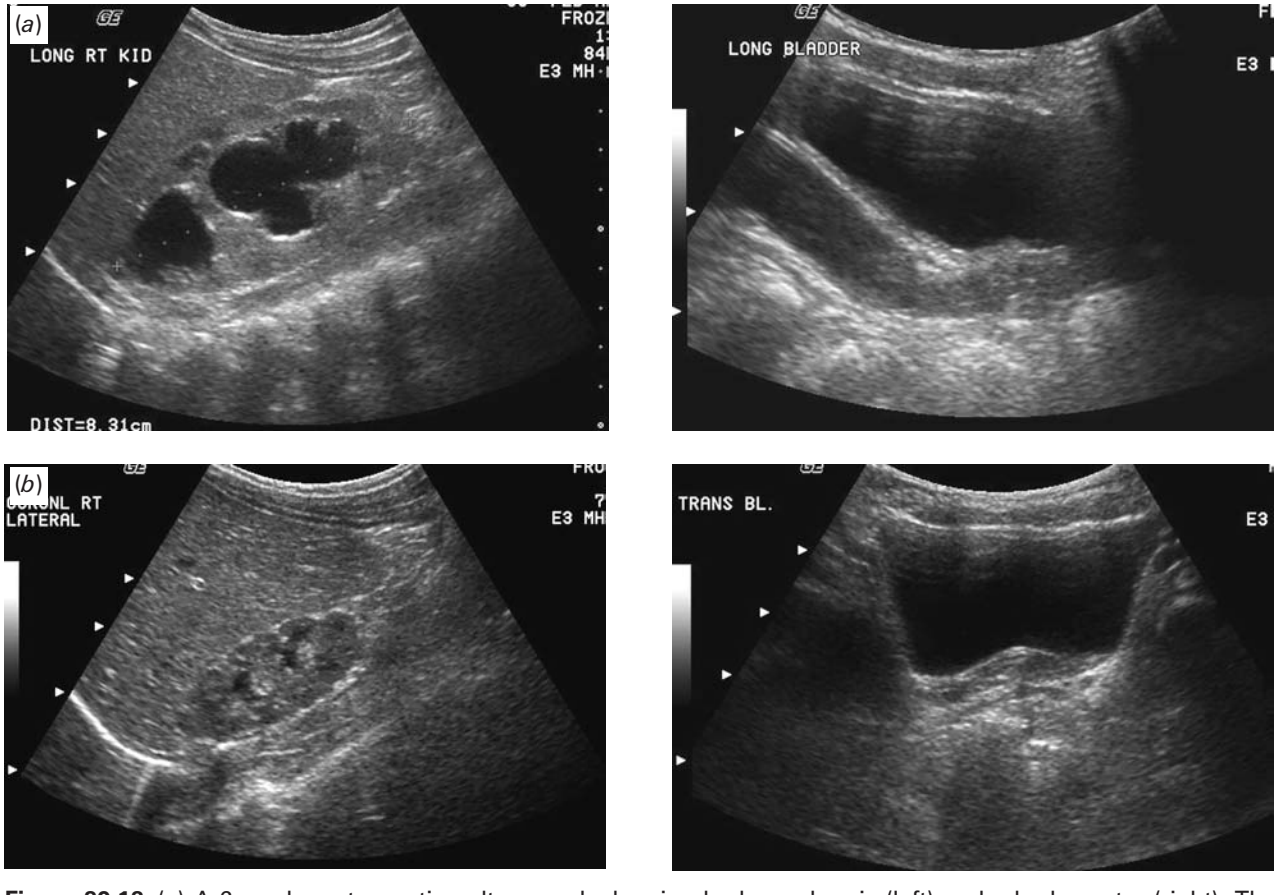

Figure 39.12 (*a*) A 6-week postoperative ultrasound, showing hydronephrosis (left) and a hydroureter (right). The preoperative ultrasound was normal. (*b*) A 3-month postoperative ultrasound. The hydronephrosis (left) and hydroureter (right) has resolved.

A postoperative voiding cystourethrogram at 6 months is performed to confirm the absence of vesicoureteral reflux. Prophylactic antibiotics can be discontinued with resolution of the reflux.

Complications

Successful operative outcome of megaureter reconstruction has been reported to be 93–95% for imbrication,[68,71,74–78] and 74–90% for excisional tapering.[68,74,76,79–82] However, the complication rate and morbidity is greater than when performing a non-tapered ureteroneocystostomy. The two most common complications are obstruction and persisting reflux.

Postoperative complications are not simply due to technical error; inherent ureteral characteristics and bladder dysfunction affect a successful outcome. Increased collagen deposition and altered smooth muscle may be the etiology for a higher rate of persisting vesicoureteral reflux following repair.[29,37]

Postoperative edema can lead to obstruction that requires temporary percutaneous nephrostomy diversion. Physician patience is prudent to allow for the operative edema to subside, which might take 2–3 months. Persistent obstruction is probably the result of ureteral ischemia and will ultimately require revision.

Persisting vesicoureteral reflux has been reported to occur in approximately 5% of tapered reimplants.[68,71,74–84] Transient mild reflux noted at 6 months can resolve with further time. Reflux persisting greater than 3 years is unlikely to improve:[68] when it is significant and symptomatic, secondary corrective intervention is required. A formal reoperative procedure is undertaken, with attention paid to preserving the ureteral blood supply and maximizing the ratio of ureteral tunnel length to diameter of at least 5:1. In-situ ureteral tailoring is an appealing alternative to a formal excisional repair. It achieves a gradual decrease in intraluminal diameter without compromising vascularity and avoids the difficult ureteral dissection. This should be considered in cases when the ureteral tunnel length had been maximized at the first encounter.[83] Contralateral reflux may occur more following repair of the refluxing megaureter compared with the obstructed megaureter. It has been suggested that the functional anatomy of the trigone is impaired in reflux but not in obstruction.[85]

Summary

The asymptomatic megaureter is commonly encountered as a result of the routine use of fetal sonography. The natural history of the megaureter supports observation and non-operative management of most infants. When operative management is required, precise classification of the pathophysiology, along with intervention by a pediatric specialist, should result in a successful outcome.

Ureteral duplication anomalies: ectopic ureters and ureteroceles

40

Michael A Keating

Introduction

Ureteral duplication is one of the most common anomalies affecting the genitourinary tract. Variants, including incomplete ureteral duplication and complete duplications with normally developed renal moieties, constitute the vast majority. As such, they represent no more than radiologic curiosities. Anomalies with clinical significance, including ectopic ureters and ureteroceles, are much less common. Historically, the majority of these were probably clinically silent.[1] A smaller portion became evident as a consequence of hydronephrosis, vesicoureteral reflux (VUR), or incontinence, either in combination or alone. More recently, antenatal diagnosis has uncovered many urologic anomalies, including different variants of ureteral duplications, which are asymptomatic. Antenatal detection enables the preservation of renal function and the avoidance of illness for some children. For others, perinatal identification creates controversy by introducing a large group of abnormalities that may have gone harmlessly undetected in the past.

Despite these decision-making dilemmas, it seems prudent to institute pre-emptive therapy for urinary tract anomalies that pose risk to a child, until those characteristics that typify their spontaneous resolution or a lifetime free of urologic problems are better defined. Spontaneous resolution seems unlikely for most ectopic ureters and uretereoceles. As a consequence, pediatric urologic surgeons must remain familiar with the natural history of duplication anomalies, well versed in the evolving recommendations for their management, and familiar with the variety of surgical techniques available for their reconstruction.

Embryologic considerations

Normal development

A review of normal development provides the basis for understanding the pathophysiology of anomalies of the ureter and, in some cases, aids in their diagnosis and clinical management.

Ureteral development coincides with that of the kidney between 4 and 8 weeks of gestation. The ureteral bud (metanephric duct) projects from the wolffian (mesonephric) duct just proximal to its junction with the cloaca (Figure 40.1). As the ureteral

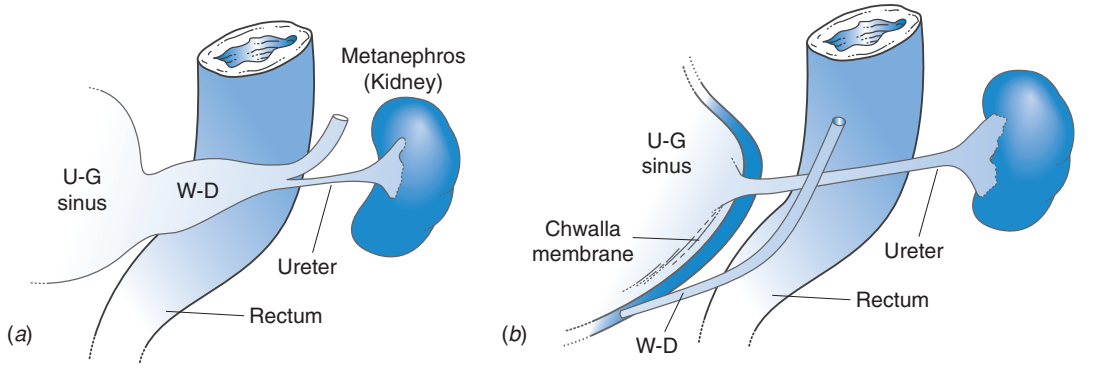

Figure 40.1 (*a* and *b*) Relationships of ureteral bud, wolffian (mesonephric) duct (W-D) and urogenital sinus (U-G). The segment of wolffian duct between urogenital sinus and ureteral bud represents the common excretory duct.

bud elongates in a cephalad direction, it penetrates the adjacent metanephric tissue and divides into the calices and collecting ducts. Proper fusion of the bud and the nephrogenic blastema is critical to tubular maturation within the renal anlage and ultimate function of the kidney. Mesenchymal–epithelial interactions, perhaps under the influence of local paracrine factors acting via receptors on the ducts, help pattern normal formation.[2]

The segment of wolffian duct between the cloaca and takeoff of the ureteral bud (the future ureteral orifice) is called the common excretory duct. The migration of tissue that occurs during the excretory duct's incorporation into the urogenital sinus helps to explain the variable relationships that sometimes occur between the ureter(s) and the trigone of the bladder, urethra, and genital ducts. Conceptually, these events represent some of the most difficult to understand in urinary tract embryology.

In brief, as the common excretory duct is absorbed into the bladder, the ureteral orifice migrates in a cranial and lateral direction. While this occurs, the excretory duct migrates to the midline and fuses with its contralateral partner to form the primitive trigone. This would explain the presumed mesodermal origin of the trigone, although recent studies have suggested that the tissue may instead be endodermal in origin.[3] The orifice of the wolffian duct ends in a caudal and medial position at the utricle. The wolffian (mesonephric)) duct ultimately differentiates into the prostate, seminal vesicles, vas deferens, and epididymis in males. In females, the wolffian ducts guide the müllerian ducts into position in the midline, where the latter fuse to form the uterus, proximal vagina, and fallopian tubes. After their involution, wolffian remnants persist in as many as 25% of women as Gartner's duct lying along the anterolateral vaginal wall and uterus, and the epoophoron and oophoron within the broad ligament supporting the fallopian tubes.

Explanations for the variety of anomalies that affect the ureter have their basis in this developmental progression, although the causes of the initial insult remain unclear.[4] An alteration in timing seems key.

Abnormal development

Lateral orifice ectopia occurs when the ureteral bud originates from a more caudal position than usual on the mesonephric duct. As a result, the ureteral orifice has more time to be absorbed within the bladder and begin its cranial and lateral migration. As the degree of laterality becomes more exaggerated, the length of submucosal ureter is progressively shortened. In addition, because the common excretory duct is shortened by the premature takeoff of the ureteral bud, its mesenchymal contribution to the trigone is blunted. This results in muscular deficiency of the trigonal–ureteral complex. Primary reflux becomes a common consequence of lateral ectopia and is thoroughly discussed elsewhere (see Chapters 42–46).

Caudal ectopia of the ureter results from an abnormally high takeoff of the ureteral bud. This allows less time for the orifice to be absorbed into the bladder. Now more closely positioned to ductal tissue typically destined to become wolffian, the ureter arrives in a medial trigonal or urethral location or extravesically positioned along the path of wolffian duct structures or remnants. The location of wolffian remnants helps explain an important difference in presentation of ectopic ureters between males and females (Figure 40.2). Ectopic ureters in males are connected to structures that continue to drain into the bladder proximal to the urinary sphincter. Urinary control should be normal. In contrast, ectopic ureters in females potentially vent into remnants adjacent to the fallopian tube (epoophoron), body of the uterus (paroophoron), and vagina (Gartner's duct), where they presumably rupture or are absorbed. Since the urinary sphincter is bypassed, incontinence results.

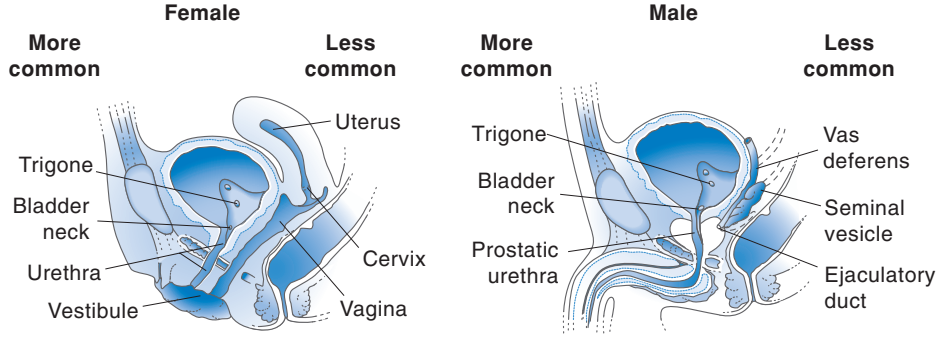

Figure 40.2 Anatomic locations of ectopic ureters.

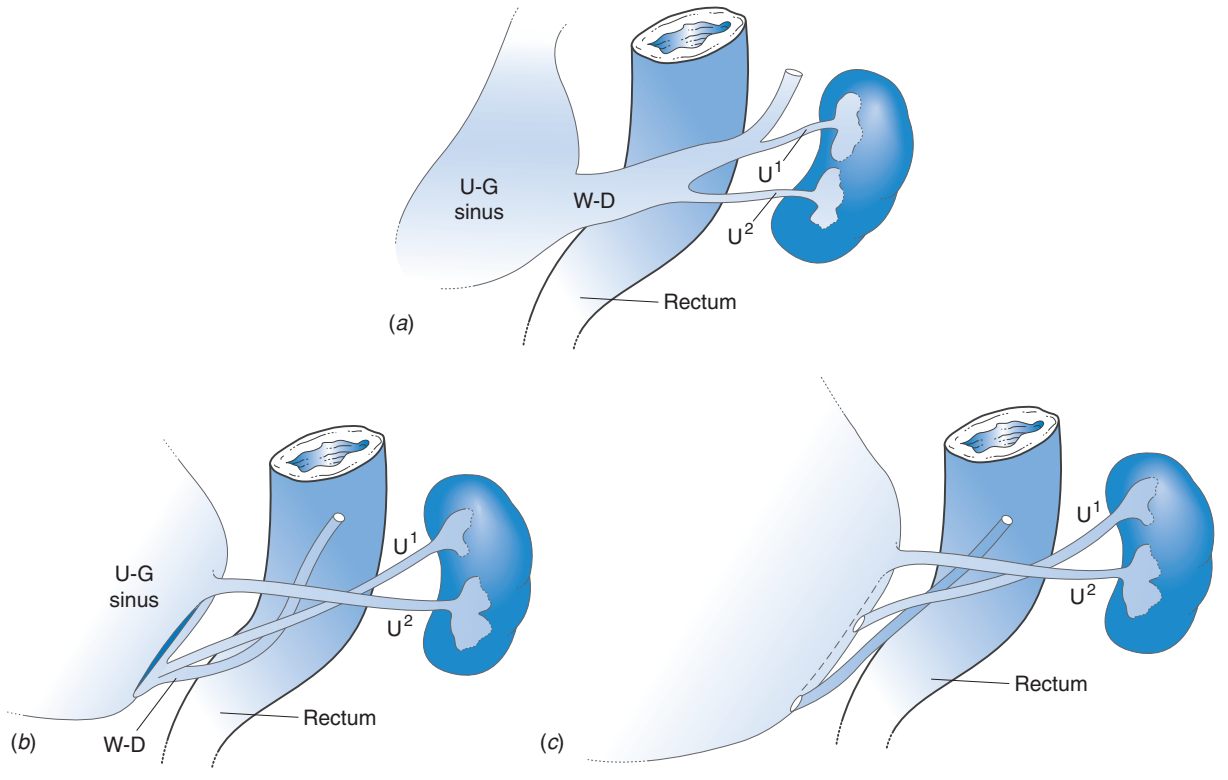

Figure 40.3 (*a–c*) Complete ureteral duplication. Caudal ectopia (U^1) results from abnormally high takeoff of ureteral bud, which remains positioned near wolffian duct tissue. Lateral ectopia (U^2) results from more caudal position, allowing more time for intravesical migration.

Ureteral duplication occurs when a single ureteral bud branches prematurely during its ascent or when two distinct ureteral buds arise from the wolffian (mesonephric) duct (Figure 40.3). The clinical significance of these anomalies depends on the location of the buds and their interplay with the developing kidney.

Branching of a single bud after its takeoff from the mesonephric duct results in incomplete ureteral duplication. The configurations that can occur range from anomalies as mild as a bifid renal pelvis (late branching) to nearly complete duplications having a common intravesical stem (early branching). The location of the ureteral orifice with incomplete duplications depends upon the takeoff of the ureteral bud in the sequence cited above. Bifurcations can occur at any level from the bladder to the renal pelvis but begin in the lower third of the ureter.[5] Most buds are normally positioned along the mesonephric duct and, as a consequence, incomplete duplications are usually radiologic curiosities having little clinical significance.

Complete ureteral duplication occurs when two ureteral buds project from the mesonephric duct, each having a separate interaction with the metanephric blastema. During their early takeoff, the buds interact with the primordial kidney in logical fashion. The most superior/cephalad bud induces the upper portion of the blastema (upper pole), while the lower bud joins the lower pole moiety. However, the ultimate positions of the ureteral orifices are governed by the same enigmatic rules of tissue migration and incorporation into the bladder described for singlets above.

When both buds are close together and project from a normal position along the mesonephric duct, both ureters will have normally positioned orifices. When the buds are more widely separated, one or both will be ectopic. If the superior/upper pole bud projects from an abnormally high position along the mesonephric duct, caudal ectopia is the outcome. If the bud to the lower pole originates from a more caudal position along the duct, lateral ectopia results. To achieve their ultimate positions, the ureters and their orifices complete a 180° clockwise rotation along their longitudinal axes. These relationships, defined by the Weigert–Meyer law, are unusually consistent.[6,7] Exceptions have been described but are rare.[8,9]

Recent studies using angiotensin type 2 receptor (*AGTR2*) gene mutant animals have demonstrated features similar to those of humans with duplication anomalies.[10,11] Similarities in renal development to the relationships defined by the Weigert–Meyer principle and the theories proposed by Mackie and Stephens (below) have been correlated with this genetic abnormality. There is a high likelihood that *AGTR2* plays a part in the polygenic mode of inheritance of ureteral abnormalities in humans.

Ureteroceles

Several theories have been proposed for the development of ureteroceles, though their etiology remains unclear. Some of the more popular theories are:

1 Persistence of Chwalla's membrane, which is a two-layered membrane that transiently separates the caudal end of the wolffian duct from the urogenital sinus (37 days' gestation),[12] is possible. Incomplete dissolution of the membrane could account for the cystic dilatation of the terminal ureter and stenosis of the orifice found with ureteroceles.
2 Abnormal muscular development of the terminal ureter has been implicated by a number of studies.[13] Ballooning of the distal ureter could be explained by a deficiency or an absence of its muscular investing layers, a finding shown in over 90% of specimens in one study.[14] By comparison, the distal segments of ectopic ureters consistently have musculature that is better developed than ureteroceles.[15] The ureterocele itself is covered with vesical mucosa, whereas the internal lining is made up of ureteral mucosa. Varying degrees of attenuated smooth muscle and connective tissue are sandwiched between. An element of meatal or perisphincteric obstruction,[16] may also contribute to the dilatation. However, some ureteroceles present without a functioning kidney, suggesting to some clinicians that urinary output is an unnecessary impetus to distal ureteral ectasia.[17] It is also plausible that the kidneys associated with these so-called 'blind ureteroceles' produce urine during an early critical stage in development but subsequently involute.[18]
3 Abnormal widening of the mesonephric duct may occur in the segment between its insertion at the urogenital sinus and the ureteral bud. This area normally dilates in concert with an undefined stimulus for vesical and urethral expansion. Ureteral migration is presumably completed before this expansion occurs. Proximal extension of the widening process into the distal ureter could result in ureterocele development.[4] This explanation seems plausible for intravesical ureteroceles, the ureter and orifice of which have migrated appropriately. Late incorporation of the ureteral bud from an abnormally proximal position within this dilated segment is another possibility. This explanation is more compatible with extravesical ureteroceles accompanied by ectopic orifices. Notably, ectopic ureters associated with even more proximal buds that insert into wolffian remnants are rarely ectatic at their distal ends. They are presumably unaffected by the stimulus that alters the urogenital sinus.[13] As discussed below, the concept of abnormal bud position may also account for the renal dysplasia that accompanies many extravesical ureteroceles.

Ureteral–renal interactions

The ultimate maturation of the renal blastema is dictated by its interaction with the ureteral bud. When this interplay is experimentally altered, the expected transformation of blastema to normal nephron does not occur.[19,20] Mackie and Stephens[21] proposed the mid-region of the elongate metanephric blastema as being most conducive to becoming normal renal parenchyma. Ureteral buds that originate from abnormally cephalic or caudal positions along the wolffian duct are destined to induce polar blastema, which results in cystic dysplasia (Figure 40.4). This theory offers a ready explanation for the dysplasia and scars found within kidneys with associated VUR where urinary tract infections (UTIs) have never occurred. It could explain why ectopic ureters with urinary insertions (GU-ectopy) are more likely to be associated with functioning renal parenchyma than ectopic ureters having wolffian or gynecologic (GYN-ectopy) insertions, where dysplasia is often present.[22] Ureteral bud takeoff could also explain the difference between the salvageable renal function usually seen with intravesical ureteroceles, and the poor function that occurs with extravesical ureteroceles.

Clinical correlates offer only guarded support of this theory, despite its attractiveness. Most studies generally cite poor renal function in the presence of severe reflux or marked ureteral ectopia,[23] though the difference between GU- and GYN-ectopy has come into question.[24] In addition, antenatal detection has added some new twists. In one review of specimens from 50 consecutive patients undergoing hemi-

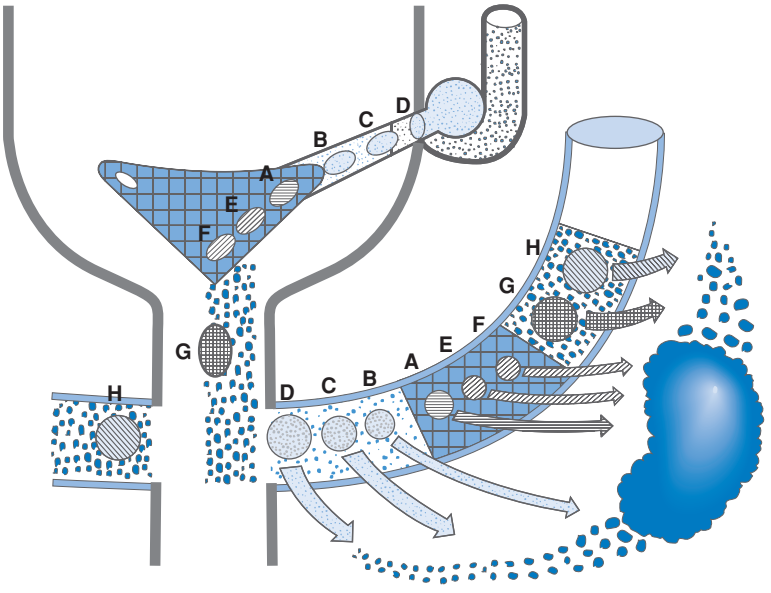

Figure 40.4 In theory, the position of the ureteral bud on the wolffian (mesonephric) duct corresponds to the final position of the ureteral orifice and differentiation of the metanephric blastema. Lateral and caudal ectopia can both result in renal dysplasia.

nephrectomies, dysplasia was seen in 70% from ureteroceles and 30% from ectopic ureters.[25] Each had been diagnosed antenatally, yet none were felt to have histologic changes that may have benefited from renal preservation surgery. By contrast, in a similar series of 40 consecutive antenatally diagnosed duplication anomalies, only six required heminephrectomy because of poor function and none of these showed evidence of dyplasia.[26]

Most historical reports cite salvageable renal function in only 20–30% of patients with ureteroceles. This pales next to the yield of contemporary series, whose numbers are inflated by the addition of antenatally diagnosed anomalies and the sensitivity of better diagnostics. The clinical implications are obvious (see Recommendations). Are these renal moieties that were previously destined to lose renal function as a consequence of progressive obstruction? Do they truly benefit from being surgically diverted or endoscopically decompressed? Or is renal parenchyma being preserved that has an intrinsic developmental insult? Nodular renal blastema has been reported in upper pole heminephrectomy specimens removed with ectopic ureteroceles.[27] Dysplasia is also a common finding.[28] The study by Arena et al[29] failed to show any evidence of reversible histologic changes in heminephrectomy specimens of patients whose ureteroceles had been prenatally diagnosed. It is unclear as to whether this is cause for concern. To date, no chronic complications of renal salvage unrelated to the surgery itself (e.g. hypertension or tumor formation) have been reported.

Nomenclature and classification

Ectopic ureters

The term ectopic ureter refers to a ureter that has migrated with the wolffian duct structures and is more caudally positioned than a normal ureter. Such ureters drain into the urethra, wolffian, or müllerian structures. The ureter to the lower pole of a duplication, which is often laterally displaced and ectopic in the purest sense, is regarded as orthotopic. Single-system ureters, that are laterally misplaced and reflux as a consequence, are discussed elsewhere (see Chapters 42–46).

Ureteroceles

Historically, ureteroceles associated with single systems were regarded as orthotopic or simple and considered adult type, despite the fact that some such variants are clearly ectopic and are found in children (Figures 40.5–40.9). Ureteroceles subtending the upper pole ureter of a duplex system have been described as ectopic and pediatric, although exceptions to both descriptions also commonly occur.[30] Gonzalez[31] felt it simplest to describe the anomaly based on the location of its orifice. Other than their

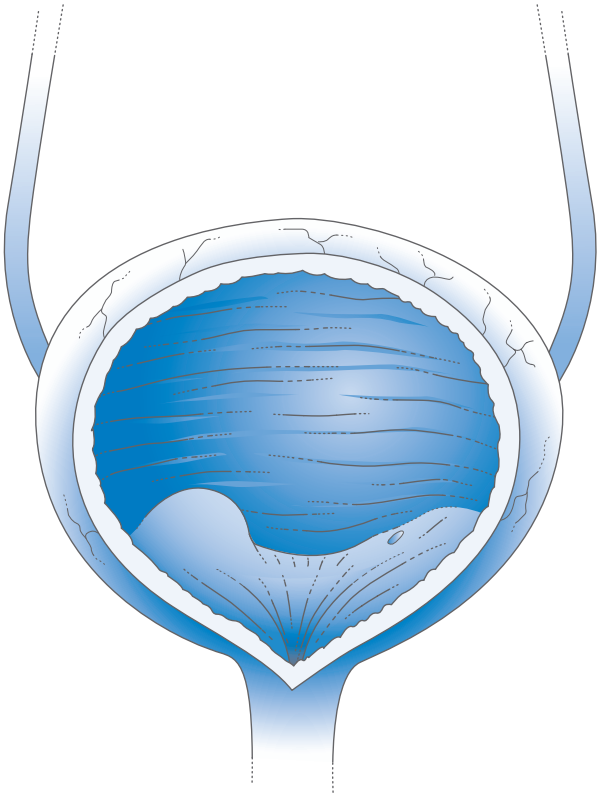

Figure 40.5 Intravesical ureterocele subtending a single ureter. This can also be classified as orthotopic or simple.

Figure 40.6 Excretory urogram shows bilateral single-system intravesical ureteroceles, right larger than left. Renal function is typically preserved.

Figure 40.7 Ultrasonic appearance of a similar patient with bilateral intravesical ureteroceles.

Figure 40.8 Intraoperative photograph of bilateral intravesical single-system ureteroceles.

association with a single or duplex system, two types of ureteroceles exist: intravesical or extravesical. This definition avoids the confusion associated with the terms ectopic and orthotopic. In addition, such nomenclature reflects the embryologic importance of

Figure 40.9 Large ureterocele extending towards the bladder neck (top). There is a catheter in the lower pole ureter, which is displaced and freely refluxes.

the ureteral bud/orifice to renal development and distortion of the bladder neck. However, this form of categorization potentially mislabels ureteroceles with an intravesical orifice but an extension into the bladder neck or urethra. Anatomically, these could also be considered extravesical.

A variety of other classification schemes have been proposed for ureteroceles, although no system has been adopted universally. Stephens' categorization[16] can be used to provide additional information about the location and configuration of the orifice of the ureterocele. These factors presumably account for the degree of distortion of the bladder neck and urethra, as well as the extensiveness of the renal dysplasia accompanying the anomaly (Table 40.1; Figures 40.10 and 40.11).

Characteristics

Ureteral duplications

Duplication is the most common congenital anomaly in the urinary tract: a 0.7% incidence was found in one series of more than 50 000 autopsies.[32] Intravenous urograms demonstrate duplications in 4% of studies, and hydronephrosis and scarring is seen in 27% of these.[33] Females are affected two to four times more commonly than males. The right and left collecting systems are affected equally. Bilateral duplications occur in 17–33% of cases.

The anomaly is an inheritable defect transmitted in an autosomal fashion having variable penetrance.[34]

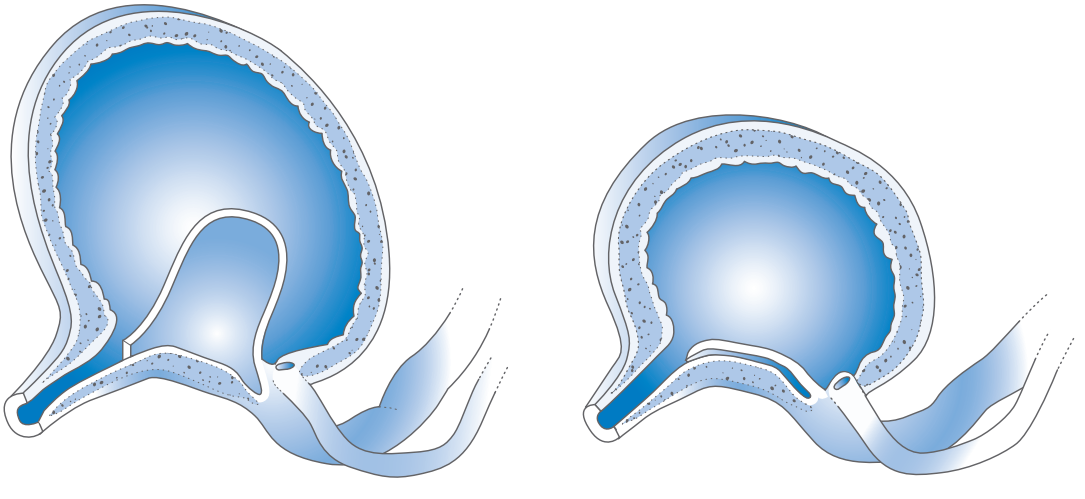

Figure 40.10 Sphincteric variant of extravesical ureterocele subtending upper pole ureter of duplex system. The orifice opens proximal to the external sphincter. Normal contraction of the bladder neck may contribute to ureteral obstruction.

Table 40.1 Classification of duplex ureteroceles

Ureterocele	Frequency (%)	Features
Intravesical		
Stenotic	40	Involve a congenitally small ureteral orifice adding an element of obstruction for the upper pole
Non-obstructed	5	The ureteral orifice is large and balloons open without any ureteral obstruction
Extravesical		
Sphincteric	40	The orifice opens outside the bladder and the ureterocele extends into the bladder neck and urethra. The orifice is normal or large and usually opens proximal to the external sphincter. In females, the meatus may open distal to the sphincter. At rest, the bladder neck and sphincter contract on the ureter and orifice, causing obstruction
Sphincterostenotic	5	Similar to sphincteric, but the ureteral orifice is stenotic
Cecoureteroceles	5	A large orifice opens in the bladder but a blind pouch or cecum extends into the submucosa of the urethra. When the cecum distends with urine, urethral obstruction can result
Blind ectopic	5	Similar to sphincteric, with no ureteral orifice

From Stephens.[13]

The parents or siblings of a child with a duplex ureter have as much as a one in eight chance of having a similarly affected child.[35]

Ectopic ureters

The incidence of ureteral ectopia was approximately 1 in 2000 in one series of autopsies in children. Many remain asymptomatic and a true incidence is difficult to determine.[36] Ectopic ureters occur in females two to three times more commonly than males,[37,38] although as high as 12-fold increases have been cited.[39] More than 80% of females with ectopic ureters have duplex systems. The majority (75%) in males are singlets.[40,41] Between 70 and 80% of ectopic ureters are associated with complete duplications. Nearly 20% of patients with ureteral ectopy have bilateral involvement.[37] In one report of nearly 500 ectopic ureters, the posterior urethra and prostatic urethra (57%) were the most common sites of drainage in males. The sem-

inal vesicle (33%) was also commonly involved. More remote terminations at the ejaculatory duct and vas were rare (10%). The urethra and vestibule were the most common drainage sites for 69% of females. Vaginal ectopy occurred in another 25%.[37]

Ureteroceles

The incidence of ureteroceles was as high as 1 in 500 in one autopsy study. They occur in females four times more commonly than in males.[42,43] Ureteroceles in girls are associated with duplex systems 95% of the time. By contrast, up to 66% of boys have single-system anomalies.[44] Nearly all appear in Caucasians.

Eighty percent of ureteroceles are associated with the upper pole of a duplex system; the remainder are single-system ureteroceles. Bilateral involvement occurs in 15% of cases.[45] A genetic predisposition has been shown.[46]

Presentation

Antenatal ultrasonography has dramatically increased the detection of urinary anomalies and, in some cases, has altered our understanding of their natural history. The yield from routine screening is significant. Abnormalities of the urinary system are detected in approximately 1 in 500 studies, second only to those of the nervous system. The breakdown of diagnoses in a typical series is shown in Table 40.2. Notably, ectopic ureters, duplications, and ureteroceles can all be detected antenatally. Further evaluation after birth is warranted, even in instances where the anomaly was present earlier in gestation and has presumably resolved.[48] In many cases, the exact etiology of hydronephrosis, the most common antenatal finding, cannot be determined until after delivery. Prenatal cases of bladder outlet obstruction have been reported.[49] Antenatal intervention has been described for rare cases of bladder outlet obstruction caused by ureteroceles.[50,51] Because of the tendency for urinary infections with hydronephrosis, it seems reasonable to keep newborns on prophylactic antibiotics (amoxicillin) until their anatomy is better defined (see Evaluation below).

After delivery, an extravesical ureterocele represents the most common cause of bladder outlet obstruction in newborn girls and the second most common cause in boys, after posterior urethral valves (PUVs). A true pediatric urologic emergency can result, depending on the degree of obstruction. The diagnosis of an obstructing ureterocele should be considered in any infant, especially a girl, with bladder distention, anuria, or ascites.[52] When full-blown prolapse occurs, clinicians will encounter a congested, ecchymotic interlabial mass (Figures 40.12–40.15). The mass may have varying

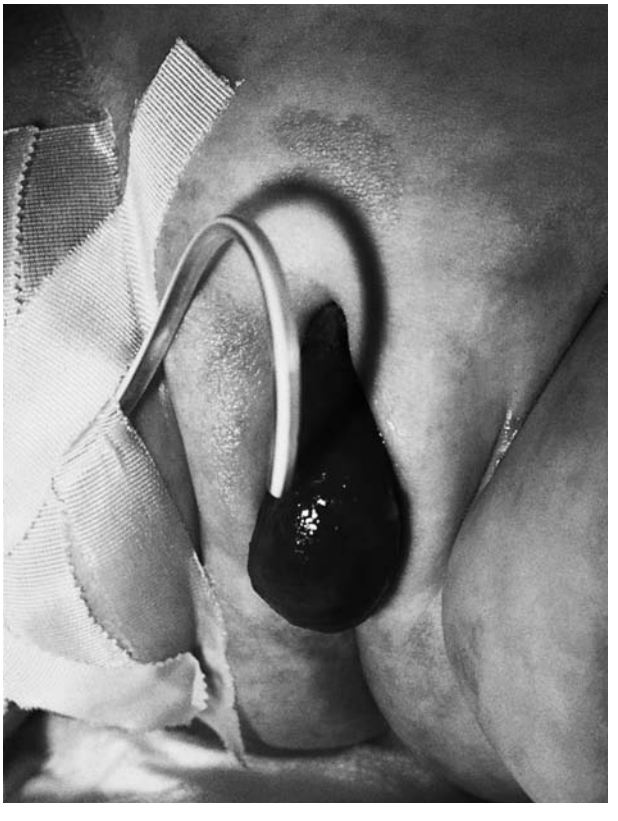

Figure 40.12 Congested and ecchymotic prolapsed ureterocele presenting as an interlabial mass.

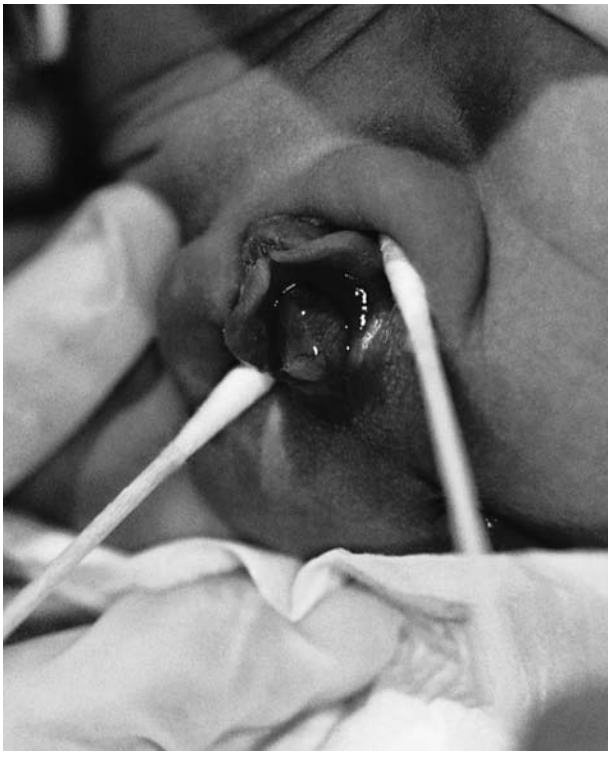

Figure 40.13 After incision at the bedside, the ureterocele is decompressed and retracts into the bladder after a few days. Given the severity of this type of defect, lower urinary tract reconstruction is ultimately warranted in affected infants.

Figure 40.14 Prolapsing ureterocele associated with non-functioning upper pole moiety appears as a filling defect occluding the urethra on excretory urography.

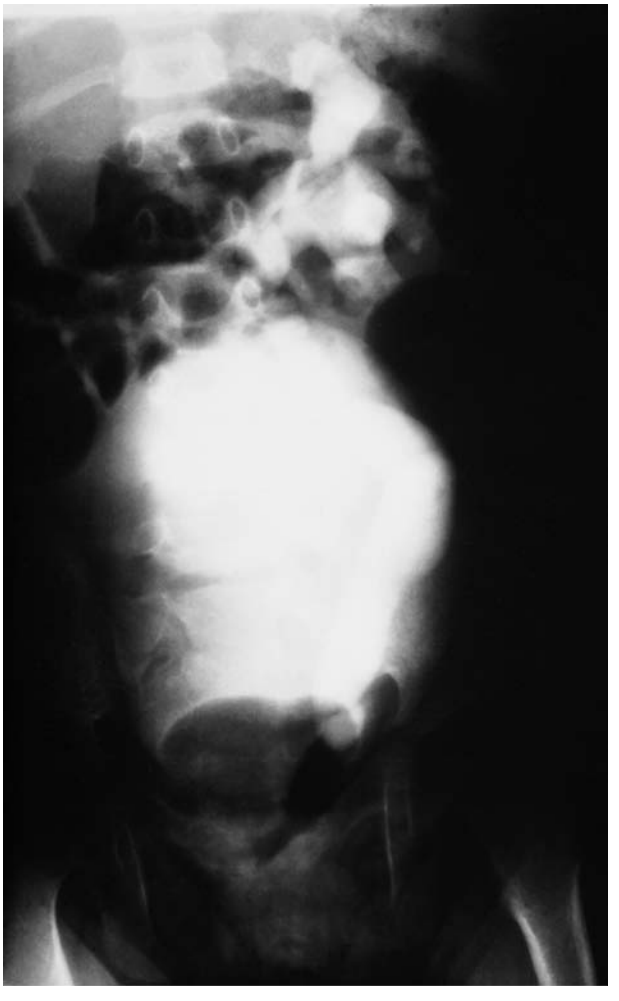

Figure 40.15 Large ureterocele associated with non-functioning right kidney occluding bladder and contralateral kidney. Given the size and position, prolapse through the female urethra of such a variant, especially with urethral extension, is easy to envision.

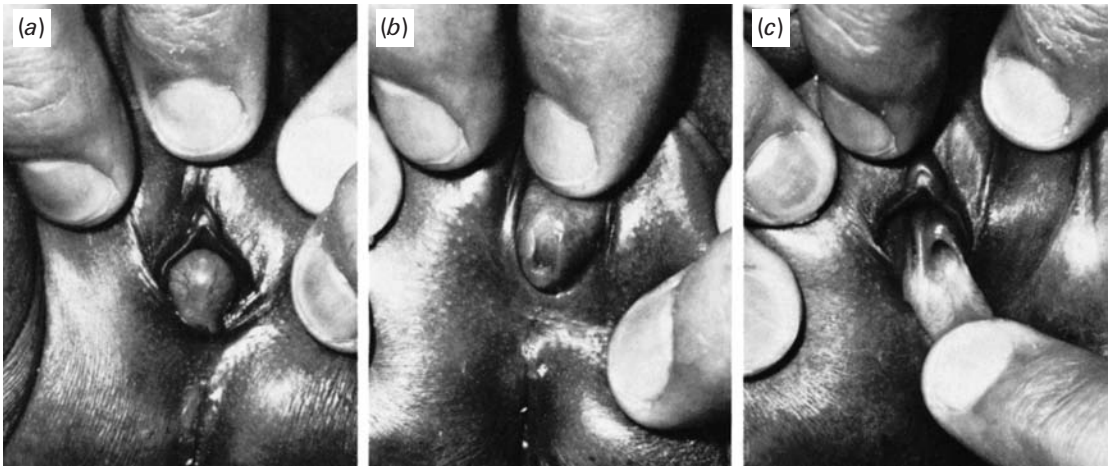
hues, depending on the degree of vascular compromise. Since prolapse usually occurs down the posterior wall of the urethra, the meatus will be evident anteriorly and can be catheterized. Cecoureteroceles, the distal projections of which extend down the urethra, have a less protuberant appearance if they reach the perineum. They are rarely ecchymotic since vascular compromise is not an issue (Figure 40.16). The smooth wall of the ureterocele helps differentiate it from the more ominous grapelike appearance of sarcoma botryoides. The white mucus-filled periurethral (Skene's) duct cyst is considered in the differential, as is Gartner's duct cyst. The latter can protrude from the vagina and become infected, and is often associated with an ectopic ureter that is blind ending at its proximal extent or connected to a rudimentary kidney.[53,54] When not evident on examination, the diagnosis of an obstructing ureterocele



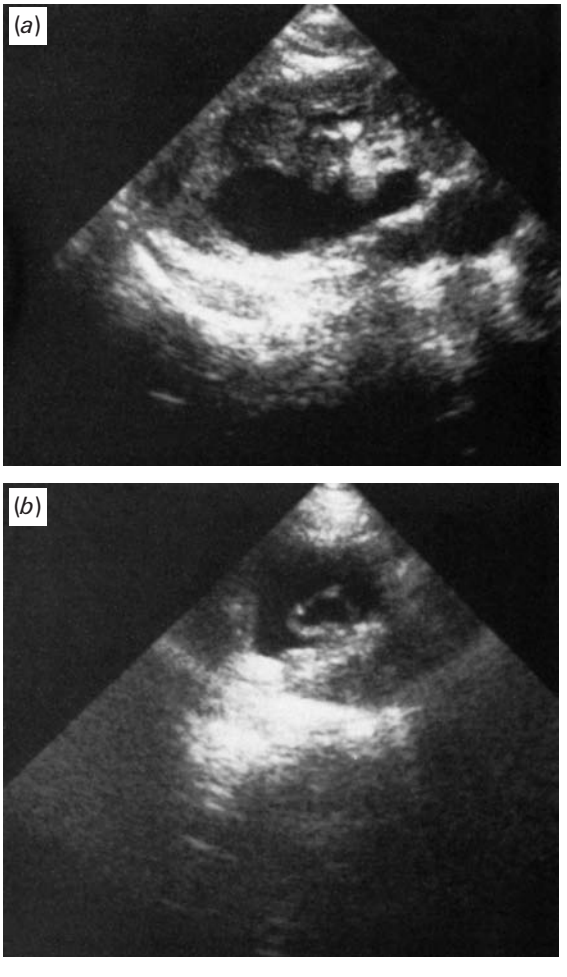


Figure 40.16 (*a*) Typical presentation of a cecoureterocele. (*b*) The cecoureterocele is pushed upward, revealing the hymenal ring below. (*c*) The urethra can be seen above the ureterocele. This ureterocele has a natural pink coloration that distinguishes it from a periurethral Skene's duct cyst, which is yellow-white and mucus-filled.

(or other urethral obstruction) is suggested by the history of a weak or intermittent stream.

More commonly, ureteroceles cause unilateral hydronephrosis from ureteral blockage. In severe cases, an abdominal mass becomes palpable. Patients not detected antenatally typically present with UTIs (Figures 40.17 and 40.18). In one series of 58 cases, 90% were identified before age 3 years, half of whom presented with UTIs.[15] Non-specific symptoms of failure to thrive and colic also occur.

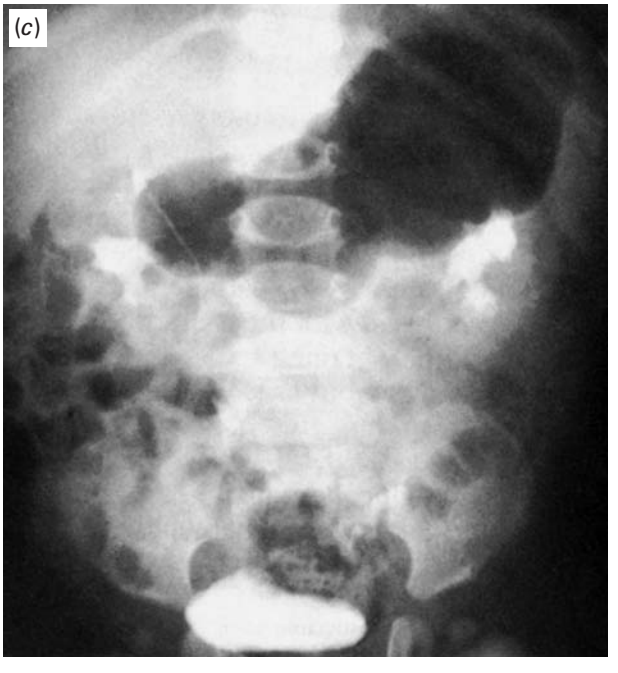

Figure 40.17 A ureterocele in a 3-month-old girl admitted with urinary tract infection. (*a*) Hydronephrosis of left upper segment. (*b*) Bladder view clearly demonstrates the ureterocele projecting into the bladder. (*c*) Altered axis of the kidney on an excretory urogram suggests the left duplex ureter but does not demonstrate an anomaly as effectively as ultrasound, which is often the case in newborns and infants.

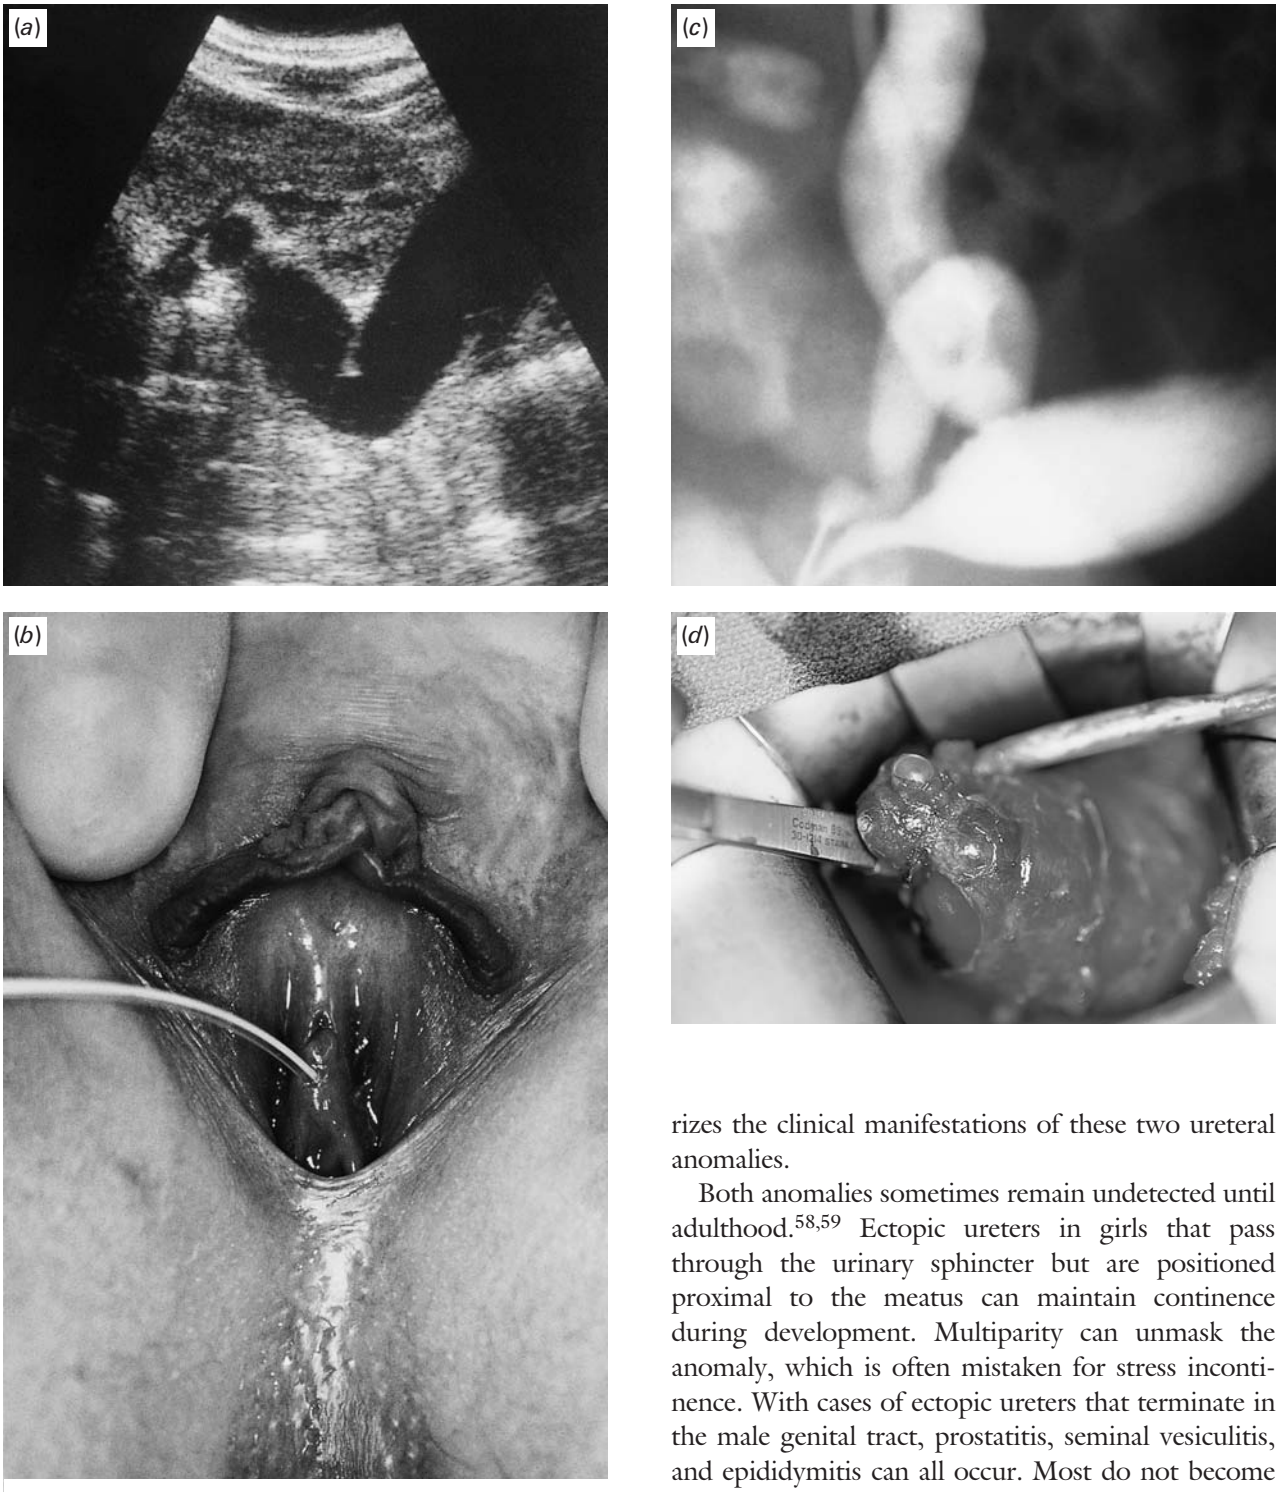
Figure 40.18 Gross pus from the vagina of an infant with an ectopic ureter.

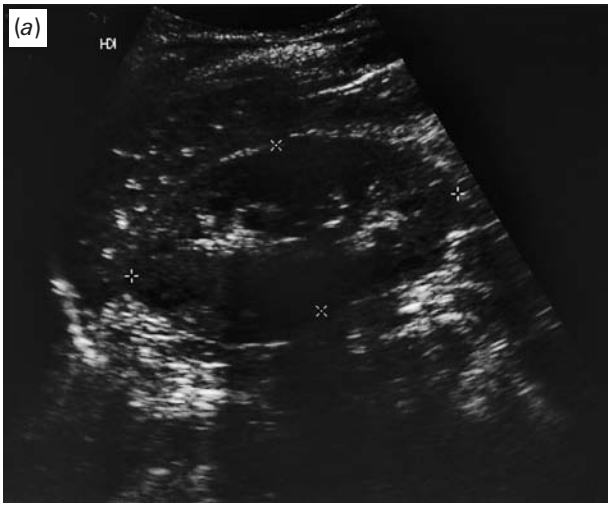
Flank pain, fever, and abdominal mass are common presentations of ectopic ureters left undetected until a later age.[55] Ureteroceles can cause irritative voiding symptoms by obstruction or infection but voiding abnormalities accompany ectopic ureters far more commonly. In addition, the distal segment of ectopic ureters inserting at the verumontanum can elevate the bladder neck, causing outlet obstruction in boys of any age.[56] It is important to remember that ectopic ureters always insert proximal to the urinary sphincter in males. As a result, incontinence does not usually occur in boys with the anomaly. Bilateral single ectopic ureters, associated with bladder neck maldevelopment and lack of sphincter control, are one exception (see below). Another is the frequency and urgency that sometimes results from the trickle of urine into the posterior urethra.[37] However, the more usual proximal insertions into structures of wolffian origin (seminal vesical, vas, epididymis) present their own problems, and ureteral ectopia should be suspected in any infant or child who presents with a culture-proven case of bacterial epididymo-orchitis.

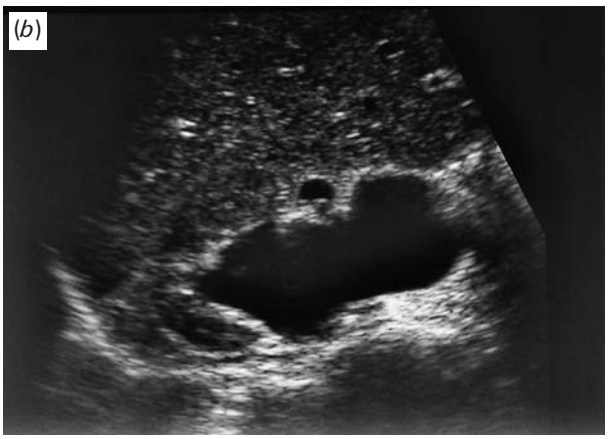
Clinicians should also be wary of any girl who reportedly has never been fully toilet trained. These patients must be approached with an open mind, and the possibility of ureteral ectopia entertained, especially when damp underwear is found on examination. In many cases, a cadre of physicians has treated the patient for presumed bladder dysfunction or psychosocial problems. When the ureter exits along the urethra, the voiding pattern often includes bladder control and spontaneous emptying (from the other ureters having normal bladder insertion) followed by an uncontrollable loss of urine as the obstructed system vents secondarily (Figure 40.19). With vaginal ectopy, continuous wetting in a girl having an otherwise normal micturition pattern and control (in contrast to bladder dysfunction) is a classic presentation[57] (Figures 40.20 and 40.21). The degree of incontinence depends on the urinary output from the affected kidney. In some cases, small amounts of urine cause sporadic incontinence that occurs only while standing. The latter is commonly mistaken for vaginal voiding or stress incontinence. Table 40.3 summa-

Table 40.3 Clinical presentations

Gender	Features
Ectopic ureters	
Both	Acute or recurrent urinary infection
	Abdominal mass/pain
	Failure to thrive
Females	Continuous dampness with otherwise normal voiding pattern after toilet training
	Vaginal discharge
	Orifice evident along the urethrovaginal septum
Males	Epididymo-orchitis
	Urgency and frequency
	Constipation, pelvic pain, painful ejaculation, epididymitis
Ureteroceles	
Both	Acute or recurrent urinary tract infections
	Hematuria
	Failure to thrive, abdominal or pelvic pain
	Abdominal mass
Females	Prolapsed interlabial mass
	Bladder outlet obstruction
Males	Bladder outlet obstruction







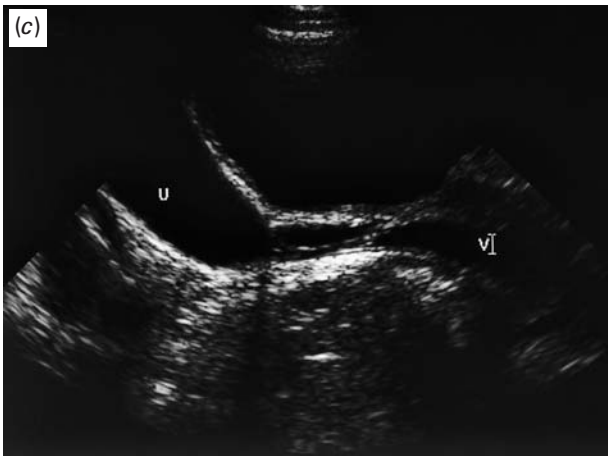


Figure 40.19 Ectopic ureter in a 7-year-old-girl with incontinence. (*a*) Ultrasound provides useful screening of such patients and often makes the diagnosis. (*c*) Retrograde study of the ectopic ureter. (*d*) At exploration, the megaureter is shown entering the cap of the cystic dysplastic upper pole moiety.

rizes the clinical manifestations of these two ureteral anomalies.

Both anomalies sometimes remain undetected until adulthood.[58,59] Ectopic ureters in girls that pass through the urinary sphincter but are positioned proximal to the meatus can maintain continence during development. Multiparity can unmask the anomaly, which is often mistaken for stress incontinence. With cases of ectopic ureters that terminate in the male genital tract, prostatitis, seminal vesiculitis, and epididymitis can all occur. Most do not become apparent until the onset of sexual activity. Historically, single-system ureteroceles usually presented during adulthood. An intravesical location, coupled with preserved renal function, allows most to go unnoticed until later age (Figure 40.22). This accounted for their prior designation as 'adult type', a label since dropped with the advent of antenatal diagnosis. Common presentations still include stones, milk of calcium, and recurrent UTIs.[60]

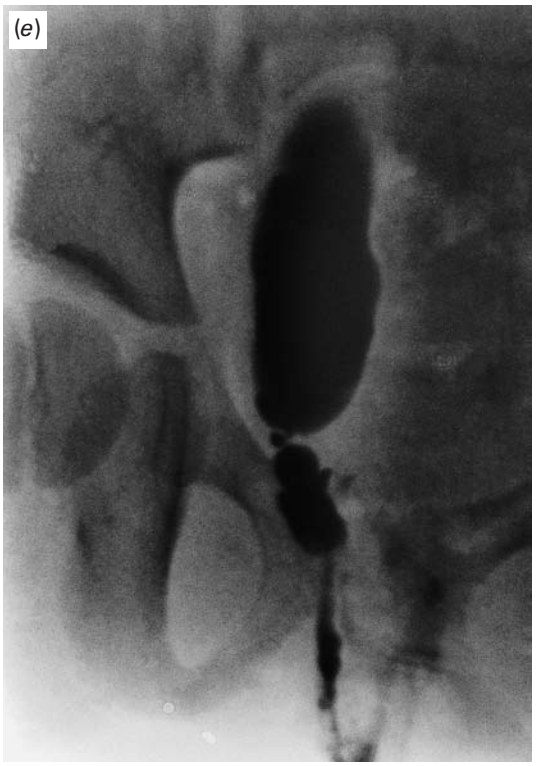

Fig 40.20 Urinary incontinence in a teenage girl felt to have bladder dysfunction. (*a*) Some views of the right kidney by ultrasound look fairly benign. (*b*) More proximal views are revealing and show a superiorly positioned cystic mass. (*c*) Pelvic views demonstrate the ureter entering the vagina. (*d*) Excretory urography shows the duplicated right kidney, with evidence of function of the upper pole. (*e*) Retrograde study of the ectopic ureter.

Figure 40.22 Single-system intravesical ureterocele presenting as a urinary tract infection in a 16-year-old. If the impressive dilatation above the small ureterocele represents a progressive change, questions are raised about the natural history of the anomaly and the validity of the expectant treatment of antenatally diagnosed ureteroceles.

Evaluation and diagnosis

Ectopic ureters and ureteroceles present diagnostic dilemmas when it is difficult to determine from which renal moiety they arise. They can also mimic one another at the bladder level, which has implications for treatment. A sonogram (also called ultrasonography, ultrasound, or US) and voiding cystourethrography (VCUG) are indicated in the initial evaluation of

any child suspected of having a ureteral anomaly. Once detected, a functional test (radionuclide renal scan) becomes necessary to the decision-making process when considering the different options in management. Additional studies – e.g. excretory urography (EU) and computed tomography (CT) – are also sometimes necessary. Cystoscopy, sometimes in concert with retrograde ureteropyelography (RUP), completes the evaluation.

Ultrasonography

During initial screening, the differentiation of single from duplex systems is usually possible by ultrasound evaluation. The renal manifestations of ureteroceles and ectopic ureters can be identical. Variable degrees of hydronephrosis of the affected kidney or upper pole moiety depend on the severity of ureteral obstruction (Figure 40.23). Hyperechoic parenchyma is sugges-

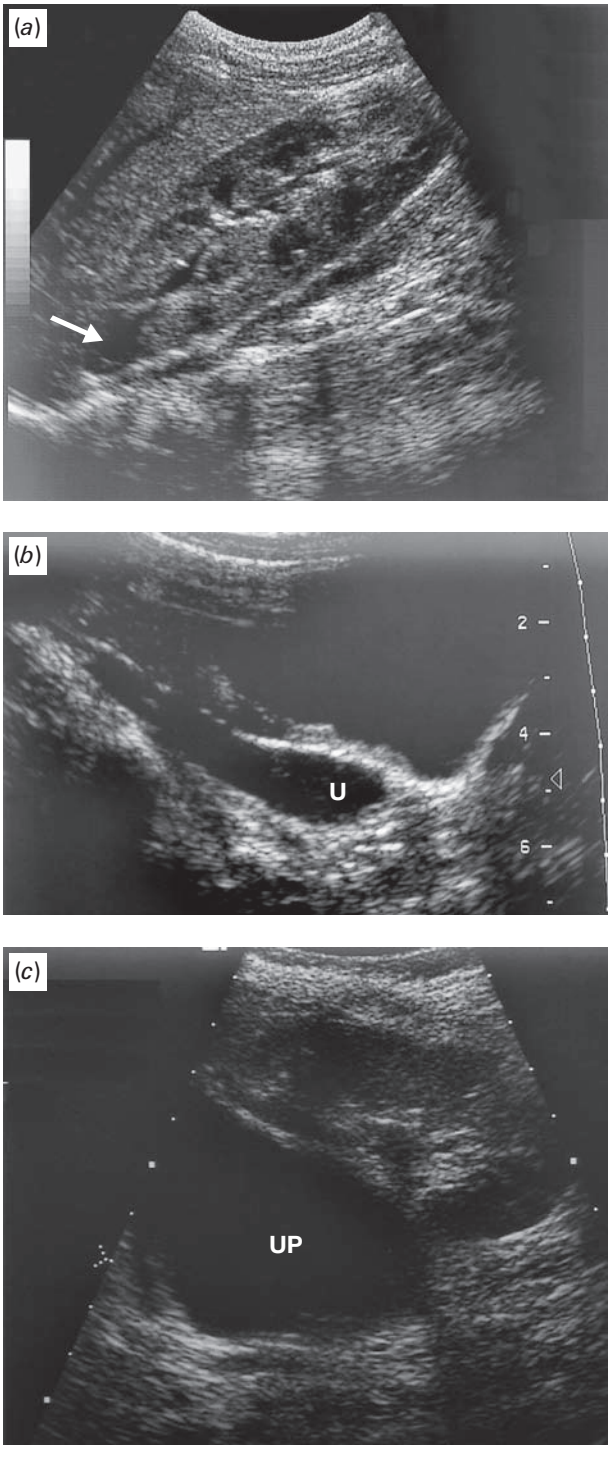

Figure 40.23 Variable appearance of hydronephrosis with duplications. (*a*) Subtle suggestion of obstructed duplication (arrow) of the upper pole in a 10-year-old girl with persistent urinary incontinence. (*b*) Dilated ureter shown behind bladder (U). Urethral ectopy was found to be the cause of wetness. (*c*) Second adolescent girl with similar presentation and vaginal ureteral ectopy. Ultrasound shows markedly dilated upper pole moiety (UP) of the left kidney. (*d*) Transverse view of bladder shows impingement by dilated ureter and pseudoureterocele appearance (*). (*e*) Renal scintigraphy shows deviated axis of the left lower pole and no function of the upper pole.

tive of dysplasia. With duplication, the adjacent lower pole moiety can also be hydronephrotic. Reflux (because of lateral ectopia) or obstruction caused by the dilated upper pole ureter must be considered. Hydronephrosis of the lower pole moiety and contralateral kidney can also result from bladder outlet obstruction or direct compression by a ureterocele.

Ultrasonography should always include a survey of the bladder, where the two anomalies can often be differentiated. Ultrasound is probably the best study for making the diagnosis of ureteroceles, which usually appear as thin-walled cystic protrusions from the posterolateral side of the bladder (Figure 40.24). The ureter can then be followed proximally into the bony pelvis and, in some cases, up to the kidney.[61,62] The degree of bladder fullness, however, can reduce the sensitivity of the study. Overdistention causes some ureteroceles to collapse, whereas an empty bladder can allow a large ureterocele to completely fill the bladder. This gives the impression of a partially full but normal bladder. Ectopic ureters will sometimes displace the bladder and mimic a ureterocele, resulting in a so-called pseudoureterocele[63] (Figures 40.25 and 40.26) The muscle wall of the bladder gives a thicker line of demarcation between its lumen and that of an ectopic ureter than the thin wall of a ureterocele. More typically, the dilated ectopic ureter will taper and terminate into an abnormally inferior position beneath the bladder base. Occasionally, the ureter associated with either anomaly is so tortuous and dilated that it mimics a cystic abdominal mass with multiple septae.

Rarely, these ureteral abnormalities do not result in dilatation of the renal moieties they subserve. Instead,

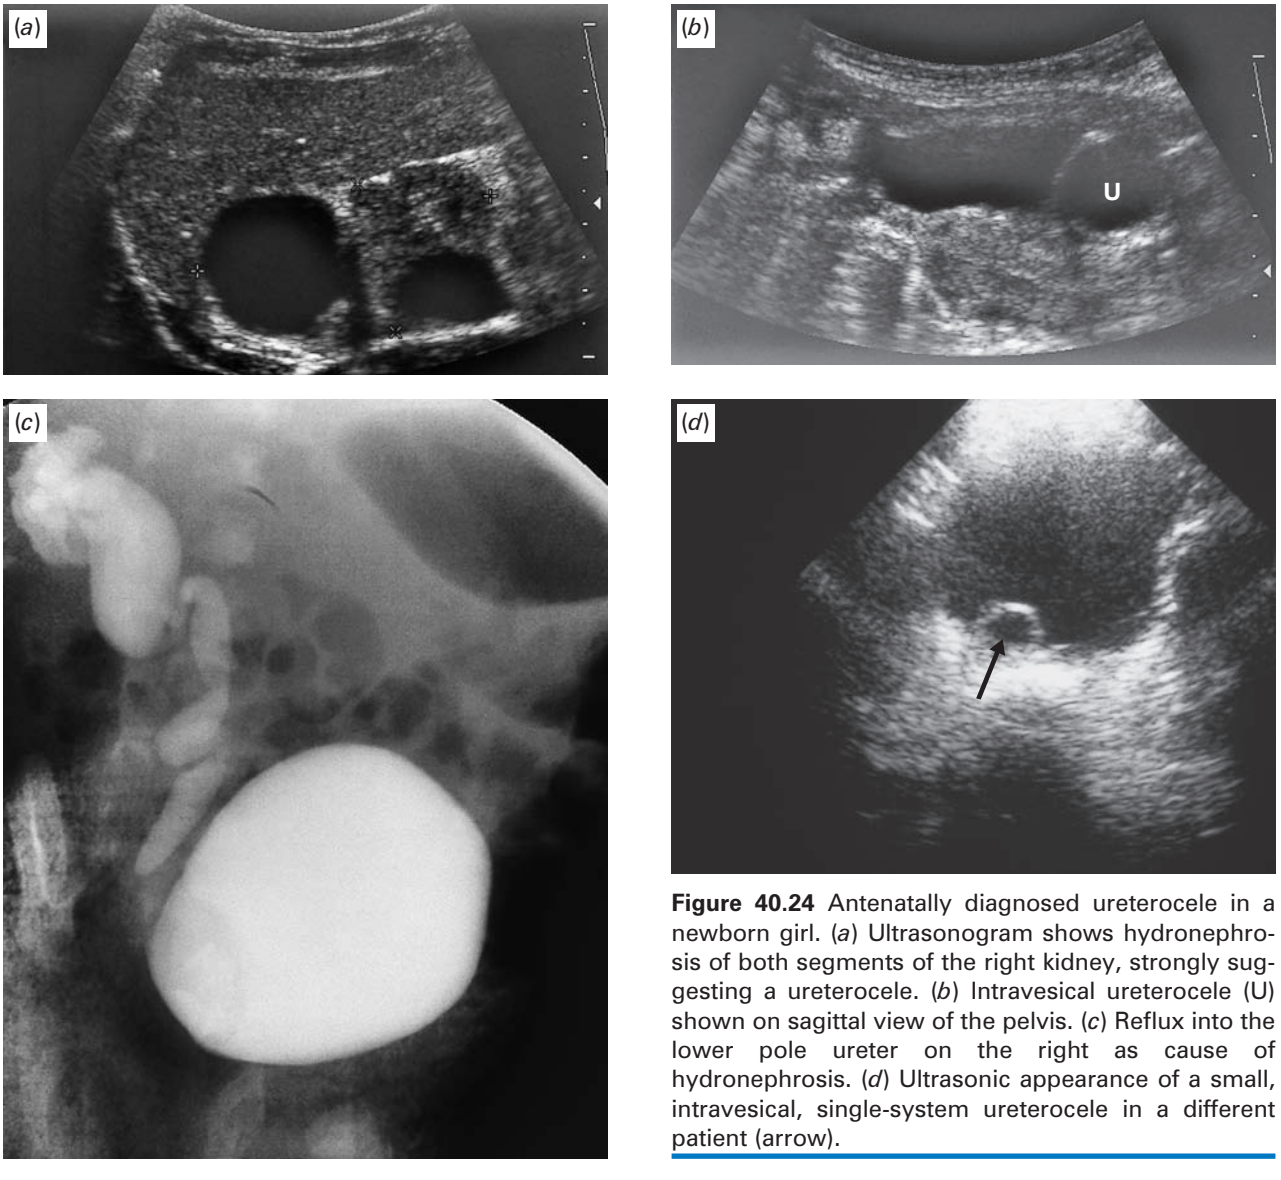

Figure 40.24 Antenatally diagnosed ureterocele in a newborn girl. (*a*) Ultrasonogram shows hydronephrosis of both segments of the right kidney, strongly suggesting a ureterocele. (*b*) Intravesical ureterocele (U) shown on sagittal view of the pelvis. (*c*) Reflux into the lower pole ureter on the right as cause of hydronephrosis. (*d*) Ultrasonic appearance of a small, intravesical, single-system ureterocele in a different patient (arrow).

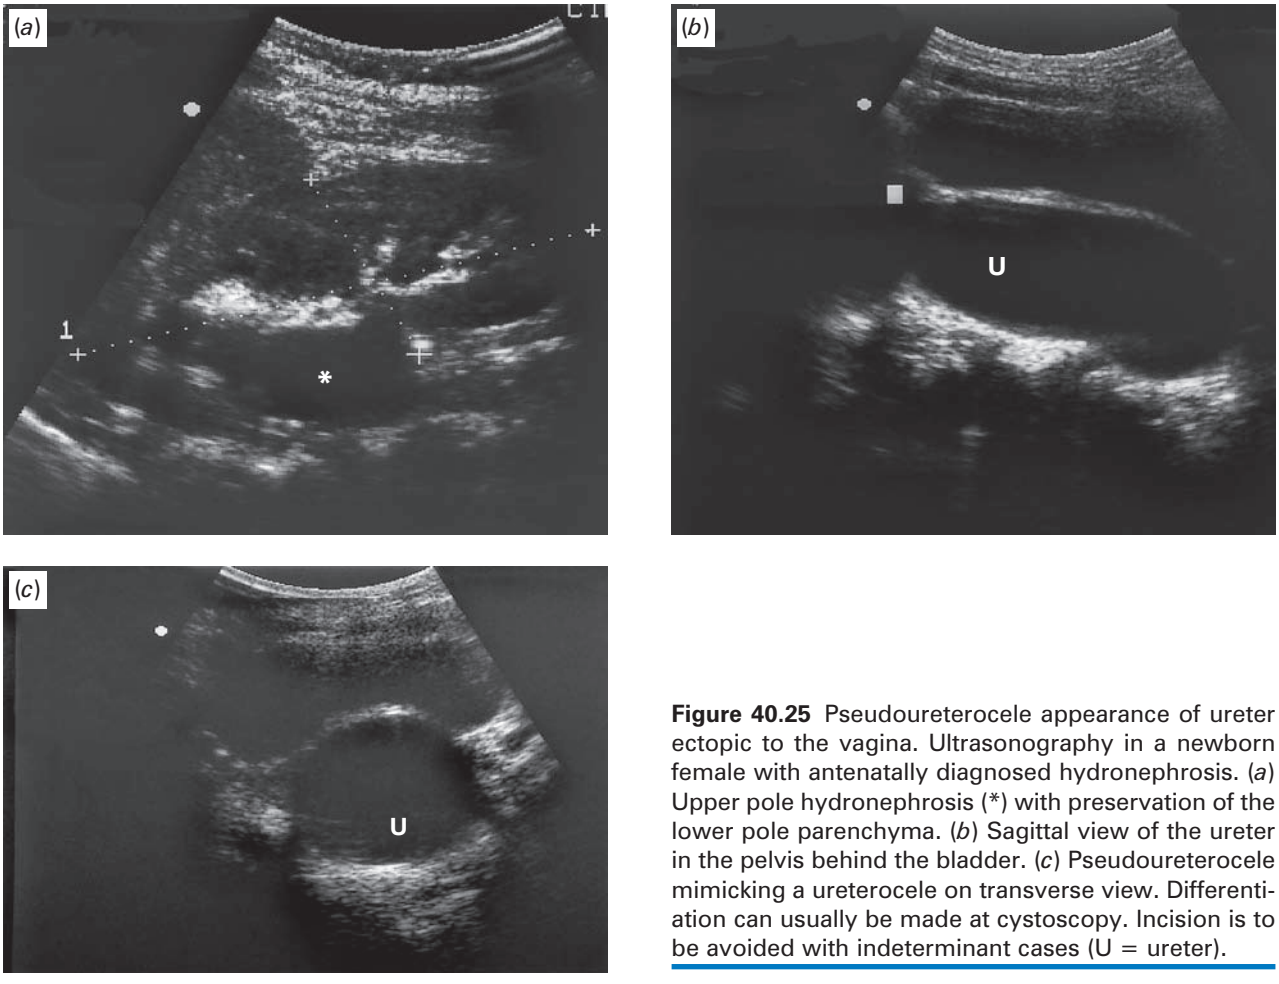

Figure 40.25 Pseudoureterocele appearance of ureter ectopic to the vagina. Ultrasonography in a newborn female with antenatally diagnosed hydronephrosis. (*a*) Upper pole hydronephrosis (*) with preservation of the lower pole parenchyma. (*b*) Sagittal view of the ureter in the pelvis behind the bladder. (*c*) Pseudoureterocele mimicking a ureterocele on transverse view. Differentiation can usually be made at cystoscopy. Incision is to be avoided with indeterminant cases (U = ureter).

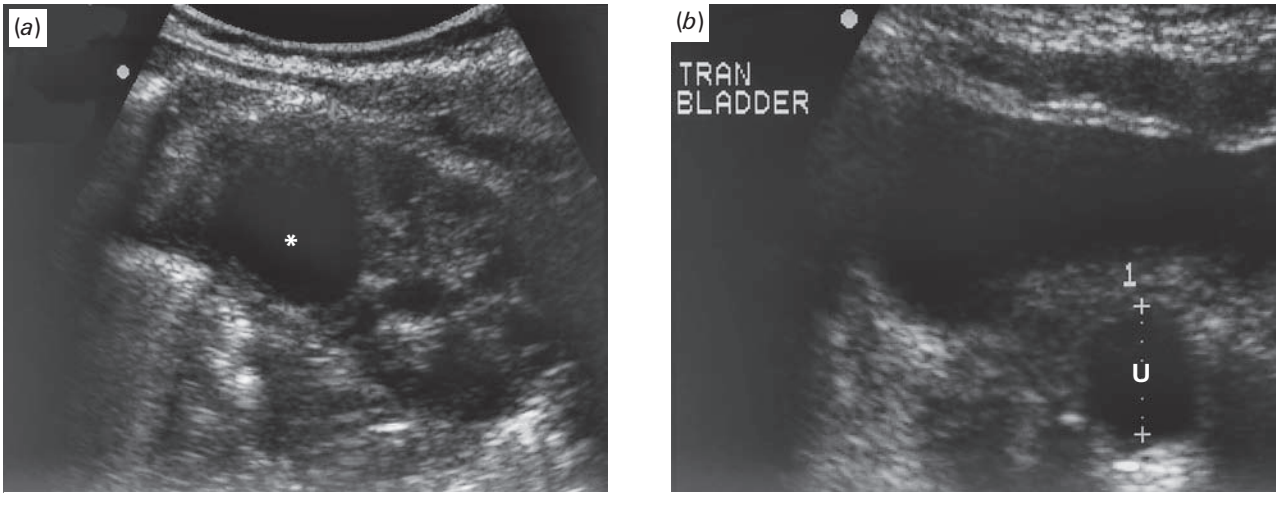

Figure 40.26 Ultrasonic evaluation of antenatally diagnosed hydronephrosis in a newborn girl. (*a*) Markedly hydronephrotic upper pole moiety surrounded by virtually no parenchyma (*). (*b*) More typical appearance of ectopic ureter (U) en route to the vagina, where the detrusor separating bladder lumen from the ureter is well developed.

the kidneys associated with single-system anomalies are sometimes small and abnormally positioned, making them difficult to localize (ureterocele disproportion)[64] (Figure 40.27). In similar fashion, the upper pole variants accompanying duplex variants can be tiny dysplastic remnants crowning otherwise normal kidneys. In both instances, a dilated ureter or ureterocele is still often visualized at the level of the bladder. Additional diagnostics become necessary to define the anatomy more fully.

Voiding cystourethrography

Infant feeding tubes are used to perform this test. These allow for spontaneous voiding and avoid any confusion or distortion offered by the balloons of Foley catheters. Ureteroceles appear as smooth, broad-based filling defects positioned near the trigone. Some ureteroceles evert into the ureter with the bladder full and appear as a diverticulum.[65] This is especially true of single-system ureteroceles, where mimics of periureteral diverticula were seen in nearly one-half of VCUG in one series.[66] Other ureteroceles efface during the latter stages of bladder filling and cannot be appreciated. Obtaining early images during the filling phase avoids these problems. An eccentric position may help define the involved side, although many ureteroceles appear centrally located. When laterality cannot be determined and cystoscopy is inconclusive, a cyst puncture with retrograde injection may become necessary.

The presence of VUR plays an important role in the management of ureteroceles. Reflux can occur into the ipsilateral lower pole, since the backing required of an effective flap valve is presumably lost with the posteriorly positioned ureterocele (Figure 40.28). Lateral ectopia, trigonal distortion, and ever-

Figure 40.27 Gross example of ureterocele disproportion. Remant dysplastic cap of tissue as shown are typically associated with massively dilated ureteroceles and ectopic ureters whose renal moiety cannot be appreciated diagnostically.

Figure 40.28 Massive reflux into the lower pole ureter. An element of obstruction from the significantly enlarged ureterocele can also contribute to the dilatation.

Figure 40.29 Reflux into the ureterocele and upper pole system of the left kidney.

sion of the ureterocele can also contribute. At times, the ipsilateral reflux is severe enough that the ureterocele and its duplex kidney are not detected until the time of surgery.[67] Reflux is also seen in the contralateral system if the anomaly is large enough to distort the trigone and opposing submucosal ureteral tunnel. In one series of 148 ureteroceles, ipsilateral VUR was seen in 80 (54%), whereas contralateral VUR was appreciated in 28%.[68] Smaller series have documented similar incidences.[69,70] Reflux into the ureterocele itself is uncommon but can also occur (Figure 40.29).

VUR is also a common finding with ectopic ureters (Figure 40.30). The ipsilateral lower pole ureter refluxes in at least 50% of cases. Upper pole VUR can also be appreciated, depending on the position of the ectopic orifice. Ectopic ureters whose distal extent is positioned within the bladder neck can both reflux and obstruct. Obstruction is intermittent and emptying occurs during voiding, in concert with relaxation of

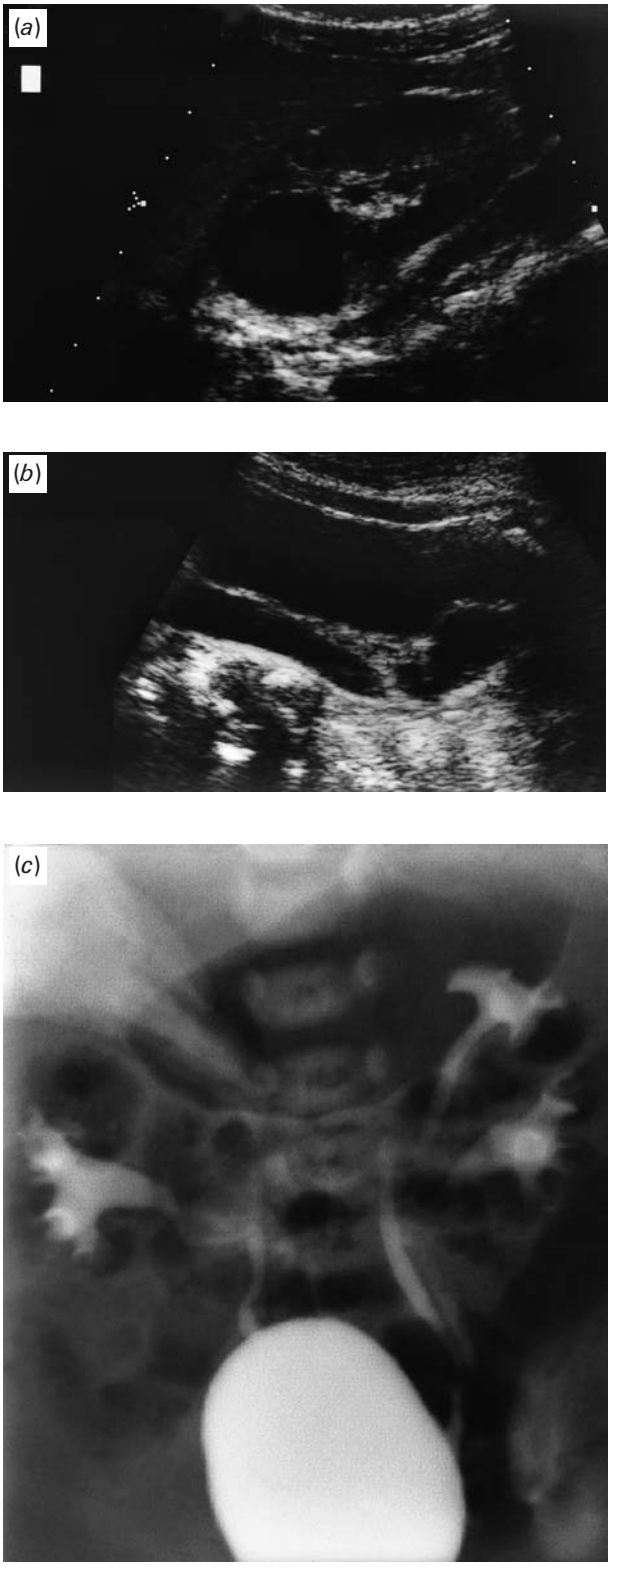

Figure 40.30 Vesicoureteral reflux associated with ectopic ureter to the urethra. (*a*) Duplex right kidney with hydronephrotic upper pole. (*b*) Ectopic ureter behind the bladder could be confused with a ureterocele. (*c*) Voiding cystourethrogram shows reflux into duplicated ureters on the left and lower pole on the right.

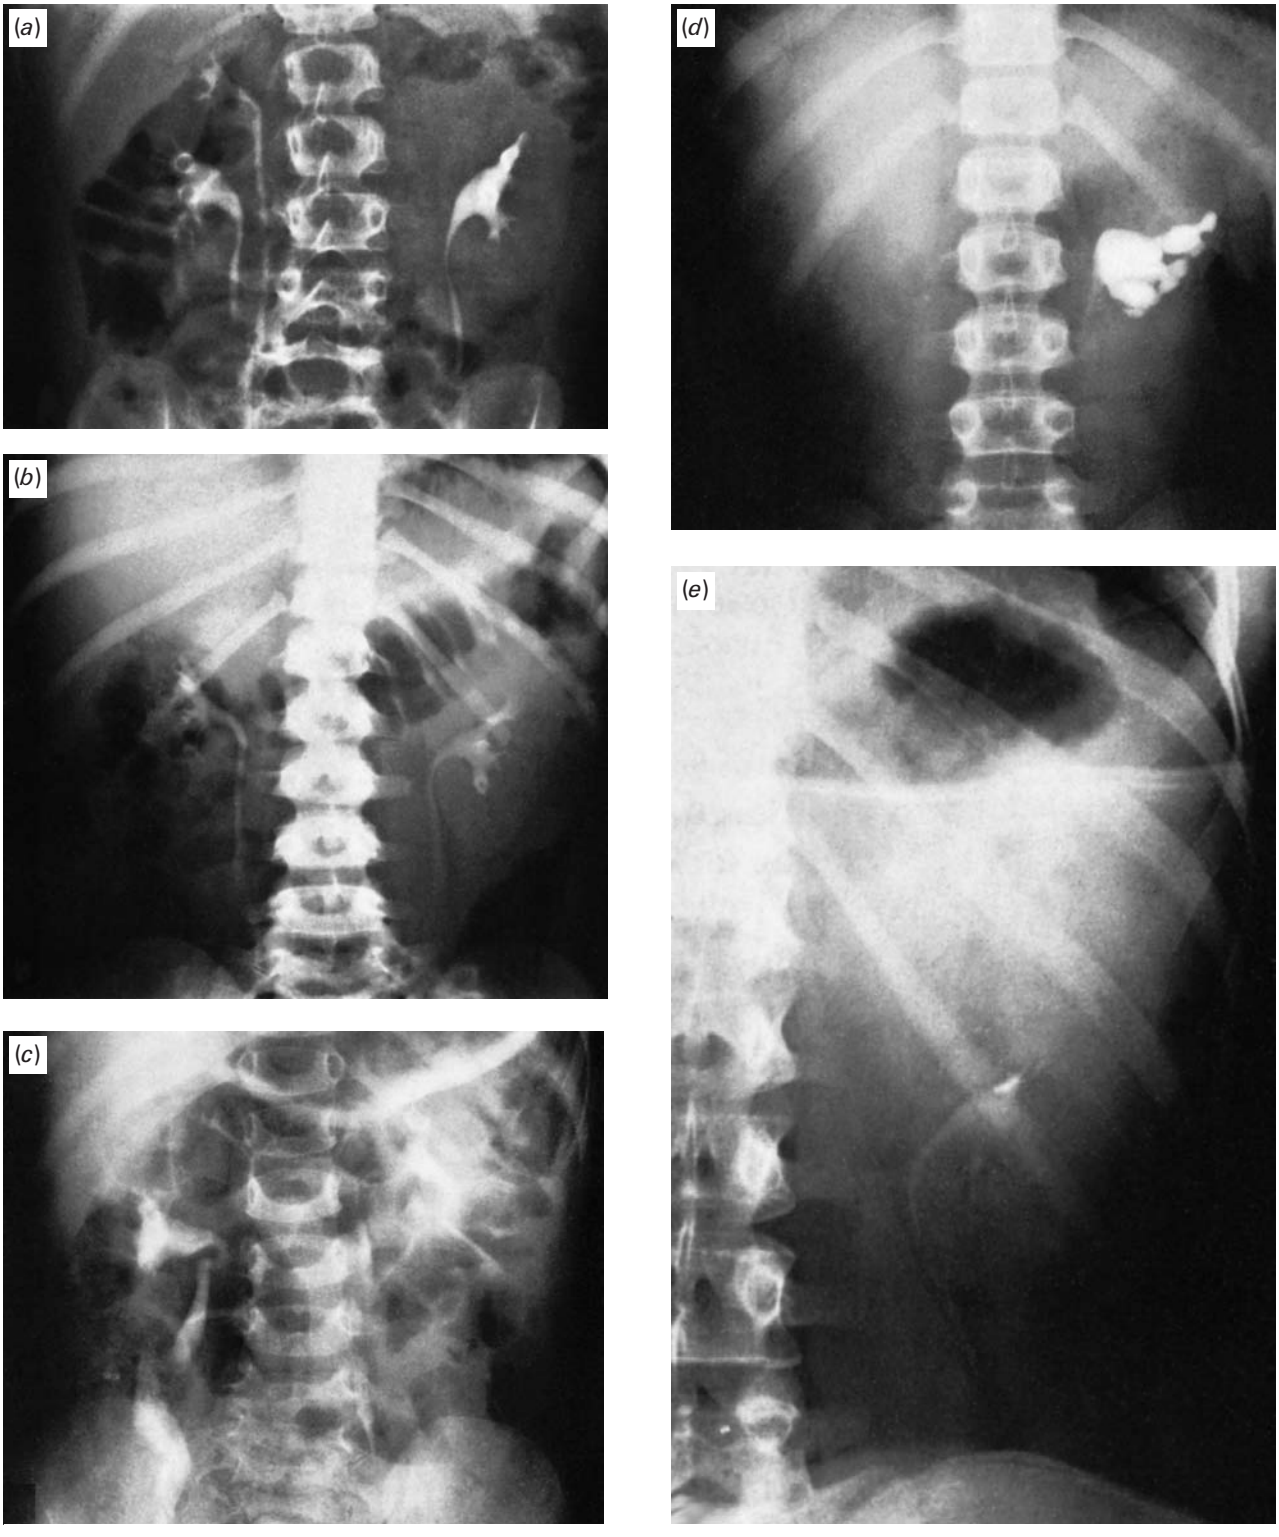

Figure 40.31 Examples of characteristic lateral and downward displacement of lower segment when the functionless upper pole is dilated. (*a*) Functionless upper left segment. (*b*) Poorly functioning upper right segment and functionless upper left segment. (*c*) Functionless upper right segment and displacement of the lower segment. (*d*) Reflux into displaced lower pole segment of the left kidney. (*e*) Minimally functioning upper left segment simulating mass effect of the upper pole.

the surrounding musculature. Reflux occurs once the ureter is somewhat emptied. This phenomenon may only be appreciated by performing cyclic (repeated) voiding studies.[71] Orifices proximal to the bladder neck can reflux freely with or without voiding.

Excretory urography

Despite its declining role in the routine evaluation of children with UTIs, excretory urography remains a useful tool in the work-up of certain ureteral anomalies (Figures 40.31 and 40.32). This is occasionally the case with ureteroceles, when the anatomy is undefinable with ultrasound and renal scintigraphy alone, and is especially true of ectopic ureters. Some clinicians remain steadfast in their belief that EU remains the definitive diagnostic study for the latter. For girls with infrasphincteric ectopia, who arrive with the classic history of constant urinary dribbling despite being successfully toilet-trained, EU is often the only imaging study necessary to make the diagnosis.[72] (Figures 40.33 and 40.34). Radiographic signs of the non-functioning, occult duplications found with ectopic ureters are shown in Table 40.4.

Ureteroceles with minimally functioning upper pole moieties can cause identical upper tract findings. The ureterocele appears as a filling defect within the bladder that gradually fills with contrast from the other functioning kidney. When ureteroceles are associated with a functioning kidney, they appear as a contrast-filled 'cobra head' at the ureterovesical junction.

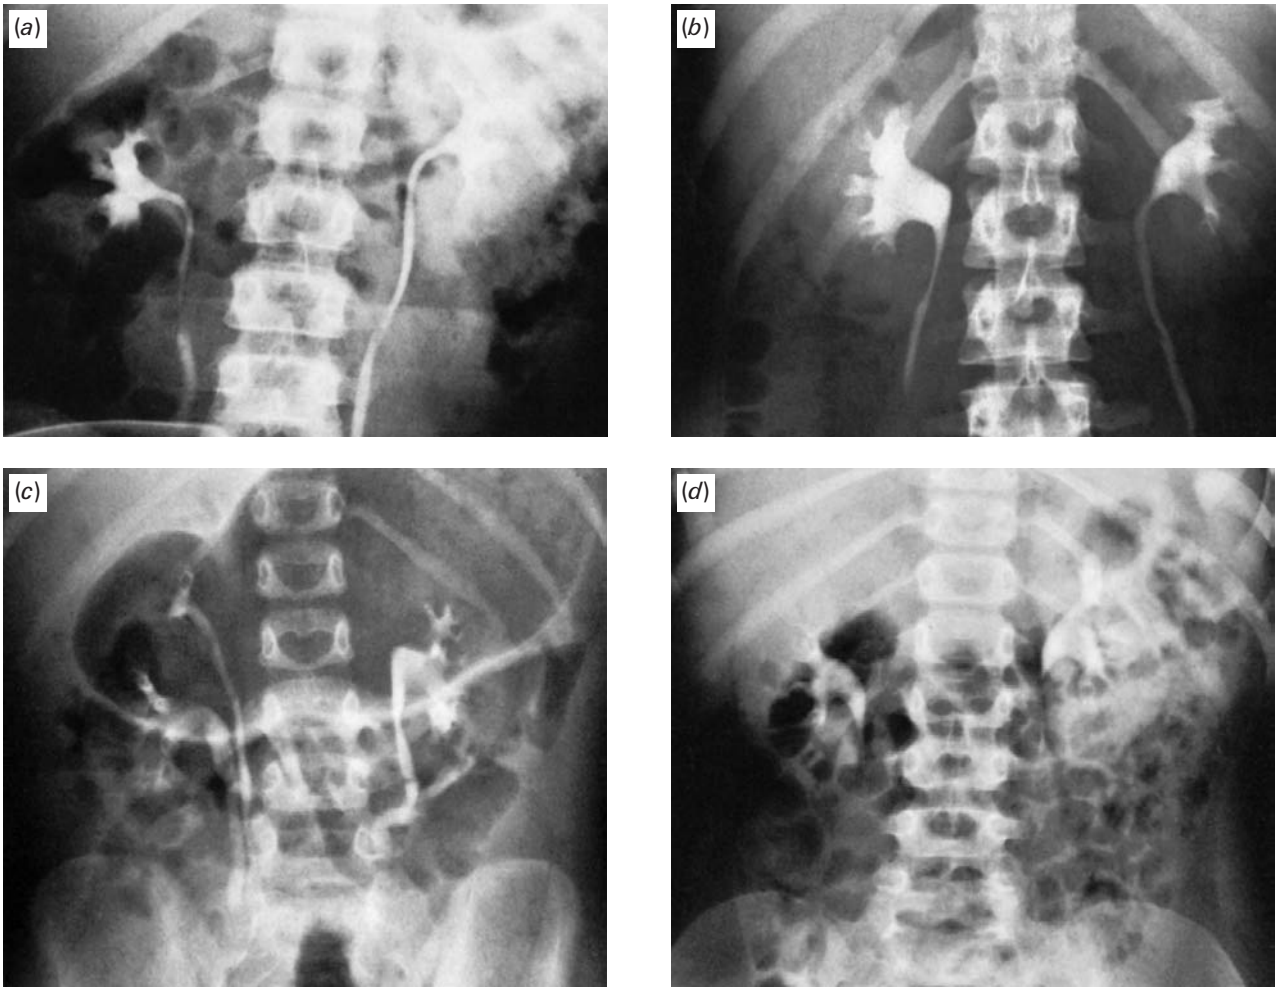

Figure 40.32 Appearance of lower pole pelvis when the upper pole is functionless and non-dilated. (*a*) Functionless upper right segment. The caliceal system of the lower segment is smaller but relatively normal. (*b*) Functionless upper pole on left, with decreased number of calices of the lower segment. (*c*) Functionless upper left segment, with apparent increase in renal substance of upper pole. The presence of a duplication of the contralateral kidney is often a key to diagnosis. (*d*) Functionless upper right segment, with apparent increase in renal thickness on the medial side of the upper pole.

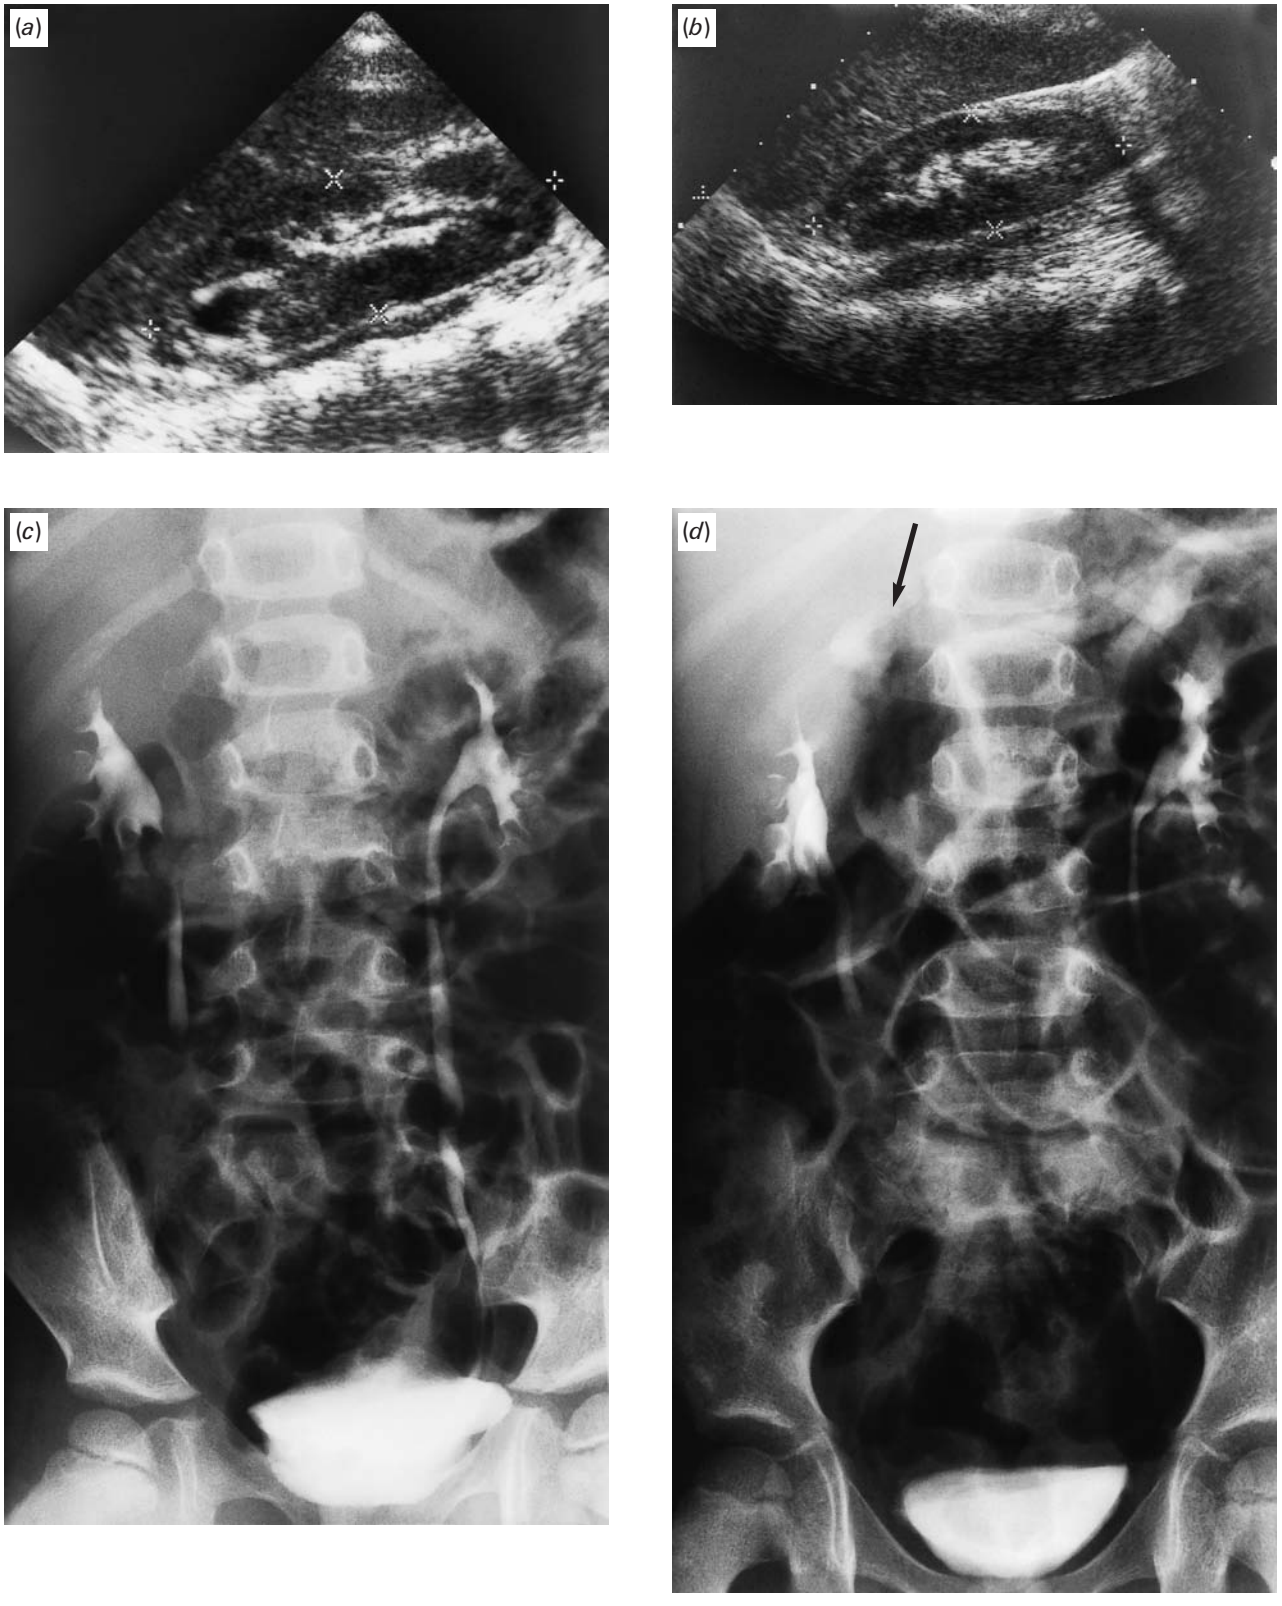

Figure 40.33 Utility of excretory urography. Studies in a 13-year-old girl with continuous wetting were strongly suggestive of an ectopic ureter. Sonograms for the past 7 years read as normal. (*a*) Initial ultrasound at 6 years old suggests mild upper pole dilatation. (*b*) Current ultrasound is essentially unremarkable. Retrieval and review of early excretory urogram confirms the clinical impression. (*c*) Note the deviated axis of the right kidney and ureteral displacement on early sequence of excretory urogram. (*d*) A later film shows delayed uptake of contrast in the upper pole (arrow).

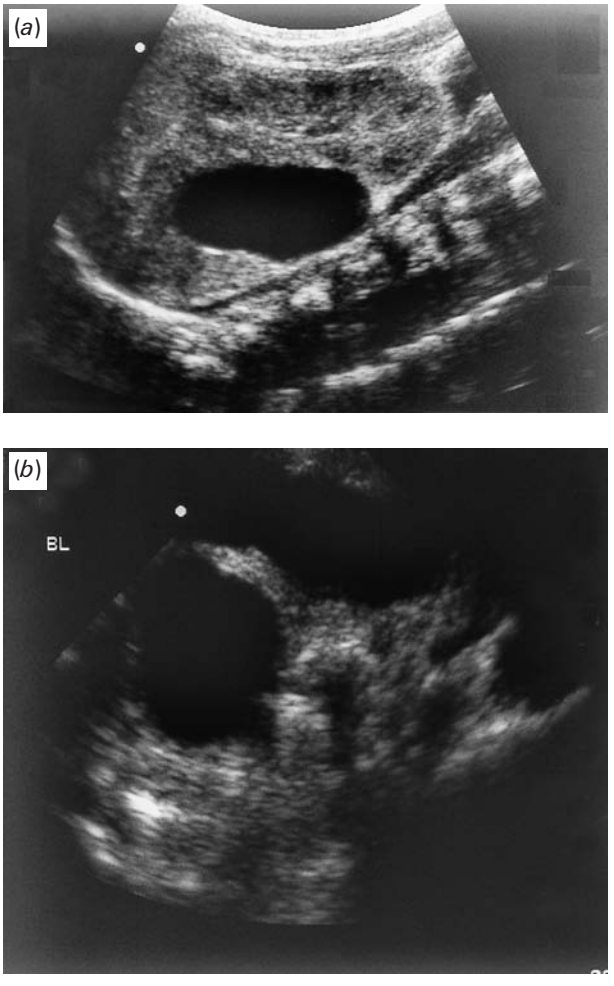

Figure 40.34 An infant boy with urinary tract infection. The role of excretory urography. (*a*) Ultrasonogram initially felt to represent single-system hydronephrotic right kidney. (*b*) Pelvic sonogram demonstrates a markedly dilated right ureter behind the bladder. (*c*) Excretory urography shows displaced lower pole of the right kidney.

Table 40.4 Excretory urography: findings suggesting occult duplex kidney with ectopic ureter

Finding	Features
'Drooping lily sign'	Inferior and lateral displacement of lower pole by minimally or non-functioning upper pole. Delayed films may show function, but most are 'silent'. Axes of the kidneys should normally cross the body of the 10th thoracic vertebra
Lateral displacement of lower pole ureter	Compared with contralateral ureter, differences in the distance from an adjacent vertebral pedicle
'Missing calyx'	Incomplete compliment of calices with absence of system draining upper pole. A shortened or cut-off infundibulum to the upper pole calyx, which is normally the longest
More upper pole parenchyma than expected with increased renal length	
Duplex kidney on the contralateral side	
Dilated, ectopic ureter appreciated on postvoid film	

Renal scintigraphy

Radionuclide scans help to quantify the amount of functioning renal parenchyma. This is crucial information when renal salvage is being considered. The degree of obstruction is also assessed, although most ectopic ureters and ureteroceles, by default, exhibit delayed drainage because of ureteral dilatation. Technetium 99m (^{99m}Tc) diethylenetriamine penta-acetic acid (DTPA) and mercaptoacetyltriglycine (MAG3) scans provide reasonable assessments of function and obstruction. Since ^{99m}Tc dimercaptosuccinic acid (DMSA) scans result in renal tubular labeling and are unaffected by obstruction, they are more sensitive to low levels of renal function and are sometimes helpful in detecting occult duplex anomalies and small kidneys associated with ureteral anomalies that are not identified by other techniques,[73,74] DMSA scintigraphy can also detect subclinical cortical defects and functional impairment in lower pole moieties that show no ultrasonic evidence of parenchymal damage.[75]

Some clinicians believe that the transitional physiology of the newborn may affect the perinatal kidney's handling of radionuclides and contrast. This could contribute to the lower yield of functioning kidneys in historical series when EU was obtained in newborns and provided the measure of function. It could also result in overestimates of the recovery of function after procedures done to alleviate obstructed newborn kidneys, when early scans are compared with studies performed when the physiology is more conducive to scanning. As a consequence, scans performed early after delivery may not provide an accurate assessment of renal function and should probably be deferred for 4–6 weeks after delivery to allow for some maturation of renal function.

Other diagnostic modalities

CT scans may help define the anatomy of kidneys with collecting systems of bizarre appearance. Duplications in which both ureters and renal pelves are dilated are one example. CT can also be considered for patients suspected of having ureteral ectopia or ureterocele disproportion but whose poorly functioning renal moiety cannot be defined by other modalities[76,77] (Figure 40.35). Magnetic resonance imaging (MRI) is becoming increasingly useful in cases where conventional imaging studies fail to delineate occult dysplastic renal moieties, ectopic ureters, and ureteroceles.[78,79] Respiratory gated excretory and static fluid MR urography appear to complement each other well in evaluating such systems.[80] Percutaneous drainage can also be used to vent obstructed kidneys or renal segments that appear salvageable by ultrasound but function poorly. However, recoverability of function is rare when renal scintigraphy demonstrates little function.

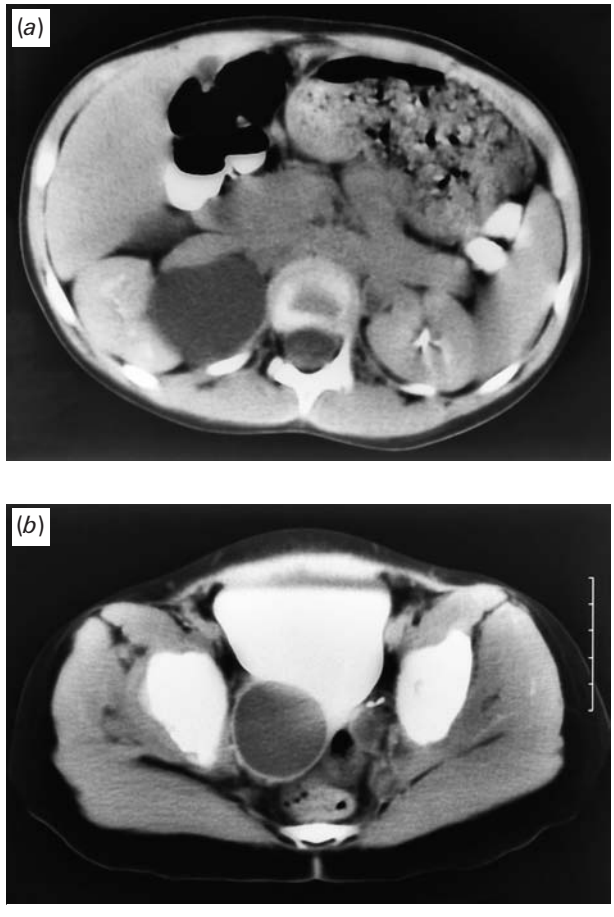

Figure 40.35 Computed tomography in a female toddler with abdominal pain and palpable mass. (*a*) Markedly dilated ureter displacing the right kidney associated with duplication. (*b*) The ureter is shown behind the bladder.

A variety of dye tests have been used clinically to diagnose ectopic ureters. For example, indigo carmine or methylene blue can be instilled in the bladder with a catheter, which is then removed. Continued evidence of dampness and leakage of clear urine implicates ureteral ectopia. Another test involves placing a dental roll in the vagina. After indigo carmine is given intravenously, the roll will appear blue, provided there is some function in the affected kidney and the child has not stained the roll by spontaneously voiding. The relative invasiveness of such tests, coupled with the increased sensitivities of today's diagnostics, has reduced their utility in most cases.

Cystoscopy

Examples of the cystoscopic appearance of ureteroceles are shown in Figure 40.47. With smaller intravesical ureteroceles, the cystic dilatation expands with each peristalsis, then shrinks as urine drains through its orifice. Not all variants are as easy to appreciate, however. Extravesical variants have ill-defined borders that can undermine the bladder neck and urethra. If the bladder is overfilled, they efface and can even appear to be a diverticulum. The orifice of the ureterocele may be difficult to appreciate but is often positioned distal to the bladder neck and, with cecoureterocele and sphincteric variants, will balloon open with the efflux of irrigant. With larger ureteroceles, the adjacent ureteral orifices are also difficult to appreciate because of displacement.

Cystoscopy is less helpful for ectopic ureters. The ectopic orifice cannot be appreciated in more than half of cases. Bladder neck and urethral ectopy offer a higher yield. Prostatic ectopy sometimes presents as a widened ejaculatory duct that allows easy retrograde study.[40] Examining the vaginal vault along its anterior/lateral aspect for GYN-ectopy is less fruitful. In rare cases, a small cystic structure is identified that can be unroofed and cannulated for retrograde study.[31] Intravenous indigo carmine is sometimes excreted by even minimally functioning kidneys and can aid in identification. Within the bladder, the hemitrigone on the affected side is often underdeveloped and may be elevated from behind by the dilated ureter. In some cases, the dilated ureter can be palpated on rectal examination. Failure to identify the ectopic orifice rarely changes management. In cases where a lower tract approach is planned, the ectopic ureter can be identified outside the bladder or transvesically after incising the trigone on the affected side (see Management, below).

Management considerations

Once the work-up is complete and the diagnosis made, the management of ectopic ureters and ureteroceles is defined by the answers to the following questions:

1 Is the affected ureter(s) a singlet or portion of a duplex system?
2 Is the affected ureter(s) obstructed, refluxing, or both?
3 Are the contralateral and/or ipsilateral ureter(s) and/or the bladder affected by the primary anomaly?
4 What is the status of the kidney or portion of kidney associated with the ureter(s) in question?
5 What is the age and clinical status of the patient?

A description of the experience with various techniques and their technical nuances follows. Simply put, the algorithms in management of these two anomalies historically branched with two main decisions: whether to save or discard the involved kidney and whether or not there is a need to reconstruct the bladder. These remain the mainstays of management for ectopic ureters.

The recommendations for ureteroceles have become controversial, however, with the inclusion in the treatment armamentarium of selective puncture. A minimally invasive and seemingly simple solution, the benefits of cystoscopically decompressing ureteroceles must be weighed against the risks of creating reflux in the involved ureter.

Until recently, the two main areas of contention with ureteroceles dealt with the salvage of functioning upper pole moieties and the need, if any, for removal of ureteroceles subtending upper pole segments after heminephrectomy or proximal ureteral diversion (ureteroureterostomy or ureteropyelostomy) caused by their collapse (Figure 40.36). The introduction of selective puncture offers the obvious third controversy of which ureteroceles to decompress. The answers to these questions continue to be modified by contemporary clinical studies.

A ‘cookbook approach’ should be avoided when composing algorithms for the management of any urinary abnormality. Each patient requires individualized treatment, since there is often no uniform solution to every urologic anomaly. Nevertheless, trends become apparent in reviewing the literature that allow certain recommendations to be applied to most cases, which give the highest likelihood of a favorable outcome.

Recommendations for management

Ectopic ureters

Single system – minimal or non-functioning kidney

Most kidneys (90%) that accompany single-system ectopic ureters do not function appreciably. Nephrectomy is the treatment of choice. In some cases, the question of renal salvage is raised by the appearance of marginal function on nuclear scintigraphy. How much function is enough to warrant ureteral reconstruction rather than ablation of its associated kidney? Nephrectomy is indicated when the creatinine clear-

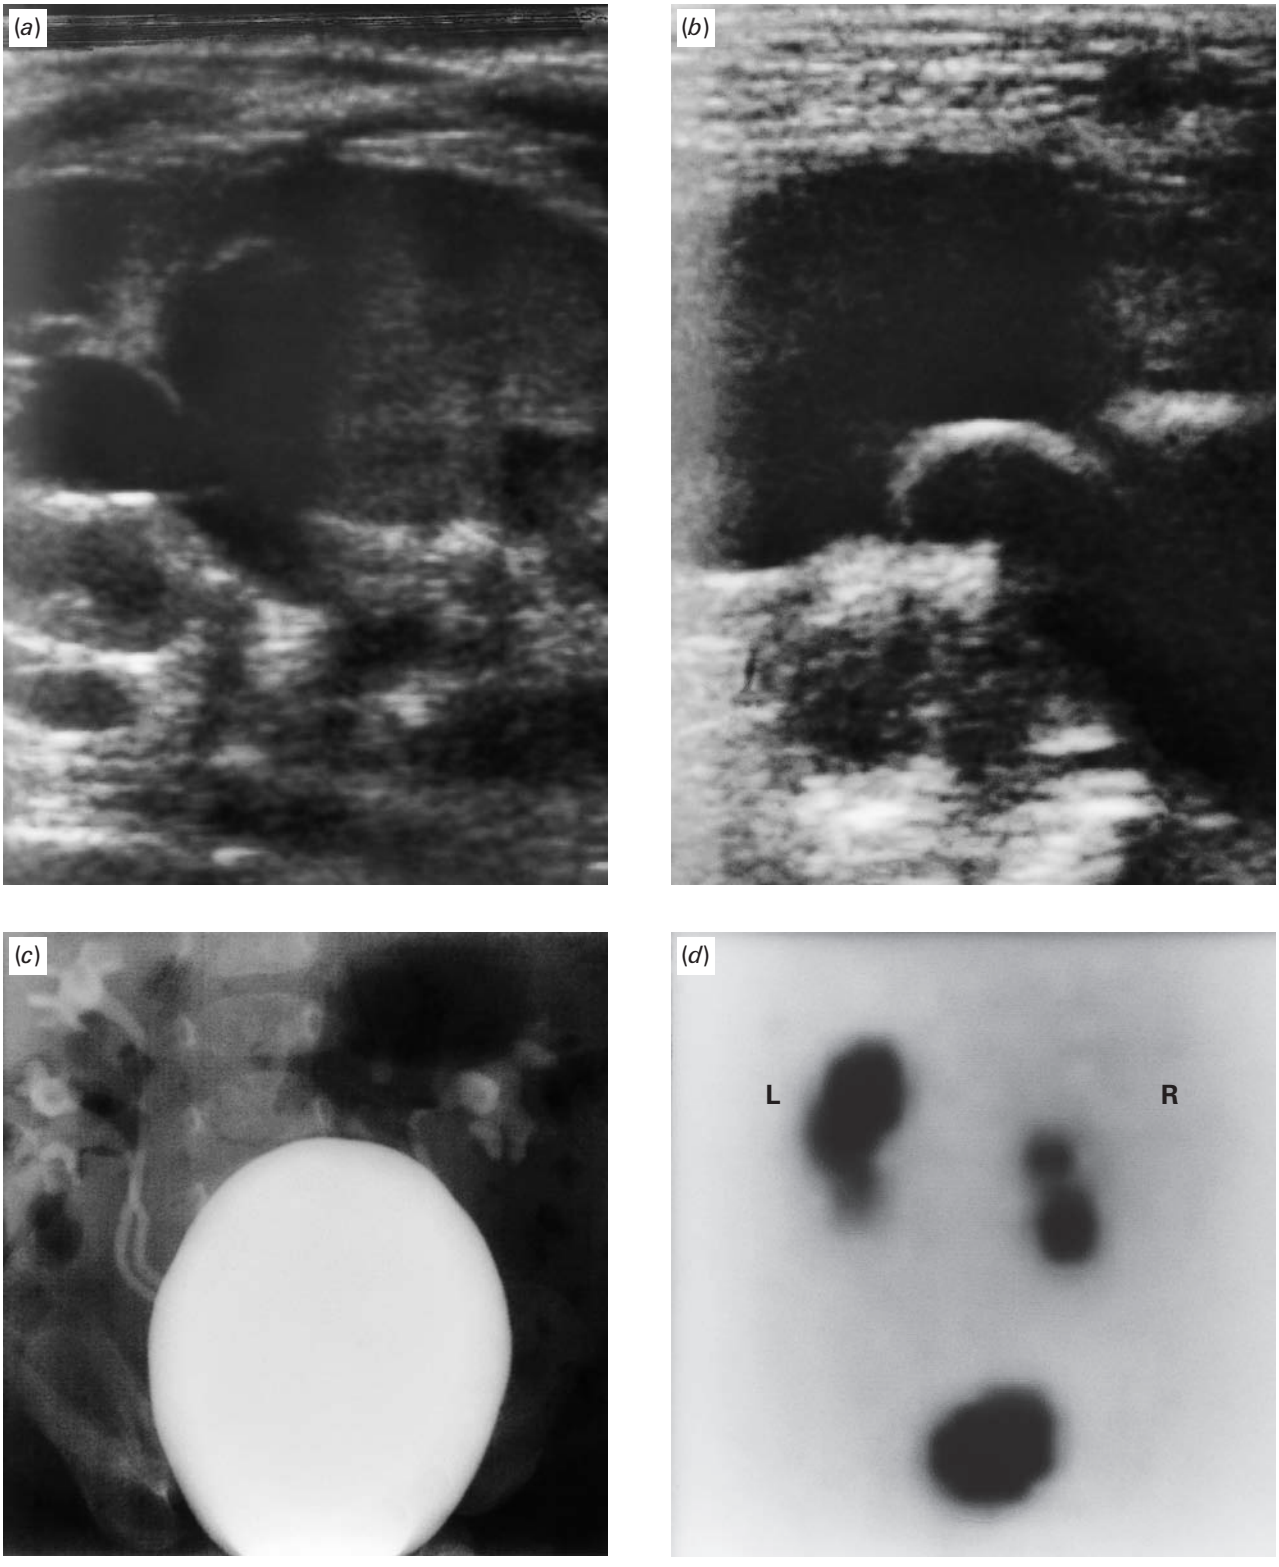

Figure 40.36 Antenatally diagnosed ureterocele in a newborn girl. (*a*) The sonogram shows a dilated upper pole segment of the duplex left kidney. (*b*) Pelvic view of the ureterocele projecting within the bladder. (*c*) Cystogram demonstrates reflux into the contralateral duplex ureters and lower pole ureter on the left. (*d*) Renal scan shows preservation of function and hydronephrosis of the left upper pole moiety.

ance provided by the affected kidney, if it were isolated, would not eliminate the need for dialysis. Using percent function as a cut-off, like the commonly cited standard of 10 or 15%, may have little meaning, especially if the contralateral kidney also exhibits impaired function. In addition, kidneys that function marginally in infancy sometimes assume a progressively smaller portion of overall renal function with interval growth of the affected child. An intrinsic developmental insult and/or the rules governing renal hypertrophy, where healthy kidneys do not relinquish the additional renal function they are asked to assume, can be implicated when this occurs.

One area of controversy for some ectopic ureters involves the management of the lower ureteral segment. In cases of wolffian or GYN-ectopy, where an element of obstruction is the rule, the lower ureter need not be removed. Once decompressed, ascending infections of these dry, isolated segments are uncommon and the need for secondary ureterectomies after subtotal ureterectomy is rare. The obstructed ureters found with GU-ectopy typically enter the bladder neck or urethra. These can also remain, although a small number will predispose to recurrent urinary infections that ultimately necessitate their removal. It may be that such systems begin to reflux after the outflow of urine ceases from above (see Voiding cystourethrography, above).

Refluxing lower ureters have typically been removed in concert with nephrectomy. An extravesical approach through a second lower transverse muscle-splitting (Gibson) incision adds little additional morbidity. However, the necessity for a simultaneous approach for these variants has been questioned. In a study by Plaire et al,[81] secondary surgery for removal of the distal ureter was required in only 4 of 38 such patients. Subsequent series have drawn similar conclusions. Long ureteric stumps or those in patients with dysfunctional voiding appear to pose the most risk.[82] In cases where a ureteral stump is left, be it refluxing or obstructed, it should be taken as distal as possible, ligated with absorbable sutures, and urine should be aspirated from its distal end. Urinary fistulas have occurred when presumably obstructed ureteral stumps have been left open and unappreciated reflux commences.

Duplex system – minimal or non-functioning upper pole

Heminephrectomy is recommended for the affected upper pole.[83] The case made for salvage is similar to that in singlets and depends on relative function. Developmentally, the upper 'half' of a normal duplex kidney typically contributes only one-third of that kidney's glomeruli, or, at most, 16% of overall renal function. The lack of an optimal inductive influence during fetal development combined with an element of obstruction significantly reduces the contribution of most upper pole moieties drained by ectopic ureters. As in single systems, a subtotal ureterectomy is usually sufficient, taking the ectopic ureter as far distal as possible through a flank incision. When there is reflux into the upper pole and concerns about the ureteral stump persist, it can be removed through a second incision.

Single system – salvageable function

Reimplantation of the affected ureter is the treatment of choice. It helps to initially identify the ureter outside the bladder, especially when the insertion of the ectopic meatus cannot be localized cystoscopically. Once the ureter is mobilized, a transvesical or an extravesical approach to ureteroneocystostomy can be successfully applied. The distal-most segment that enters the bladder neck/urethra should be disregarded with these and other ectopic ureters. The tedious dissection required for their removal risks damaging the urinary sphincter complex. Ureteral tailoring is often necessary and can be done using any one of a variety of techniques (see Chapter 39 Megaureters).

Duplex system – salvageable function

In cases where the upper pole is obstructed, yet provides salvageable function, its ureter can be anastomosed to the adjacent lower pole renal pelvis (ureteropyelostomy) or ureter (ureteroureterostomy). The lower ureteral segment can be mobilized to the pelvic brim and excised, and the remainder left alone. Concerns about discrepancy in size between the ectopic and recipient ureter are usually unfounded.[84] These operations are usually no more challenging than the dismembered pyeloplasties required of infants with ureteropelvic junction (UPJ) obstructions. Rates of success should be similar. When technical concerns persist or if the upper pole moiety exhibits signs of cystic dysplasia, a heminephrectomy is recommended. Visualization of the upper pole moiety in assessment of dysplasia is one advantage of this approach. Renal sparing surgeries could probably be utilized more frequently in this setting. In one study, normal histology was found in 57% of upper pole heminephrectomy specimens removed from ectopic ureters.[83]

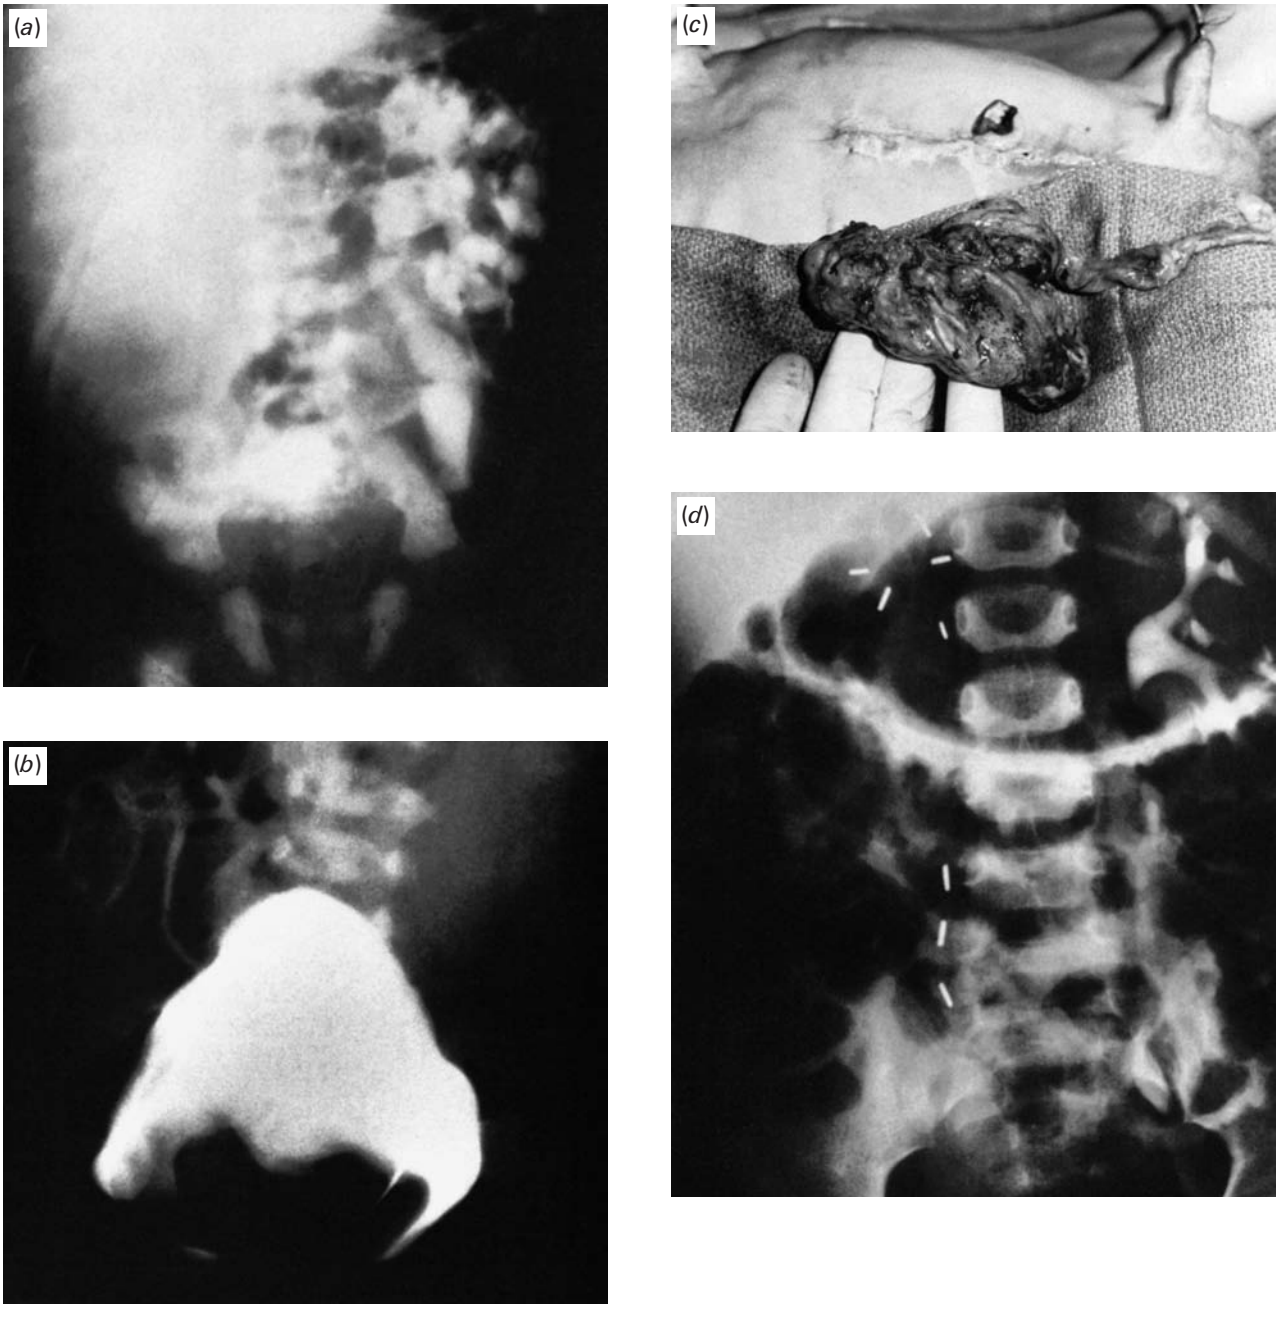

Figure 40.37 Newborn male with large, single-system ureterocele on the right side. (*a*) Excretory urogram shows poor visualization of the right collecting system and hydronephrosis of the left. (*b*) Cystogram shows a large ureterocele filling the bladder and extending through the bladder neck. (*c*) At surgery, the grossly dysplastic hydronephrotic kidney was removed and extravesical dissection of the ureterocele was completed. (*d*) A postoperative excretory urogram shows significant improvement of the left-sided hydronephrosis and collapse of the ureterocele.

Another option for obstructed systems is to approach the duplication from below. When reflux is present into one or both ureters, a common sheath ureteral reimplantation is the preferred method of treatment.[85] The repair can be technically challenging, especially in smaller infants. Tailoring of the upper pole ureter usually becomes necessary to achieve the desired length/diameter ratio required of successful ureteroneocystostomy. Revisions are made along the length of ureter opposite the common wall where vascularity is shared by the duplication. When folding techniques cause excessive bulk with larger ureters,

excisional tapering is preferred. A psoas hitch is sometimes necessary to gain additional length for the reimplantation. Another option for duplications with an obstructed upper pole ureter and refluxing lower pole ureter is to perform a proximal diversion of the upper pole ureter (ureteropyelostomy), discard its remainder, and reimplant the lower pole ureter alone. Although two incisions are required for this approach, it avoids the problems that accompany ureteroneocystotomy of duplex ureters, where one or both may be dilated.

Ureteroceles

Single system – minimal or non-functioning kidney

Nephrectomy is the treatment of choice. Ordinarily, the ureterocele remains collapsed after aspiration and any element of obstruction to the bladder neck or contralateral ureter resolves (Figure 40.37). The latter may unmask reflux into the contralateral, now solitary, kidney. With larger ureteroceles a significant reservoir for lower UTIs remains, despite their decompression. Although not well defined in the literature, some of these eventually require secondary surgery for their removal. Cystoscopic evidence of the open meatus typically accompanying sphincteric or cecoureteroceles may identify those variants particularly at risk for future problems. Simultaneous excision of the ureterocele with bladder reconstruction is not unreasonable, if the age of the patient permits. Otherwise, the patient can be followed medically after nephrectomy and repair of the bladder deferred to a later age, if indicated.

Whether antenatal diagnosis alters the long-term implications of such anomalies is unclear. A non-operative approach has been taken in a small group of infants whose ureteroceles subtended multicystic dysplastic kidneys. In limited follow-up, the ureterocele collapsed or remained stable in each case, whereas affected kidneys uniformly involuted. None required surgery.[18]

Selective cystoscopic puncture is not an option for obstructed ureteroceles associated with a non-functioning kidney. This risks converting the anomaly from one that can be potentially addressed solely from above to one requiring another incision to correct a refluxing ureterocele. Non-selective cystoscopic 'unroofing', as advocated by Tank,[86] remains an option for decompressing obstructed ureteroceles in children who are extremely ill and unable to tolerate open surgery. Interestingly, 50% of renal moieties that showed no function on EU subsequently demonstrated excretion of contrast after their decompression. These data suggest that some kidneys may recover function after being vented, but may also point to the shortcomings of EU compared with radionuclide studies in infants with obstructed kidneys. Reflux is an expected sequela of this predecessor of selective puncture.[87] Decompression can also be achieved with percutaneous drainage, which is the current preferred method of temporizing until the ureterocele can be definitively addressed.[88]

Single system – functioning kidney

The experience with selective incisions and puncture of these ureterocele variants has been encouraging enough that it should be considered the procedure of choice[69,89] (Figure 40.38). In one series, for example, endoscopic decompression was successful in 22 of 25 patients (88%) with single-system intravesical ureteroceles.[90] Reflux tends to appear into larger ureteroceles whose detrusor defects result in very little backing to the anomaly. Ureterocele excision, ureteral reimplantation, and correction of any detrusor defects usually become necessary when reflux appears, although a trial of medical management, similar to that used with primary VUR, can be reasonable, especially in younger children.

Duplex system – minimal or non-functioning upper pole

An upper pole heminephrectomy is indicated but may not finalize the problem (Figures 40.39 and 40.40). This upper tract approach effectively decompresses the ureterocele, potentially restores trigonal anatomy, and may be the only treatment needed for some patients.[91,92] In the series reported by Caldamone et al,[15] seven of 36 patients (19%) ultimately required secondary procedures for persistent reflux (three patients) or bladder outlet obstruction (four patients). VUR appeared in 10 cases after decompression, where none was present beforehand. The reflux resolved in three patients. Long-term outcomes into adulthood are unavailable in the literature. Other clinicians report similar rates (about 20%) of persistent reflux into ipsilateral lower pole or contralateral ureters after heminephrectomy alone.[43,93] In another series of 19 patients reported by Scherz et al,[94] 9 patients (47%) required intravesical surgery for urinary infection or reflux (Figure 40.41).

These types of data have led some clinicians to advocate a combined approach where heminephrec-

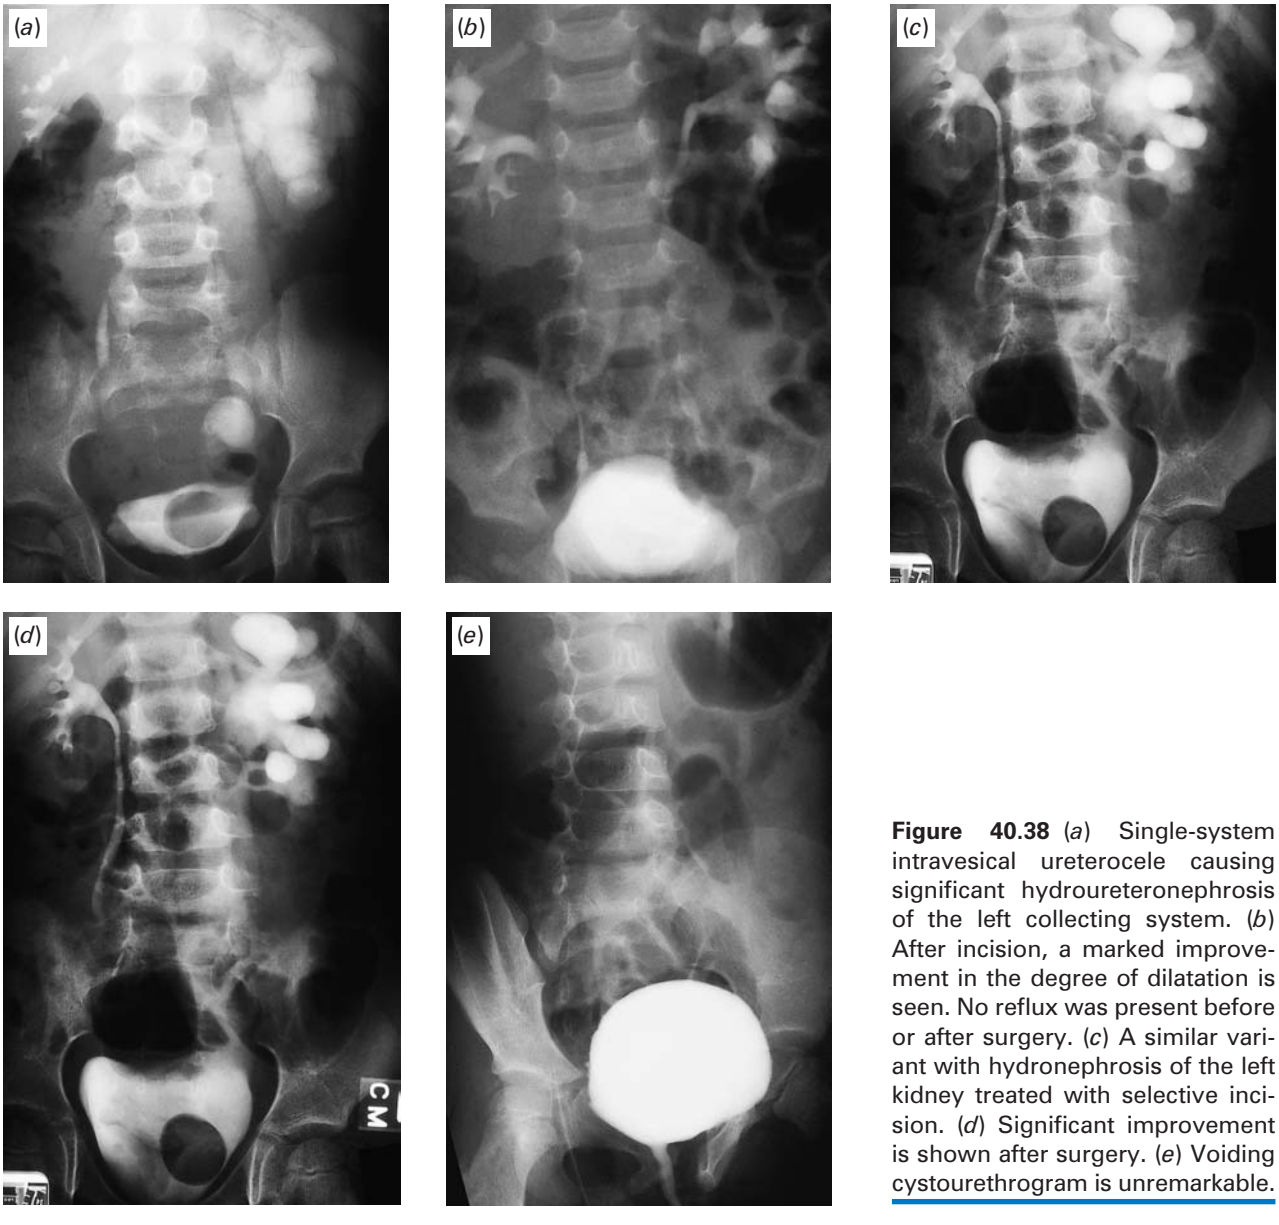

Figure 40.38 (*a*) Single-system intravesical ureterocele causing significant hydroureteronephrosis of the left collecting system. (*b*) After incision, a marked improvement in the degree of dilatation is seen. No reflux was present before or after surgery. (*c*) A similar variant with hydronephrosis of the left kidney treated with selective incision. (*d*) Significant improvement is shown after surgery. (*e*) Voiding cystourethrogram is unremarkable.

tomy, ureterocele excision, and ureteral reimplantation are completed with one surgery.[44,95] The need for secondary surgeries is far less common with the combined approach. For example, only 14% of patients in the Scherz series[94] required reoperations for persistent reflux after the combined approach. To its detriment, ureterocele excision and duplex ureteral reimplantation can present a technical tour-de-force in smaller infants. In addition, intravesical repairs are unnecessary in perhaps half of these patients. The characteristics of ureteroceles that ultimately require excision and bladder reconstruction remain to be fully defined. Such selection criteria would help identify patients whose problem would be best finalized by the upper tract approach alone and limit the combined approach to those that truly need it.

The review by Husmann et al[96] has been revealing in this regard. Of 87 patients with a ureterocele and nonfunctioning upper pole treated by heminephrectomy, subtotal ureterectomy, and observation (initial upper tract alone approach), 54 (62%) required additional surgery to correct reflux. Notably, the need for additional surgery was directly related to the number of renal moieties that originally had VUR present. When a ureterocele alone was present, 21 of 21 patients required no further surgery. If low-grade reflux (less than III/V) was present into only one ureter, eight of 15 patients (53%) did well with the upper tract alone

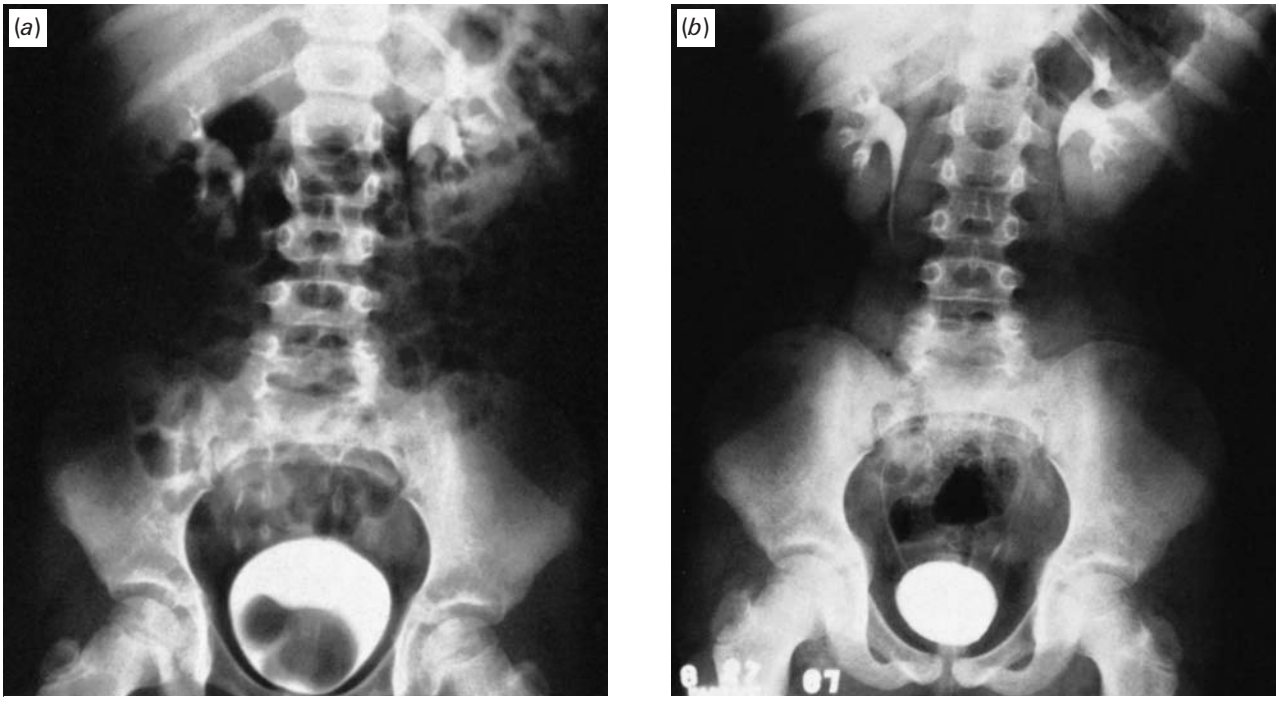

Figure 40.39 (*a*) Preoperative view shows minimally functioning upper pole moiety of the right kidney. (*b*) Postoperative view shows decompression of the ureterocele and an essentially normal right kidney.

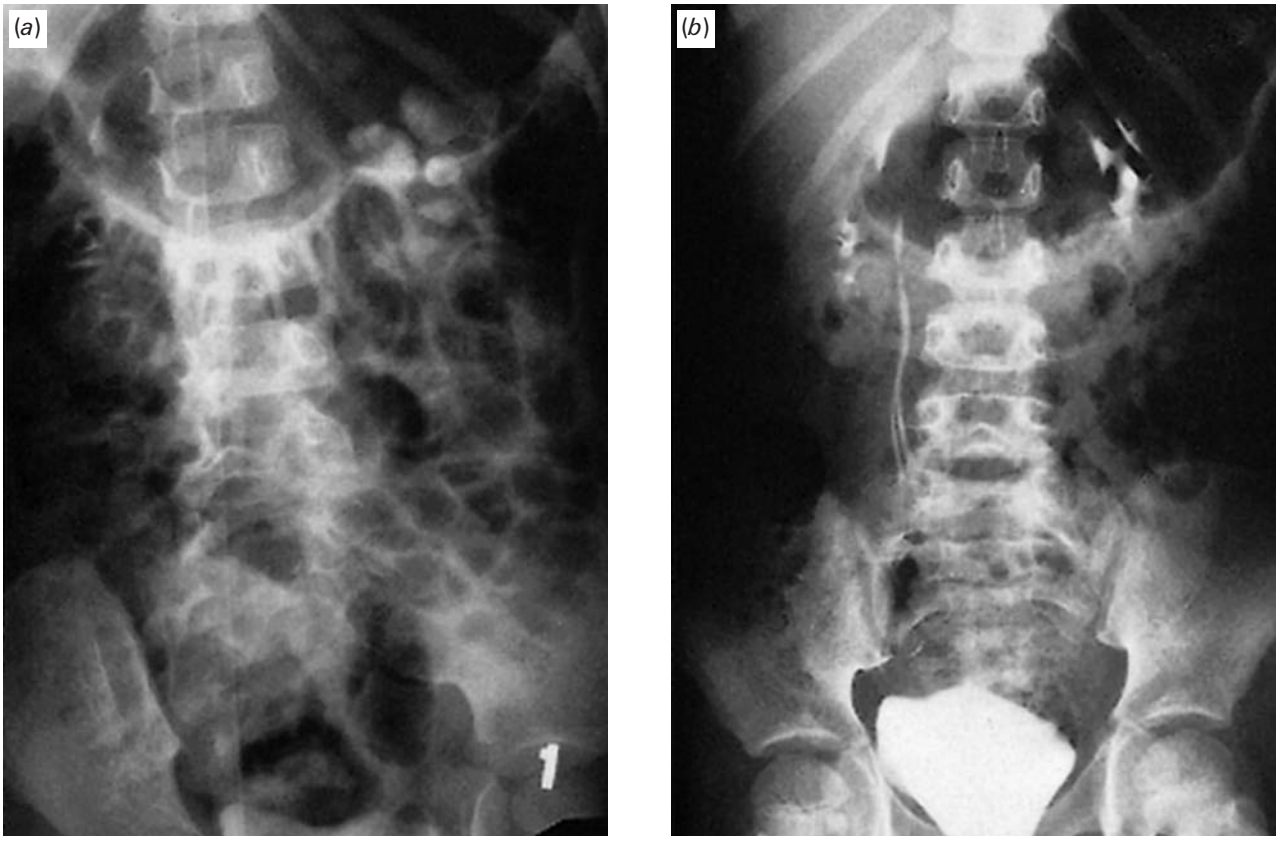

Figure 40.40 Extravesical ureterocele treated by heminephrectomy and subtotal ureterectomy. (*a*) Preoperative excretory urogram shows a left-sided anomaly and a markedly hydronephrotic lower pole. (*b*) Postoperative view. Preservation of function and appearance of remaining kidney are often surprisingly good. The ureterocele is fully decompressed.

approach. Finally, and most significantly, when high-grade reflux was seen in one ureter or reflux was associated with more than one moiety, regardless of grade, surgery became inevitable for 48 of 50 (96%) patients. A more recent review by DeFoor et al[97] echoed similar findings. Ureteroceles that involve other renal segments are more likely to require secondary surgery. Ureterocele prolapse is another finding that inevitably portends bladder reconstruction.[98] In addition, the occasional ureterocele that itself refluxes at presentation will, by default, require a combined 'up-and- down' approach for management.

Given these data, families and patients can be better informed as to the likelihood of needing lower urinary tract surgery if an upper tract approach is initially used. In addition, strong consideration can be given to a complete urinary tract reconstruction if the preoperative work-up returns such ominous prognosticators and the patient's size permits. Finally, and while it might seem an anathema to some, unroofing the ureterocele becomes an option in newborns and small infants who appear destined to require 'up-and-down' surgery regardless because of the 'clinical staging' of their anomaly. Eliminating obstruction significantly lessens the threat of urinary infections and decompression of the ureterocele simplifies the bladder repair (Figure 40.42). Most children can be effectively managed with antibiotic prophylaxis until they are old enough to have definitive reconstructive surgery. However, infections can still occur. In one series of 15 neonates with a ureterocele, eight developed infections during the first few days of life, including three who were receiving prophylactic antibiotics.[99] Assessment, with considerations to surgery, should be done at an early age to optimize the advantage given children whose anomalies have been discovered antenatally.[100]

The report of Gran et al[101] offers a different solution to the long-term follow-up required of residual ureteroceles that remain after the upper tract alone approach has been used. Rather than remove a non-functioning moiety, reconstruction of its ureter and the bladder was successfully completed in 16 patients. No morbidity has yet (mean 5 years follow-up) been associated with the non-functioning kidneys that remain. Detractors, concerned about preserving possibly dysplastic tissue, will explain that families are now offered extended follow-up of such kidneys in exchange for that of the bladder. However, if parallels are drawn with the relative benefits of removing multicystic dysplastic kidneys, the argument may ultimately prove to be a weak one. Future management may see many children with ureteroceles initially punctured and decompressed during the newborn period until they are old enough for bladder reconstruction, if reflux persists or appears, regardless of the status of their kidneys.

Finally, on the far end of the spectrum, an expectant approach has been used with success in some children with a non-functioning upper pole moiety and a low-grade lower pole VUR. In a group of 52 patients, whose anomalies were detected antenatally, 14 (27%) have done well, with a median of 8 years of follow-up.[102] Each was kept on prophylactic antibi-

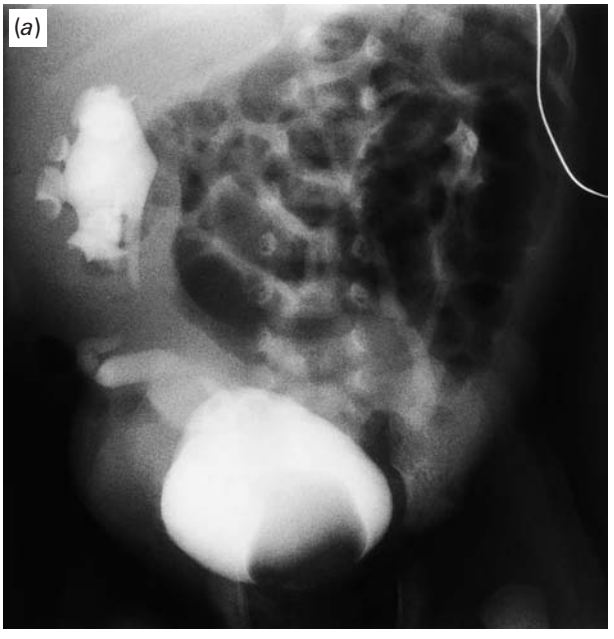

Figure 40.42 A newborn female with urinary tract infection needing a combined approach in the management of a ureterocele. (*a*) Excretory urogram shows a large ureterocele filling the base of the bladder, and a non-functioning upper pole of the right kidney. (*b*) Preoperative cystogram demonstrates eversion of the ureterocele forming a diverticulum, an indication of a significant detrusor defect. No reflux was seen. (*c*) Postincision cystogram shows bilateral vesicoureteral reflux but decompressed ureterocele. Heminephrectomy and ureterocelectomy were deferred until 1 year of age, since the child remained infection free.

otics until the completion of toilet training and none required surgery. These findings raise more questions than they answer.

Duplex system – functioning upper pole

Like their non-functioning partners, these conditions too can be addressed with an 'upper tract alone' approach. It should be remembered that upper pole duplications optimally contribute perhaps 16% of overall renal function. Because of this somewhat marginal contribution, some clinicians recommend heminephrectomies for the majority of duplications, whether they function or not. This avoids the potential complications of the reconstruction, risks to the lower pole, and the unknown long-term implications of upper pole retention.[31] The other option is salvage of the upper pole by creating a ureteropyelostomy or ureteroureterostomy in combination with a subtotal

ureterectomy. No study similar to that cited above for non-functioning duplications treated with an upper tract approach has been reported. Nevertheless, there is every reason to believe that the same risk factors for persistent reflux and recurrent urinary infections exist and result from the size and position of the ureterocele and its implications for the trigone and adjacent ureters. With this in mind, the upper tract approach is usually reserved for ureteroceles presenting without reflux into the ipsilateral lower or contralateral ureters and should offer a high likelihood of success.

In patients whose variants have associated VUR, it seems reasonable to address the majority solely at the bladder level, removing the ureterocele and correcting the reflux, and thus eliminating the need for secondary surgery. Such an approach is ideal for the older child whose bladder is large enough to allow a complex reconstruction with a high likelihood of success. The reality is, however, that the majority of ureteroceles are diagnosed antenatally. After birth, such babies remain at significant risk, as UTIs associated with obstruction are much more threatening to the child and kidney than those that occur with reflux alone. In addition, the affected kidney potentially incurs progressive damage because of distal ureteral obstruction. As a result, medical management with prophylactic antibiotics should be considered a short-term approach rather than an extended panacea and may not allow for a sufficient enough interval of time until the bladder can be safely reconstructed.

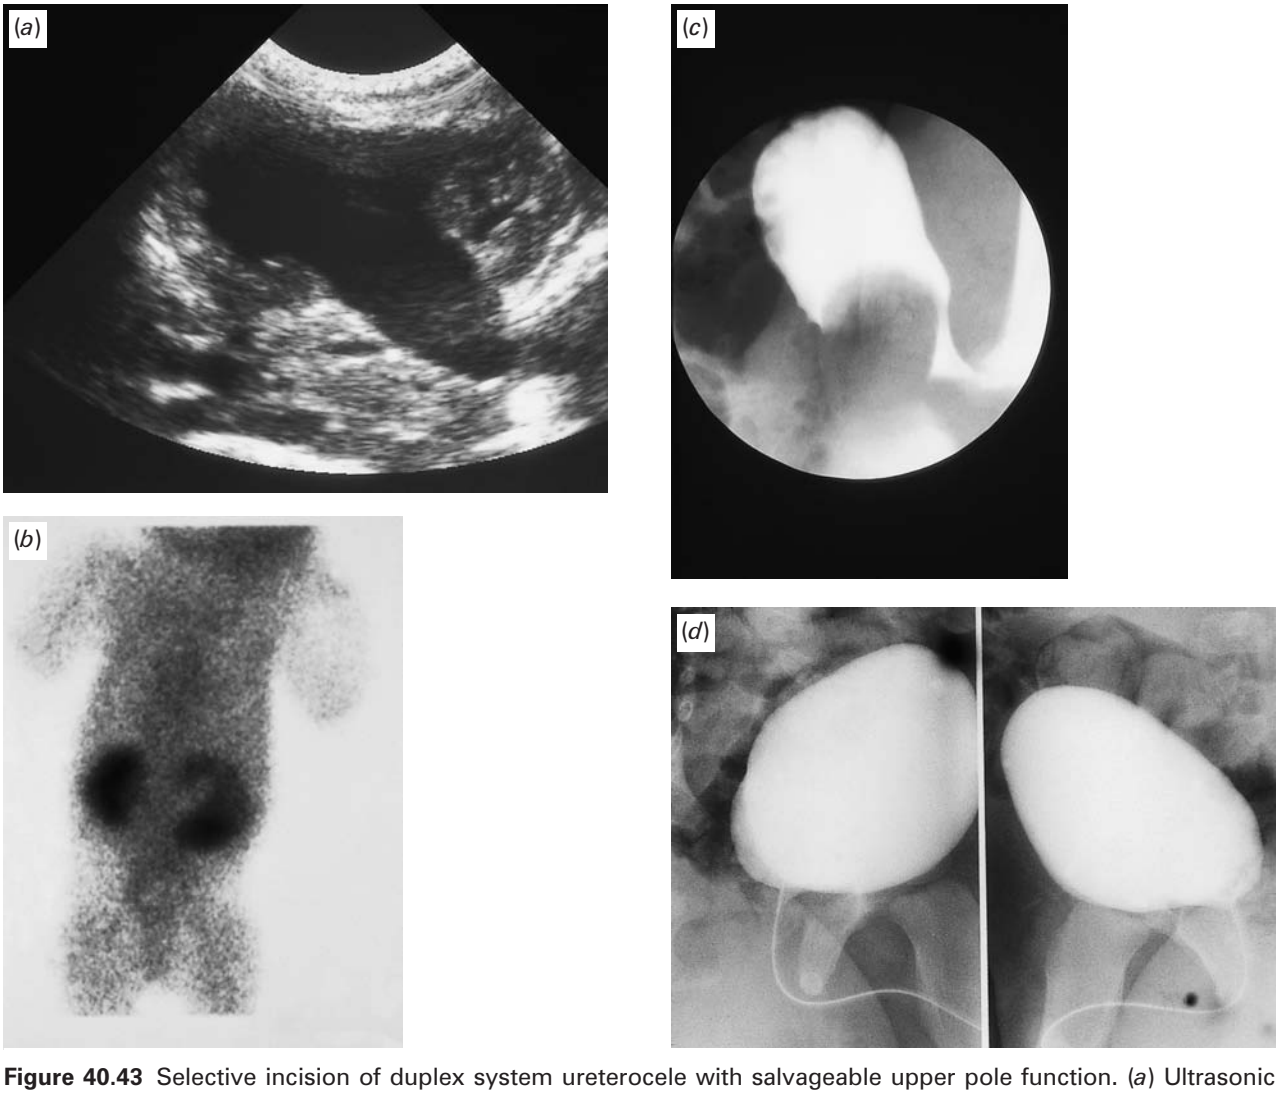

Figure 40.43 Selective incision of duplex system ureterocele with salvageable upper pole function. (*a*) Ultrasonic appearance in a newborn diagnosed antenatally. (*b*) Radionuclide scan shows function to upper pole and filling defect within the bladder. (*c*) Bladder defect during cystogram appears largely intravesical, which may have been a factor in success. (*d*) Postincision cystogram shows no evidence of reflux. Hydronephrosis had virtually resolved.

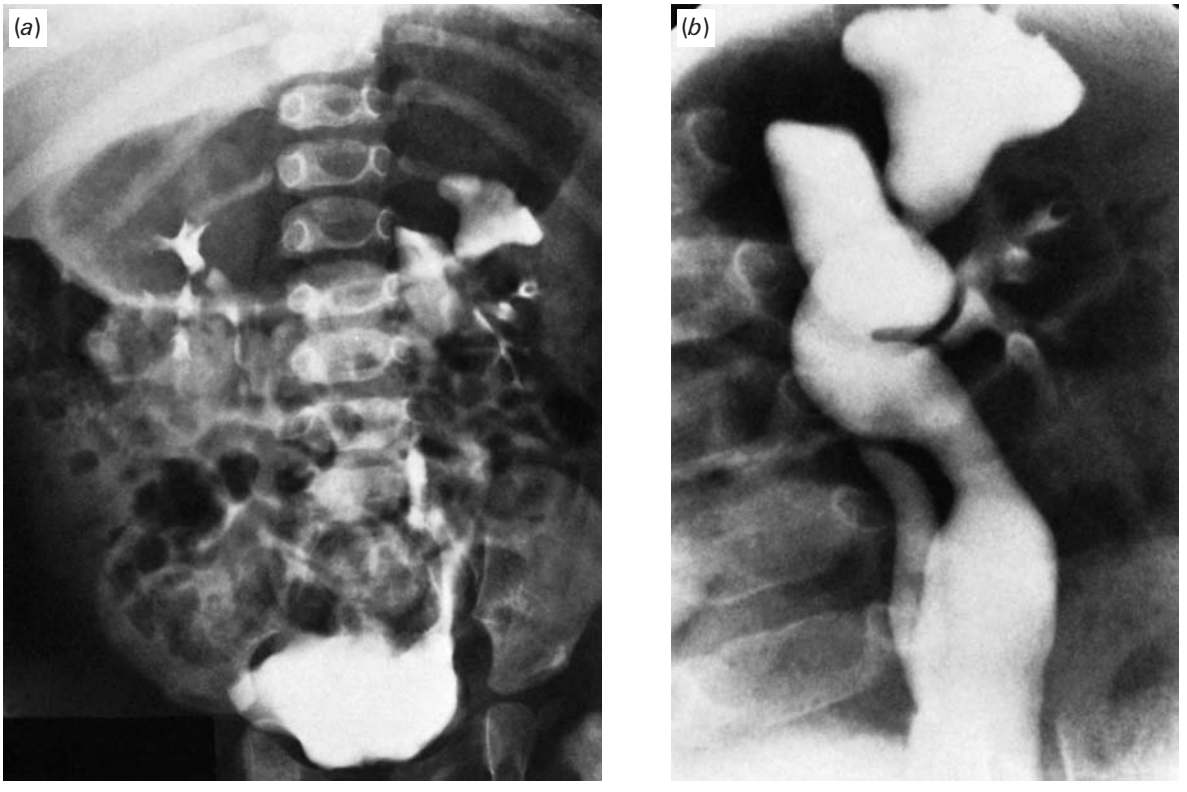

Figure 40.44 Risk of ureterocele incision. (*a*) Duplication of the left kidney associated with an extravesical ureterocele seen on excretory urography. (*b*) After incision, the previously 'obstructed' system is converted to one that significantly refluxes into both ureters.

As an alternative, endoscopic treatment provides an effective option for newborns and infants, particularly those who present with a significant UTI. Surgeons should hold realistic expectations for this approach, which rarely provides the final solution for these ureteroceles, even with selective incision. Instead, the maneuver should be considered a temporizing measure used to vent the obstructed system. This increases the likelihood of success with medical management, thus allowing for additional growth of the child until a definitive bladder reconstruction can be completed (Figure 40.43). VUR persists or results in the majority of cases. For example, in one series, 18 of 21 (86%) patients with extravesical ureteroceles treated endoscopically required additional surgery. By contrast, the results with intravesical variants were strikingly different, with 14 of 16 children successfully treated with incision alone.[103] In a larger series reported by Husmann et al,[90] the performance of selective incision was also discouraging. Ectopic ureteroceles preoperatively associated with reflux into one or more moieties required further surgery for persistent reflux in 37 of 44 (84%) cases. An identical reoperation rate occurred when heminephrectomy was used for similar variants. Notably, when VUR was not present prior to treatment, incision was more likely than heminephrectomy to result in the appearance of reflux (64% vs 15%). Based on this observation, it would appear that ureteropyelostomy or ureteroureterostomy is the treatment of choice when a salvageable duplex system is not accompanied by lower segment or contralateral reflux. Whereas success rates with endoscopic incision vary, its weaker performance with extravesical ureteroceles is repeatedly borne out in the literature[69,89] (Figures 40.44 and 40.45).

Surgical techniques

Although many of these techniques are described elsewhere, nuances of their application to the treatment of ectopic ureters and ureteroceles in children deserve comment.

Ureterocele prolapse

The prolapsed ureterocele is not the surgical emergency once supposed. Manual reduction is sometimes

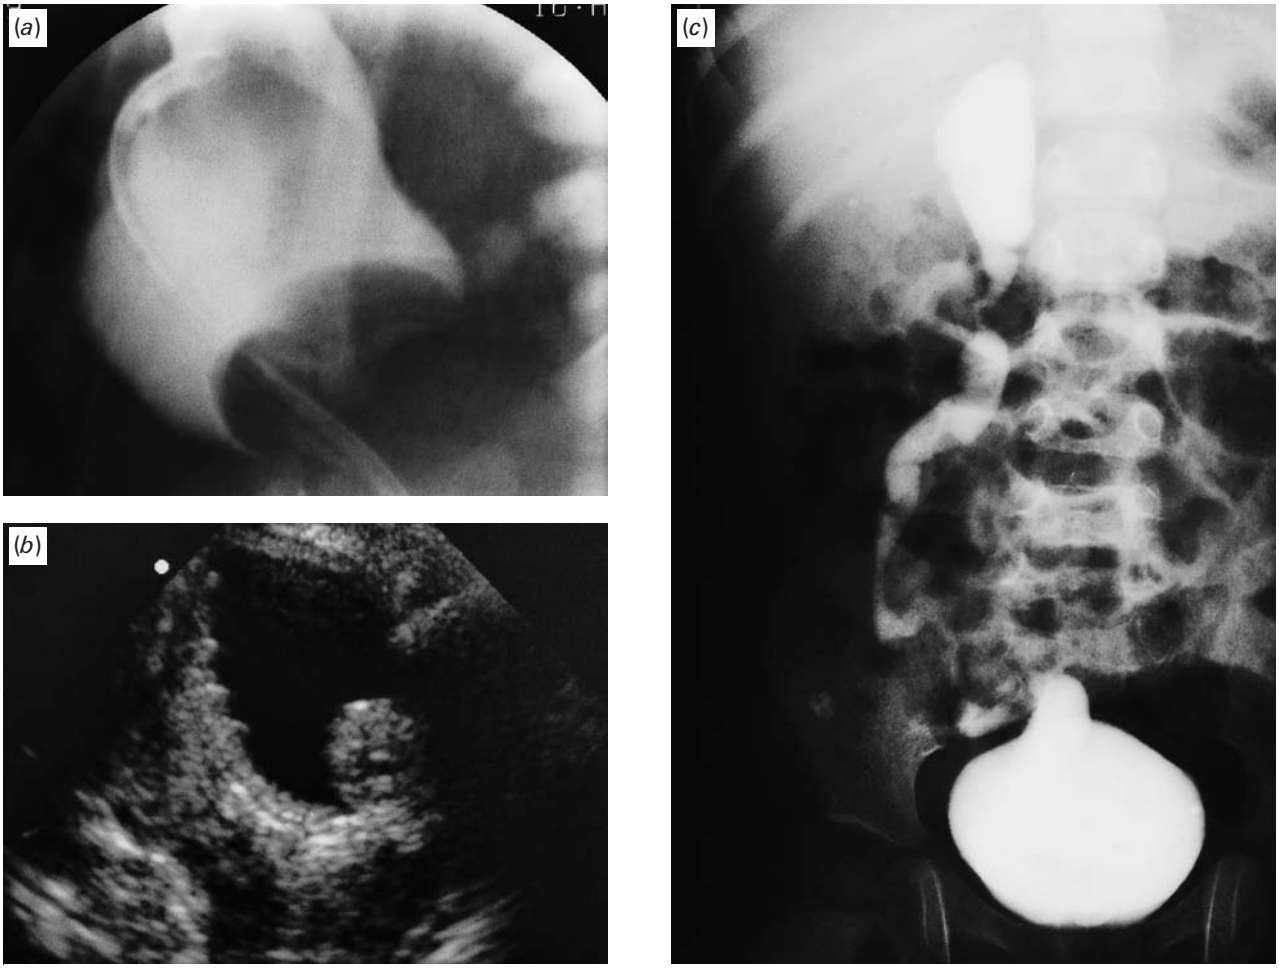

Figure 40.45 (*a*) A large extravesical ureterocele shown during cystography. Both poles functioned and no reflux was seen. (*b*) Successful decompression seen by ultrasound but (*c*) reflux into upper pole moiety is documented on a postoperative cystogram.

possible, but, because of the nature of the defect, prolapse is likely to recur. Heminephrectomy to decompress the ureterocele is another option. However, because of the size of these defects, affected bladders will uniformly require secondary reconstructions as well. A simpler solution is to incise the ureterocele at the bedside with a disposable ophthalmic cautery unit. This technique is usually effective and serves the same purpose as cystoscopic incision. In occasional cases, the latter still becomes necessary to treat the intravesical portions of a prolapsing ureterocele that will fail to decompress because of bladder neck obstruction.

Selective cystoscopic incision

The cystoscope is initially passed under vision to avoid traumatizing the ureterocele. For intravesical variants, a distally positioned puncture at the ureterocele's medial base is usually sufficient to decompress the structure yet

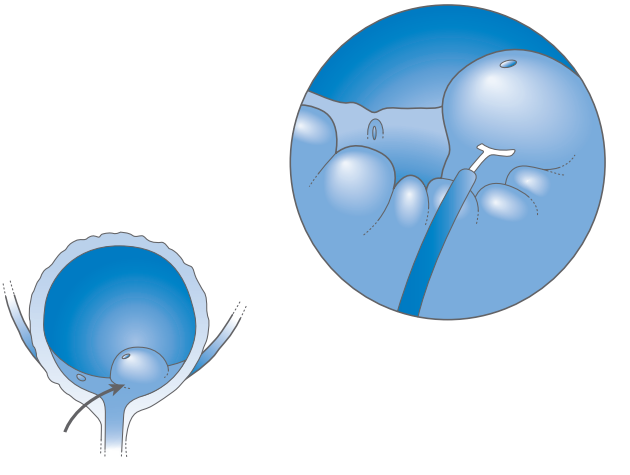

Figure 40.46 Endoscopic incision of the ureterocele with fine bugbee or wire at the medial base of the ureterocele. (Adapted from Rich et al.[104])

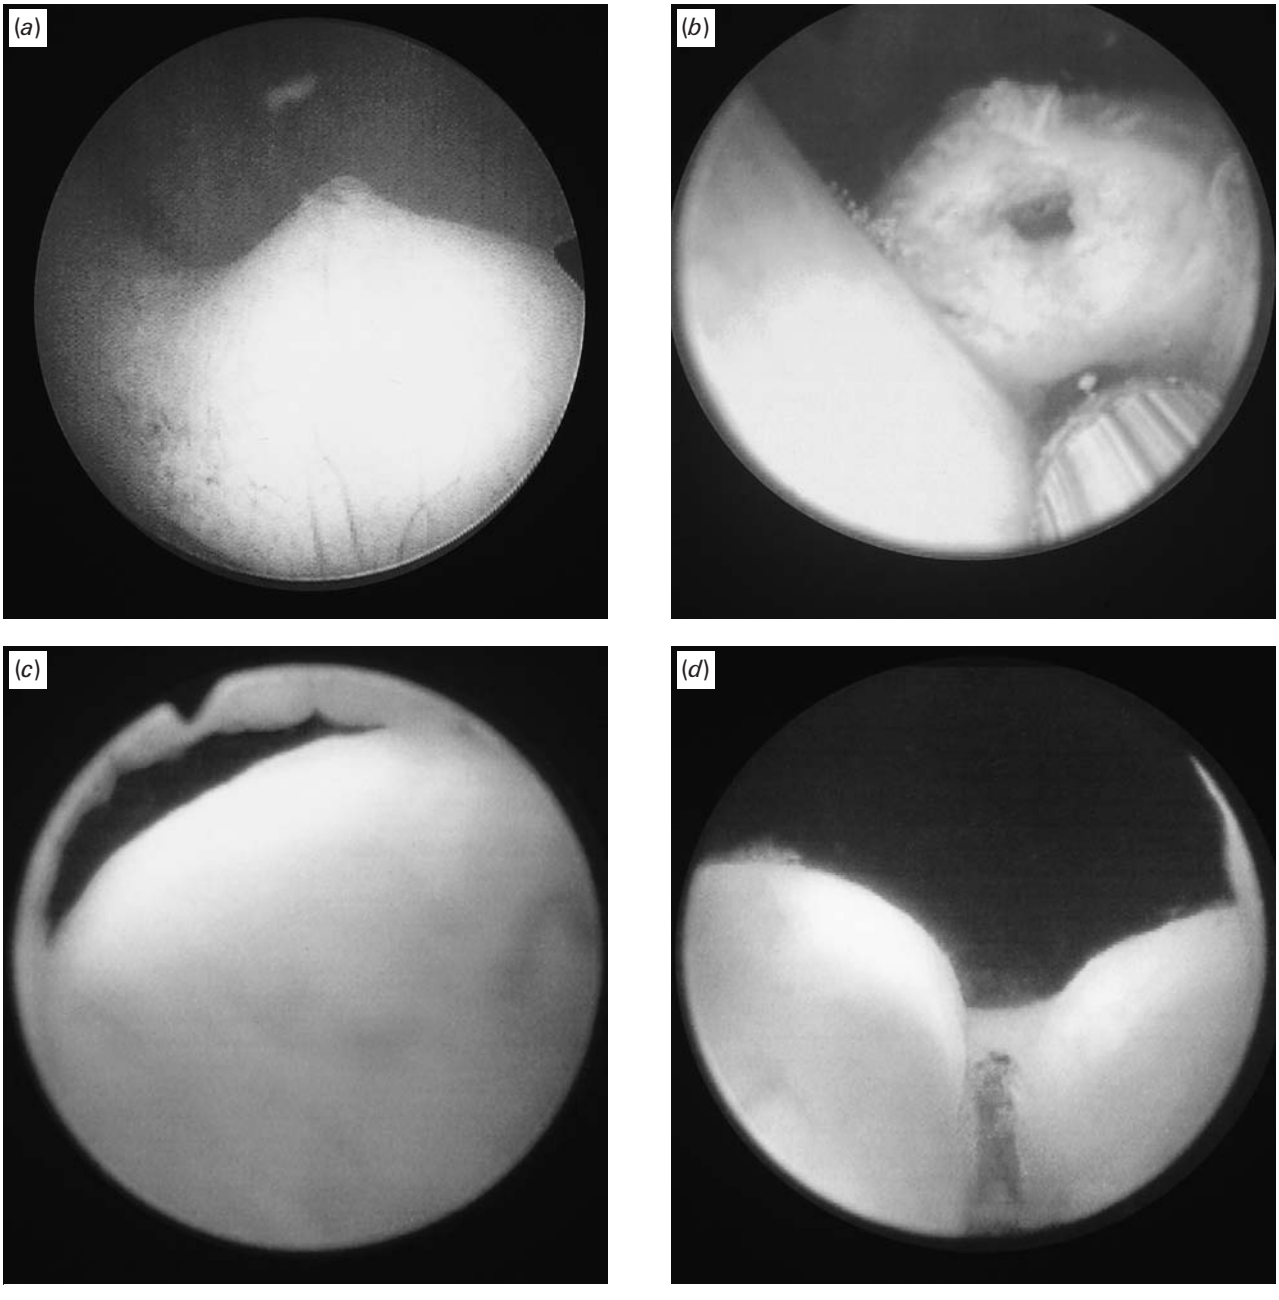

Figure 40.47 (*a*) Cystoscopic appearance of an intravesical ureterocele. (*b*) Ureterocele is decompressed after incision by fine bugbee (*c*) Extravesical ureterocele is seen occluding the bladder neck. (*d*) Wire is applied at the medial base with the intent of preserving the flap-valve effect.

preserve enough submucosal length to maintain the characteristics required of an effective flap valve to avoid reflux[104] (Figures 40.46 and 40.47). Cecoureteroceles and sphincteric ureteroceles can be unobstructed by vertically incising the meatus and extending it above the bladder neck (Figure 40.48). Cutting current is applied across a No. 3 Fr Bugbee electrode to provide a clean, full-thickness puncture of the ureterocele wall. A laser incision can also be considered.[105] Aggressive hydration and minimal instillation of irrigation helps keep the ureterocele distended to aid in placement of the puncture. Surgery can be done as an outpatient. An ultrasound obtained 10–14 days later should document resolution of hydronephrosis and ureterocele decompression. The decompressed ureterocele typically appears as a pseudomass or mucosal thickening.[106] A VCUG is performed 3 months later to demonstrate whether reflux has been created.

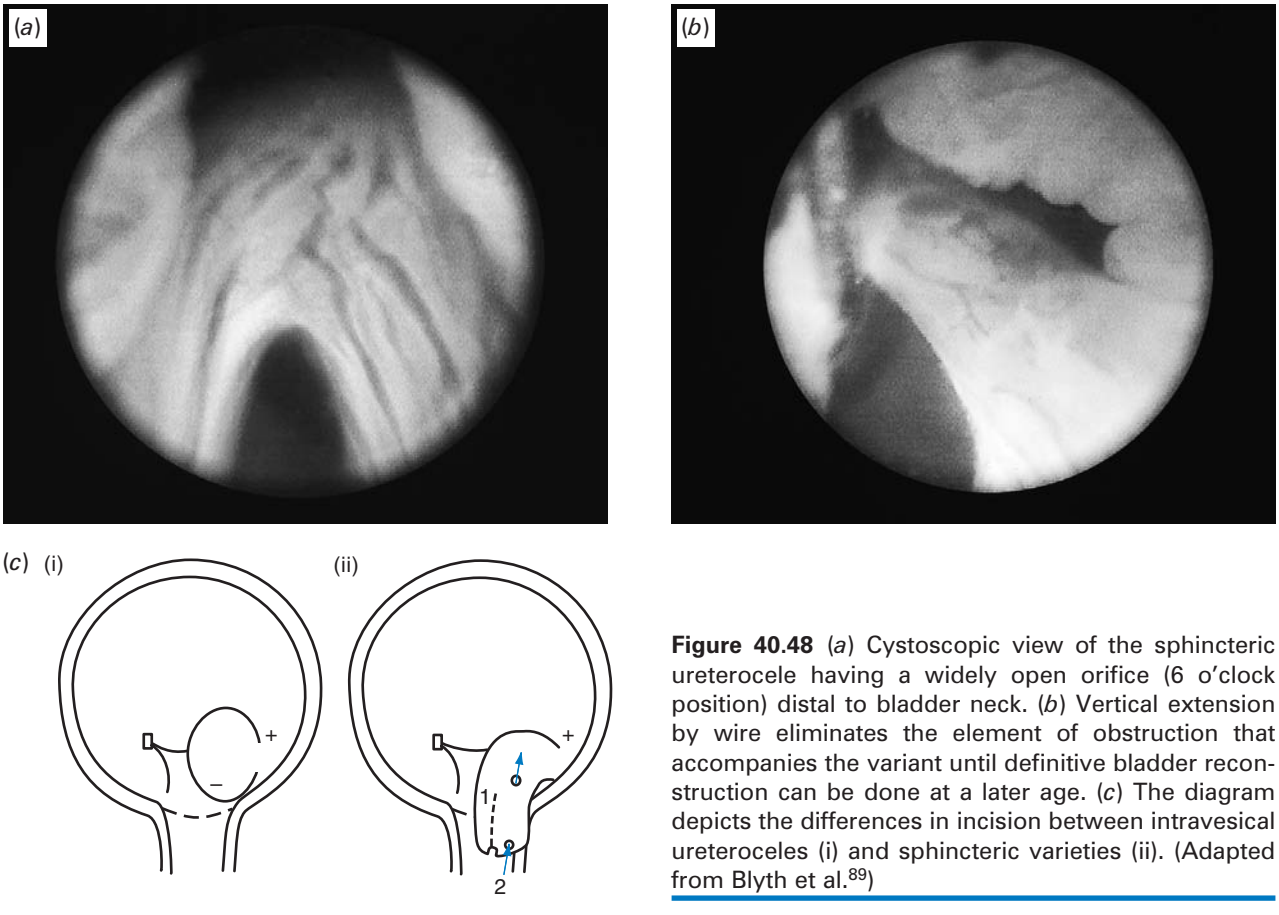

Figure 40.48 (*a*) Cystoscopic view of the sphincteric ureterocele having a widely open orifice (6 o'clock position) distal to bladder neck. (*b*) Vertical extension by wire eliminates the element of obstruction that accompanies the variant until definitive bladder reconstruction can be done at a later age. (*c*) The diagram depicts the differences in incision between intravesical ureteroceles (i) and sphincteric varieties (ii). (Adapted from Blyth et al.[89])

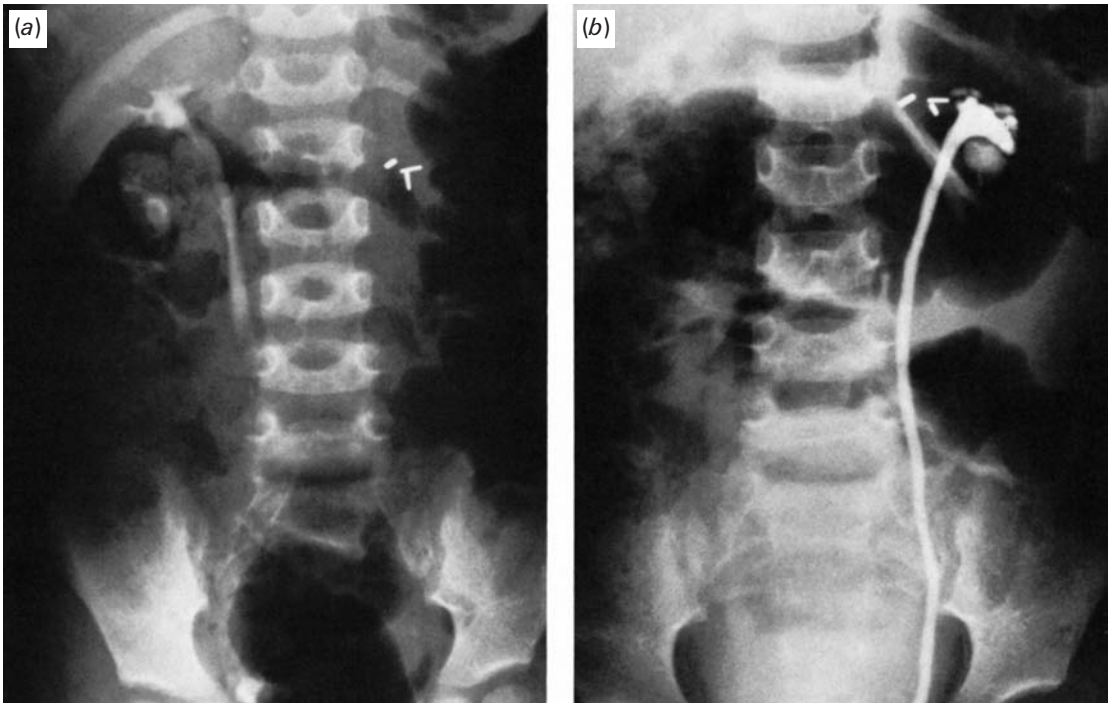

Figure 40.49 Vascular injury after left upper pole heminephrectomy and partial ureterectomy. (*a*) After surgery, failure of contrast excretion by remaining lower pole of the kidney, although the segment had been well vascularized prior to surgery. (*b*) Retrograde pyelogram demonstrates a shrunken, unobstructed lower pole moiety.

Figure 40.50 Mobilization is completed before excising the upper pole segment. The ureter has been transected and carried behind the vessels to the lower pole of the kidney, providing a useful handle and guide to demarcation for heminephrectomy.

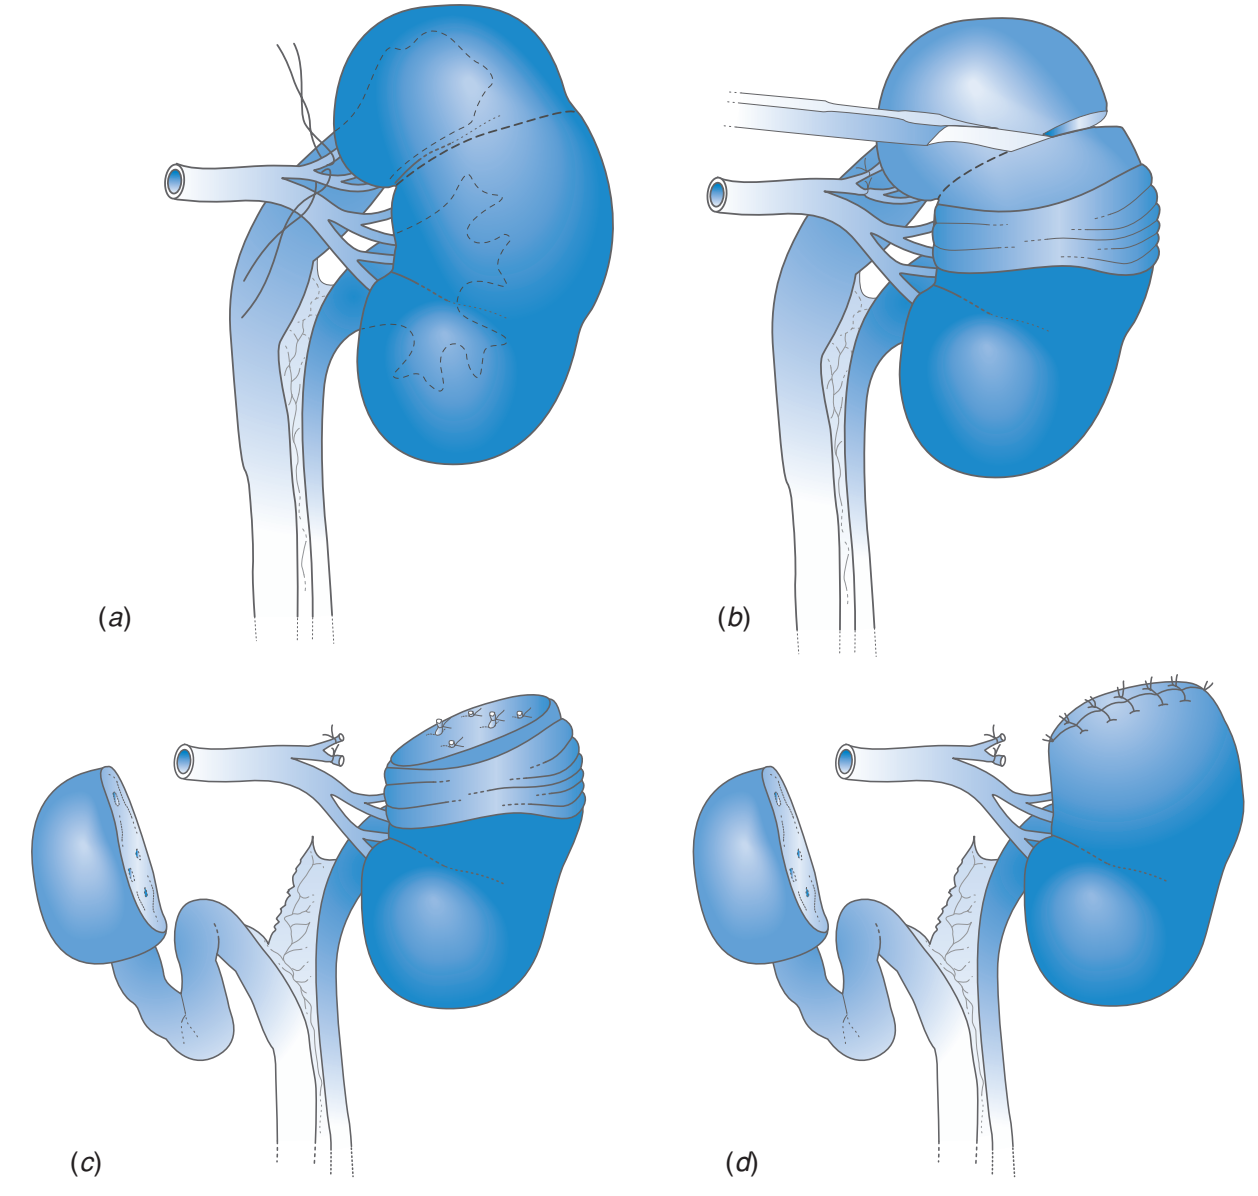

Figure 40.51 Technique of heminephrectomy. (*a*) Vessels to the upper pole are identified and ligated. At this point, the ureter can be fully mobilized from the area of the lower pole hilum and swung posteriorly and superiorly. (*b*) The capsule is peeled away from upper pole and preserved for closure. A cautery offers less bleeding than the knife. (*c*) Significant vessels are ligated. (*d*) Closure incorporates the capsule and parenchyma.

Heminephrectomy

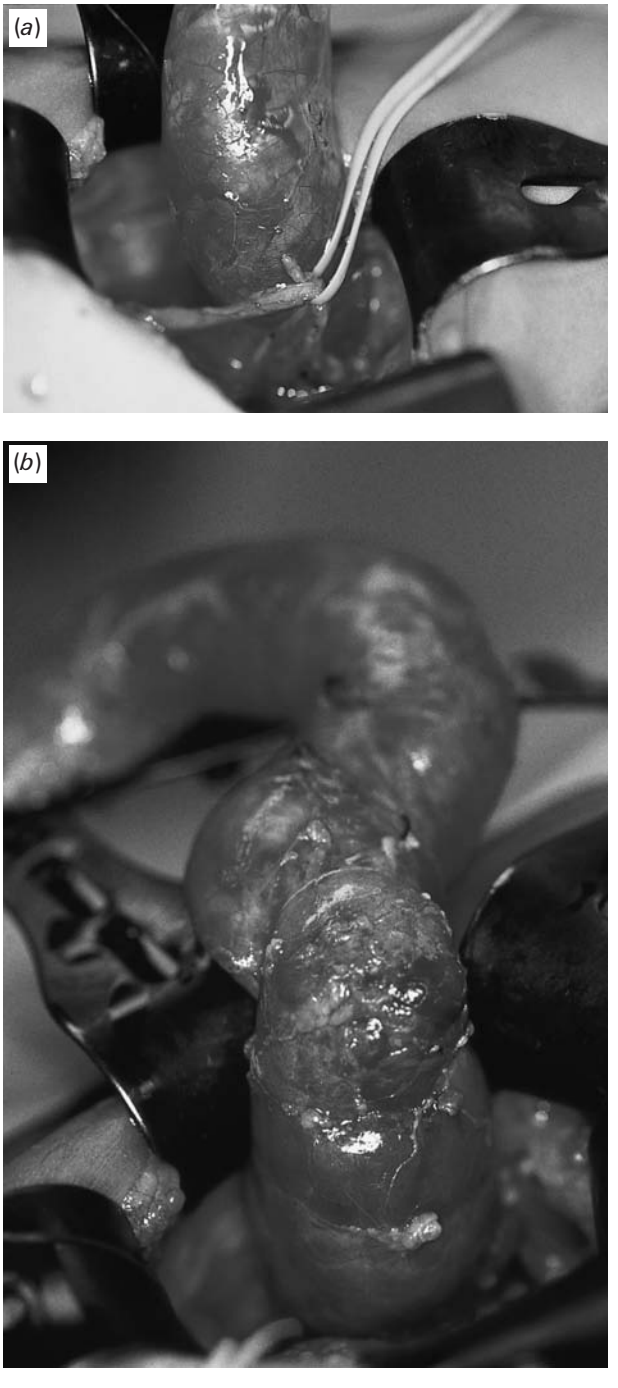
The key to success with heminephrectomy at any age, but especially in the infant, is complete and careful mobilization of the kidney. However, the vessels of babies are prone to spasm and intimal tears[93] (Figure 40.49). Undue traction must be avoided as the organ is gently cleared from the surrounding pararenal fat. It helps to intermittently discontinue the manipulation of smaller kidneys. In cases where vascular spasm persists, topical vasodilatory agents such as papaverine can be applied.

In some cases, the vascular pedicle to the upper pole is isolated from that of the lower, making it easily discernible. In others, branching of the two occurs near the renal hilum, making identification of the upper pole vessels more difficult. After the vessels are identified, vessel loops are placed around them. The ureter is transected at its midsection and mobilized superiorly, posterior to the anteriorly positioned renal vessels. Once freed, the ureter can be swung beneath the vessels and used as a handle on the upper pole during its separation from the lower (Figure 40.50). Upper pole blanching will occur after its vessels are ligated. Clamps on the lower vessels are avoided. Instead, the kidney is gently grasped between the thumb and index finger to help control bleeding. A rim of renal capsule can be peeled off the upper pole to be used in later closure. The poles are then separated with cautery (high settings) along the line of vascular demarcation (Figure 40.51).

When a fish-mouthed defect remains in the lower pole, it can be closed with chromic mattress sutures that incorporate parenchyma and capsule. Otherwise, a flap of pararenal fat can be mobilized and tacked into position to cover the defect. Suturing the capsule of the remaining lower pole to the adjacent muscle is also recommended to avoid postoperative torsion. A drain is left in the renal fossa.

Ureteropyelostomy and ureteroureterostomy

The principles of successful ureteropyelostomy and ureteroureterostomy are identical to those of dismembered pyeloplasty: minimal handling of the ureters and maintenance of their orientation. Luminal disparity between the recipient collecting system and upper pole ureter is rarely the cause for concern[107] (Figure 40.52). In most cases the anastomosis is anteromedially positioned. Traction sutures define the extent of the ureterotomy or pyelotomy on the recipient ureter. An oblique incision of the donor ureter is marked to match. Running 6–0 polydiaxanone sutures are used to complete the repair. Urinary drainage tubes are unnecessary, although a drain is left in the region of the repair (Figures 40.53 and 40.54).



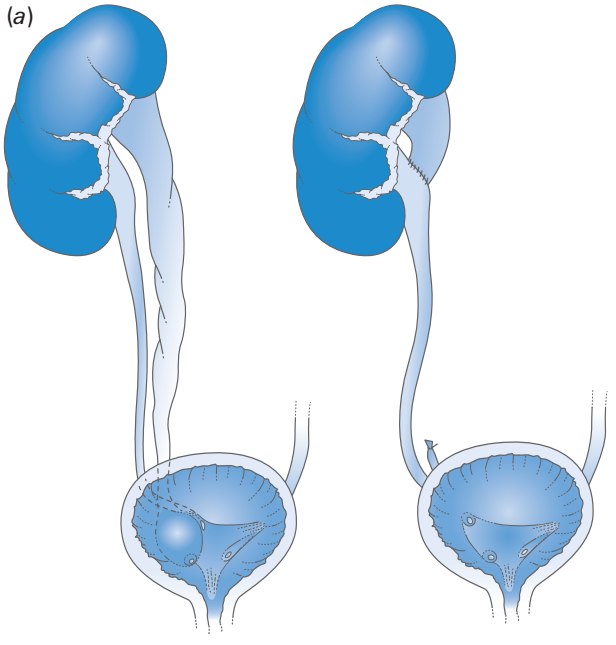


Figure 40.52 (*a*) Disparity in size between the obstructed ureter of the upper pole moiety and the lower ureter (vessel loop) sometimes poses problems for ureteroureterostomy. (*b*) Since the upper pole shown grossly provided only moderate function, a heminephrectomy was performed.

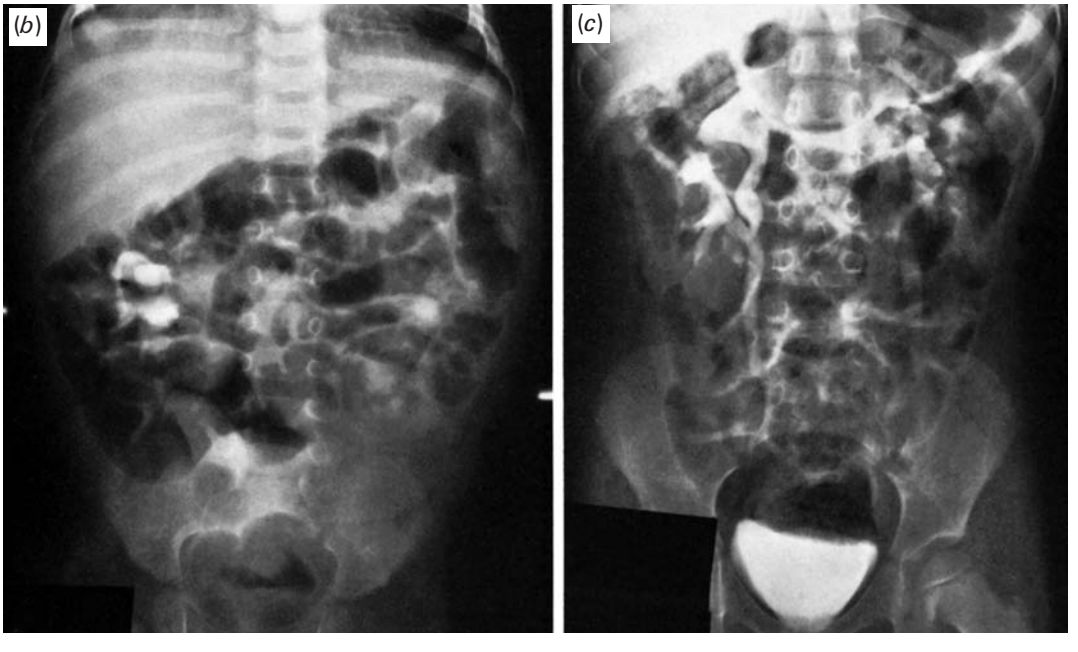

Figure 40.53 (*a*) Pyeloureterostomy and subtotal ureterectomy can be used to treat ureteroceles or ectopic ureters. (*b*) Excretory urography shows bilateral duplication and ectopic ureteroceles. Poorly functioning hydronephrosis of the right upper moiety on excretory urography showed salvageable function by radionuclide scan. (*c*) Excretory urogram after the right pyeloureteostomy and left heminephrectomy shows return of function in the right upper segment and decompression of both ureteroceles below.

Subtotal ureterectomy

As much of the abnormal ureter as possible should be removed in concert with heminephrectomy or renal salvage procedure. After dividing the ureter, a 12 Fr red rubber catheter is sutured within to provide traction during its dissection. The ureter to the lower pole is identified and minimally handled. Long, narrow retractors are used to lift away the peritoneum as the adventitia and periureteral tethers to the upper ureter are taken down with selective cautery. The dissection is ended near the level of the pelvic brim, where the ureters become more intertwined. Ligation is done with 00 or 000 polyglycolic acid suture after aspiration of the obstructed ureter.

Lower ureterectomy

When a lower ureterectomy is necessary, a transverse Gibson-type incision is made along a lower abdominal crease. The obliterated hypogastric artery is identified and ligated. This is followed posteriorly until the ureter is encountered medially. The proximal portion of the ureter is pulled into the wound and acts as a handle during the remainder of the dissection. The ureter should be mobilized from within its adventitial sheath, avoiding the adja-

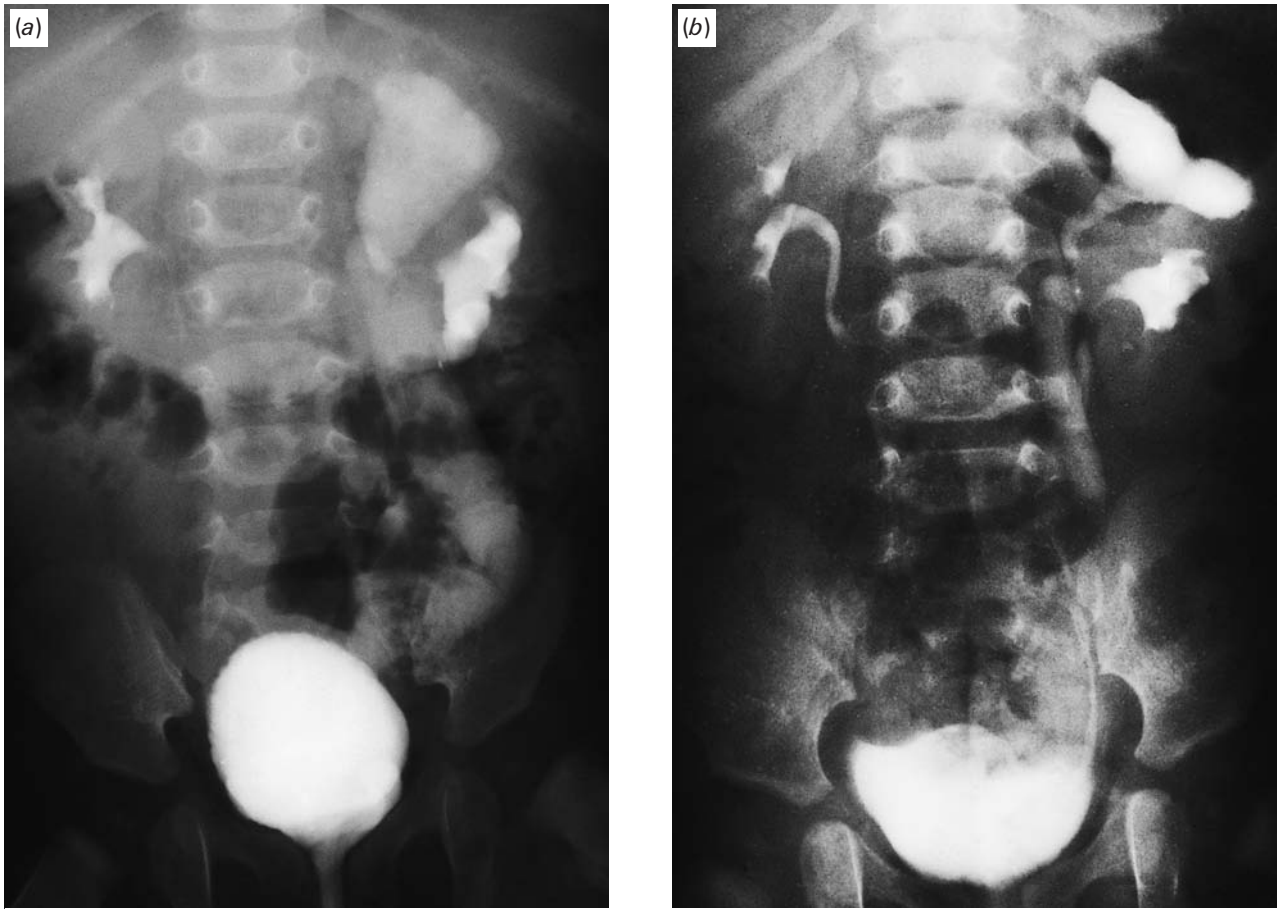

Figure 40.54 A 9-month-old female with intravesical ureterocele. (*a*) Preoperative excretory urogram shows good function to upper pole. (*b*) Decompression of the upper pole after successful ureteroureterostomy.

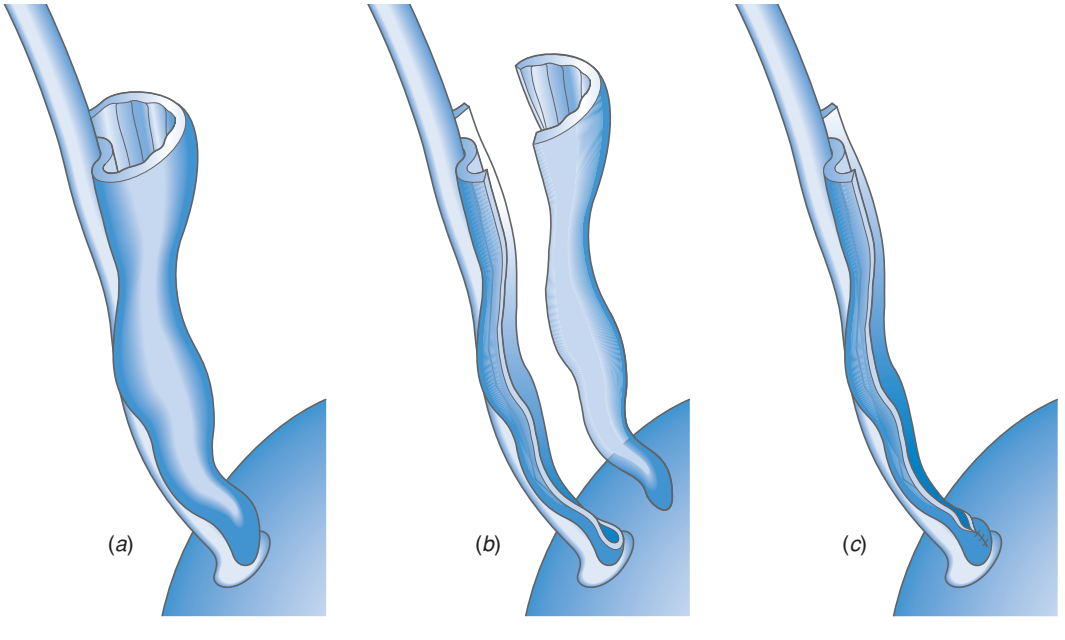

Figure 40.55 Lower ureterectomy. (*a*) It is often difficult to separate the two ureters as they near the bladder. (*b*) The outer wall of the dilated ureter associated with ectopia or ureterocele can be excised to the bladder, preserving a strip of common wall with the lower pole ureter. (*c*) Transfixing sutures obliterate its lumen, with care being taken not to injure the orthotopic ureter. (Adapted from Schlussel and Retik.[108])

cent peritoneum and vas deferens. Once the mobilization is complete, the ureter is ligated and transected just outside the bladder. When urethral ectopy is being addressed, a catheter is placed to aid in the dissection. The ureter is mobilized to just above the pelvic floor, where it is ligated and transected. The distal insertion can be left alone and undue dissection of the sphincter avoided. In the case of duplication, the shared wall of the upper pole ureter is left attached to that of the lower pole, avoiding damage to the blood supply. After resecting the ureter at the level of the bladder, several sutures are placed to obliterate its lumen at the hiatus (Figure 40.55).

Ureterocelectomy

The goals of ureterocele surgery – removal of the ureterocele itself, correction of associated reflux, and repair of any bladder defect – can be achieved by a number of different approaches. A transvesical approach gives the best opportunity to assess the problems associated with the anomaly.

The bladder is opened and the submucosal extent of the ureterocele is appreciated after incising its dome. Laterally and medially, the planes between the ureterocele lining and overlying bladder mucosa are defined using fine cautery dissection. Some bladder mucosa should be preserved for coverage of the resultant defect. As the enucleation/excision is carried posteriorly, the ureterocele lining is excised by defining its plane with the underlying detrusor. Proximally, one or both ureters are circumferentially mobilized at their entrance to the bladder. Mobilization is identical to that of ureteroneocystostomy. Lumenal tailoring is usually necessary for the ureter associated with the

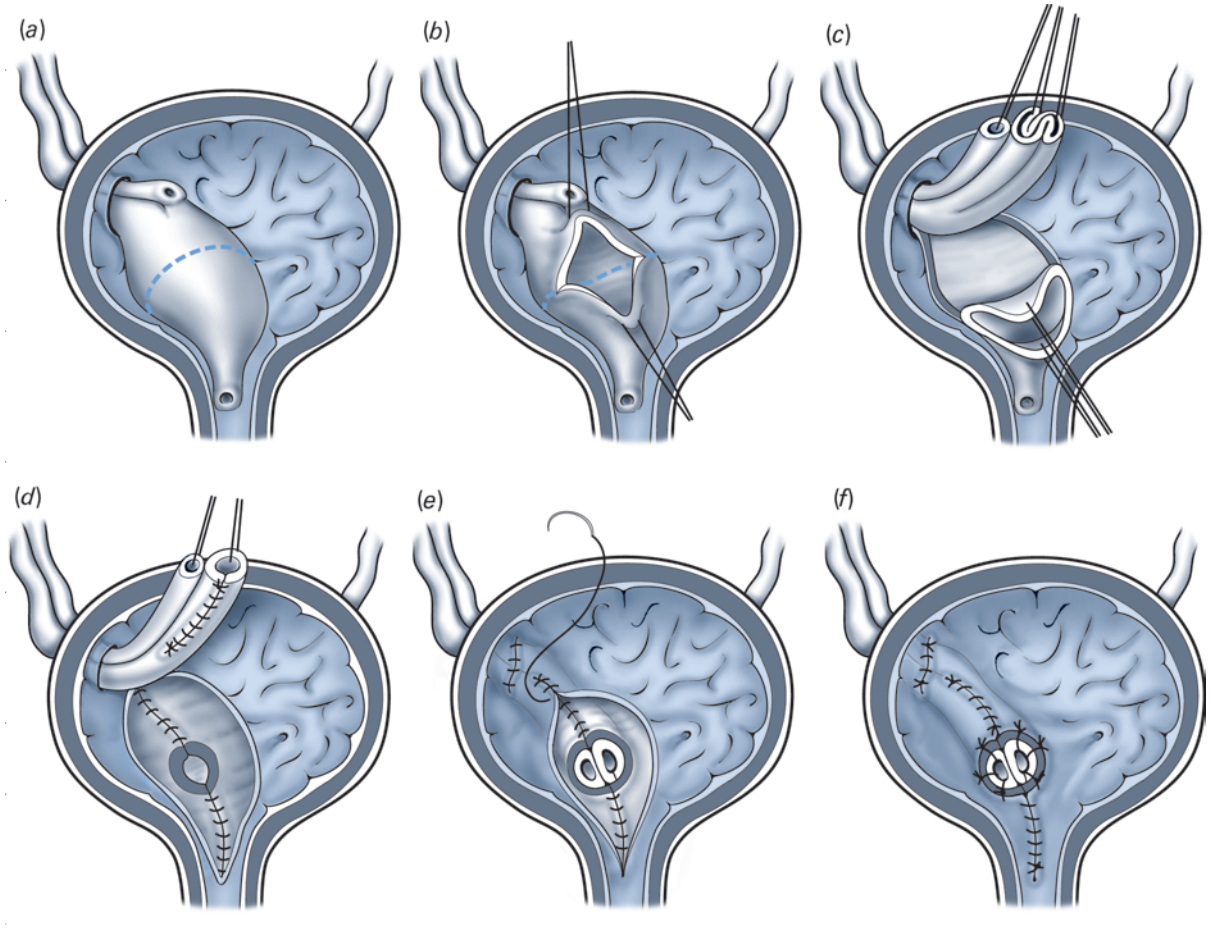

Figure 40.56 Technique for excision of ectopic ureterocele with common sheath reimplantation of both ureters. (*a*) Right-sided ureterocele. Contralateral ureter in close proximity. (*b*) Ureterocele can be opened transversely (as shown). A vertical incision can sometimes offer better visualization of the urethra. In many cases, the mucosa overlying the ureterocele is thinned out and must be discarded. (*c*) The posterior wall is incised and dissected away from the underlying detrusor. The dissection is carried around to the bladder mucosal edges to enable complete removal of the ureterocele. Ureteral orifices are circumscribed and mobilized. (*d*) Ureteral mobilization is completed. The dilated ureter is tapered opposite the common wall. The muscular defect in the bladder is repaired. (*e*) Both ureters are brought through the new hiatus in the bladder wall, although the cross-trigonal method can also be used. (*f*) Final appearance. (Adapted from Schlussel and Retik.[108])

ureterocele. The bladder defect that remains after the dissection is closed with interrupted sutures. Ureteral reimplantation is completed with ipsilateral advancement-type (Glenn–Anderson) or cross-trigonal (Cohen) reimplantation techniques (Figure 40.56).

Distally, ceco- and sphincteric ureteroceles present a special challenge because of their urethral extensions. Flap-valve obstruction of the bladder can result if tissue is left to balloon into the urethra during voiding.[109] However, extensive dissection should be discouraged to avoid damage to the sphincter mechanism. Instead, when the distal extent of the projection can be appreciated, it can be filleted open and its edges trimmed flush with the urethra. Otherwise, the opening to the projection can be defined and closed at the bladder neck, leaving the lumen intact where it rarely poses a problem.

Ureteroceles can be corrected by other approaches. Marsupialization has been successful in some cases, excising the intravesical outpouching of the anomaly and leaving its back wall in continuity with the adjacent bladder as coverage[94] (Figure 40.57). Reimplantation can be done beneath the marsupialized ureterocele, although it is often necessary to create a trough by incising its mucosa, which is more intimately attached to the posterior musculature than in normal bladder. Marsupialization is probably less likely to cause detrusor damage than enucleation. To its detriment, the modification is unable to correct defects in the detrusor and/or sphincter and thus is most applicable to smaller ureteroceles.

Another approach is to address the ureterocele extravesically. This can be combined with a heminephrectomy or a distal ureteroureterostomy done through the same incision[110] (Figure 40.58). A portion of the ureterocele wall can be excised extravesically without opening the bladder mucosa and any significant detrusor defect closed. Reimplantation of

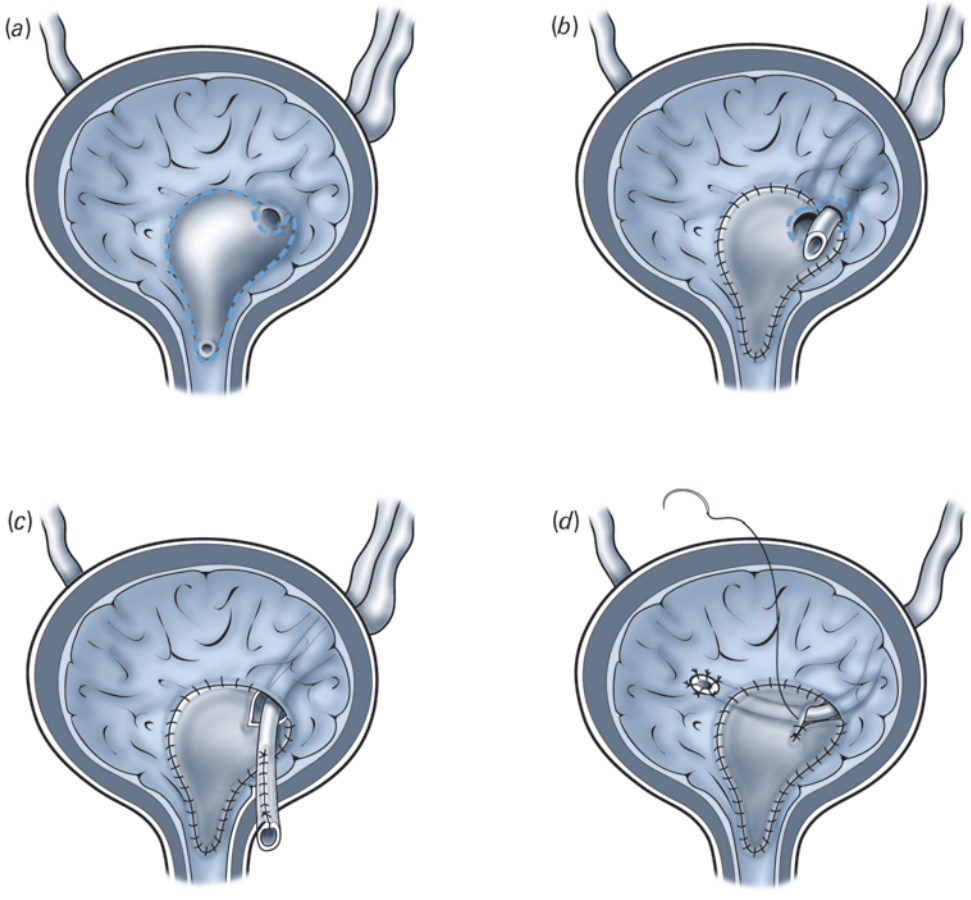

Figure 40.57 Marsupialization of ureterocele. (*a*) Ureterocele is incised at its junction with the normal bladder and sutured to mark edges and secure hemostasis. (*b*) Completed marsupialization. Mobilization of the duplex ureters is begun as common sheath. (*c*) Ureteral mobilization is complete and the bladder defect from dissection is repaired. The dilated ureter has been excised (as shown) or can be tapered opposite to the common wall. (*d*) Cross-trigonal reimplantation completed beneath the mucosa covering the original base of the ureterocele. (Adapted from Scherz et al.[94])

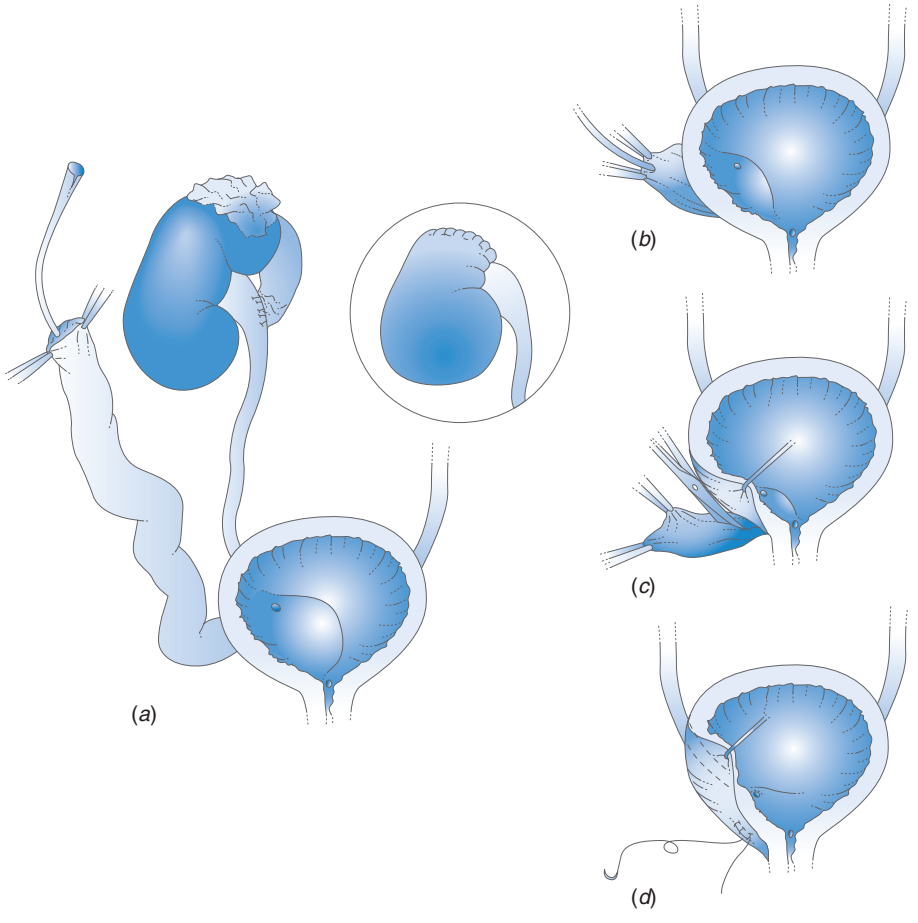

Figure 40.58 (*a*) Technique of extravesical ureterocele excision can be used after either upper pole heminephrectomy or ureteroureterostomy. The remainder of the upper pole ureter is cannulated and approached through the lower incision. (*b* and *c*) Extravesical dissection can be completed and the detrusor defect repaired. (*d*) Both ureters can be detached to allow for easy separation of their common wall and the lower pole ureter reimplanted using a Lich-type repair after repairing the detrusor defect.

an upper pole ureter can also be successfully performed. The extravesical approach may lessen the chances of developing post-management bladder dysfunction, especially in children with unilateral variants.[111] Although in some ways less invasive, this technique cannot address the suburethral extensions found with some ureteroceles and may not provide a solution to contralateral or ipsilateral lower pole reflux caused by the anomaly.

Laparoscopy

Heminephrectomies, nephrectomies, and ureterectomies can be carried out laparoscopically.[112–114] Laparoscopy also provides another option in locating ectopic ureters associated with small dysplastic kidneys that cannot be identified diagnostically.[115] Reports of increasingly larger groups of children cite results comparable to conventional open surgery with decreased morbidity.[116] Early in any experience, prolonged lengths of surgery are a concession to the learning curves required of the techniques. Nevertheless, the role for laparoscopy in the management of duplication anomalies as well other urologic anomalies will continue to expand.

Postoperative concerns

An ultrasound examination or functional study is obtained 6 weeks after surgery, depending on the procedure used to address the anomaly. The status of salvaged upper pole kidneys or remaining lower pole moieties and the effects of surgery on the bladder are assessed. Voiding studies are performed 3–6 months after bladder construction to document the adequacy of the repair. Prophylactic antibiotics are continued in the interim. Children with complex urologic his-

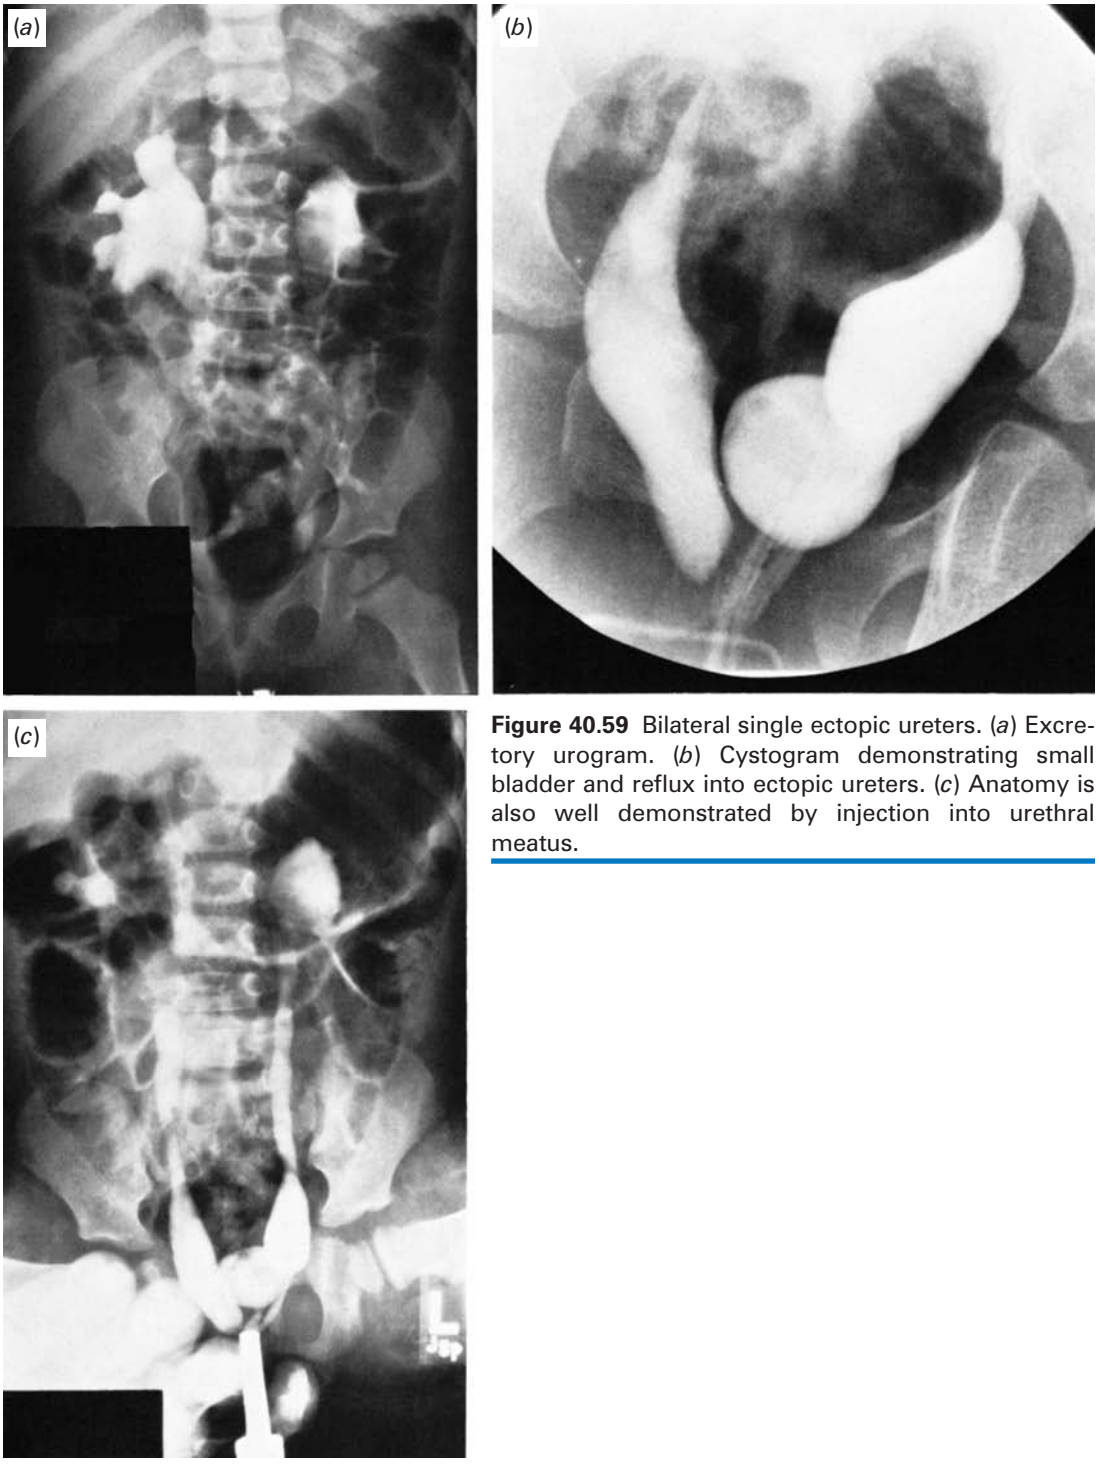

Figure 40.59 Bilateral single ectopic ureters. (*a*) Excretory urogram. (*b*) Cystogram demonstrating small bladder and reflux into ectopic ureters. (*c*) Anatomy is also well demonstrated by injection into urethral meatus.

tories require periodic follow-up. The need for prolonged serial radiographs depends on the remaining urinary configuration. In cases where the anomaly is presumably corrected, a sonogram 2 and 5 years later is probably adequate. Primary physicians complete periodic checks of the urine, blood pressure, and interval somatic growth. Patients who remain at risk, because of persistent reflux for example, require more frequent evaluation and, if necessary, secondary surgery.

Ureteroceles are particularly challenging in this regard. The length of an adequate trial of medical management for VUR that persists after an upper tract approach or selective incision has not been defined. Although spontaneous resolution of reflux associated with a ureterocele occasionally occurs, it

appears to do so at rates significantly lower than those seen with primary reflux. Most bladders are large enough to reconstruct as the child approaches the first birthday. Although it would seem preferable to address ureteroceles before the onset of toilet training, there may be no optimal age for surgery. In one series, bladder dysfunction appeared in 22 of 33 (67%) of patients whose ectopic ureteroceles were excised and bladders repaired at a mean of 10 months of age. Infrequent voiding, large capacities, and significant postvoid residuals were commonplace. The appearance of voiding dysfunction had no correlation with ureterocele size or location,[117] although children with bilateral ectopic ureteroceles may be particularly prone in this regard.[118] Whether these findings are surgically acquired or an inherent component of the anomaly is unclear. Similar rates of dysfunction in patients treated with upper tract surgery alone suggest a congenital component.[119] Regardless, the observation is an important one and may account for the lower rates of success with ureteral reimplantation in these children, when compared with ureteroneocystostomy for primary reflux. Bladder dysfunction should be considered as a contributing factor in any child who continues to have reflux after ureterocele surgery. Urodynamic testing and an assessment of bladder emptying should be obtained before considering any additional surgery.

Related conditions

Bilateral single ectopic ureters

Bilateral single-system ectopic ureters are far more common in girls, who present with significant urologic problems as a consequence. The trigone and bladder neck are wide and poorly defined because of the aberrant insertions of the ureters. These usually drain into the distal urethra, although genital ectopy has also been described. Incompetence of the outlet results, causing a presentation very similar to that in patients with epispadias. In addition, the bladder is typically small and the detrusor thin-walled, in theory because it has never been required to store urine during development (Figure 40.59). Renal dysplasia or varying degrees of hydronephrosis are usually present. Reimplantation alone does not correct these glaring urodynamic abnormalities in most patients,[41] although there have been exceptions.[120] Augmentation cystoplasty is often

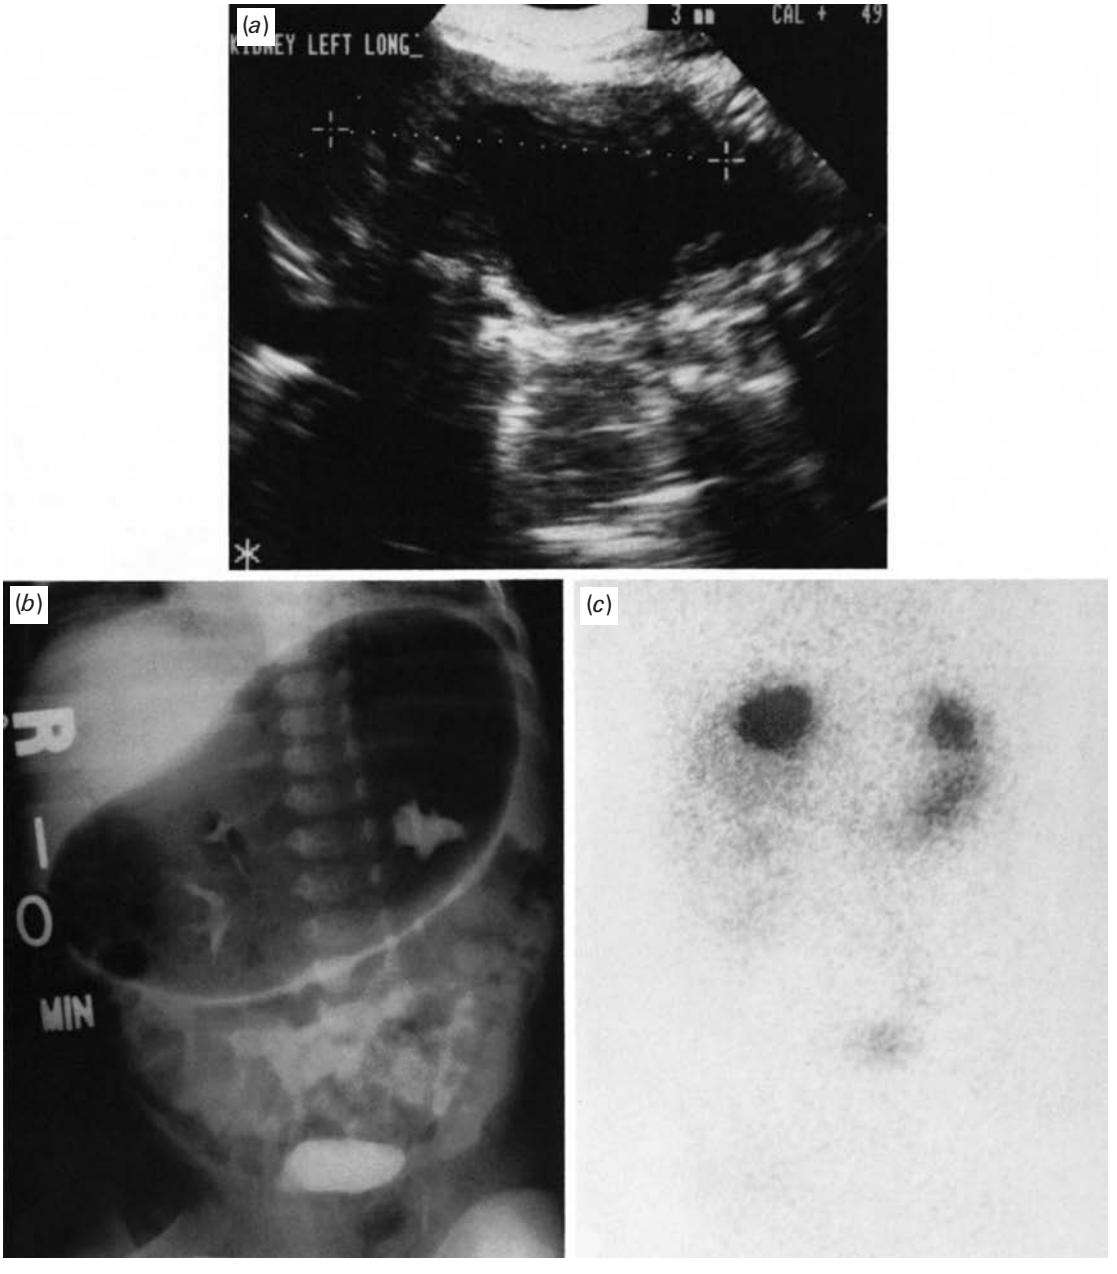

Figure 40.62 Lower pole ureteropelvic junction obstruction diagnosed prenatally. (*a*) Renal sonogram demonstrates lower pole hydronephrosis with better-developed renal parenchyma in the upper pole. (*b*) Excretory urography shows opacification of the upper pole structures on the left displaced superiorly and laterally. (*c*) Radioisotope scan demonstrates reduced but salvageable function in the left lower pole.

required and bladder neck reconstruction becomes necessary to increase outlet resistance. Boys are also occasionally affected by bilateral single-system ectopia, which insert into the prostatic urethra. Bladder dynamics are more favorable, presumably because the better-developed external sphincter helps to retain the urine necessary to stimulate bladder capacity.[121]

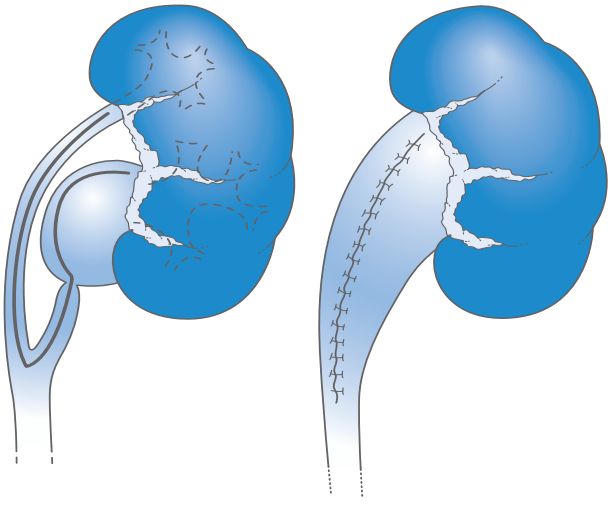

Figure 40.63 Surgical treatment of the lower pole ureteropelvic junction obstruction in duplication. Joining two systems as shown brings less risk than attempting an isolated dismembered pyeloplasty of the lower system.

Ureteral triplication

Triplication of the ureter is one of the rarest anomalies in the urinary tract.[122] The individual takeoff of three ureteral buds from the wolffian duct or the presence of two buds with early fission of one of the two accounts for the variants of complete or partial triplications that have been described. The most common is a trifid configuration, with all three ureters uniting and draining through a single orifice (Figure 40.60). Triplicate ureters are more common in females and occur more often on the left side. Common presentations include UTI and/or signs of ureteral obstruction. Ureteral triplications can be associated with ureteroceles, ectopia, and renal fusion anomalies.[123–125] The principles in management are similar to those of duplication anomalies.

Figure 40.64 (*a*) 'Yo-yo reflux' in a 2-year-old female may contribute to the mild dilatation of the two branches of the incomplete duplication shown. (*b*) An unusual duplication variant in a 4-year-old boy with lower pole ureter ending as a saccular dilatation beneath the normal kidney. Although both children are possibly at risk from to-and-fro peristalsis, both are being followed expectantly and have done well.

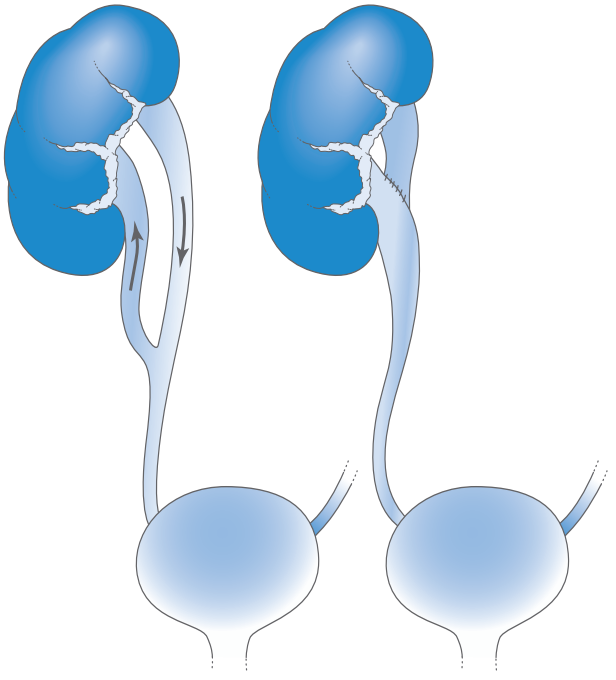

Figure 40.65 A high ureteropyelostomy with elimination of one limb of the yo-yo is occasionally required to treat ureteroureteral reflux.

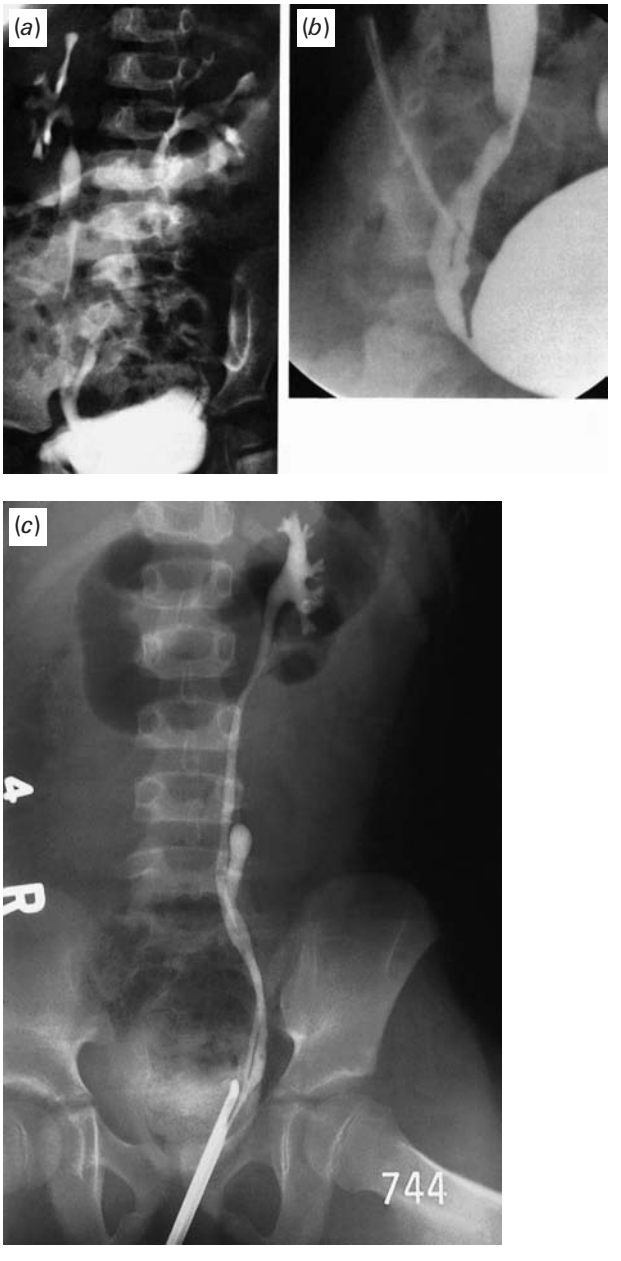

Figure 40.66 Blind-ending bifid ureter. (*a*) Excretory urogram outlines blind-ending bifid ureter on the right side. (*b*) Voiding cystourethrogram shows reflux and bifurcation. (*c*) Retrograde study of similar abortive duplication whose orifice was seen at preoperative cystoscopy. When encountered unexpectedly, these can be safely reimplanted using a common sheath technique.

Lower pole ureteropelvic junction obstruction

Proximal ureteral obstructions occasionally involve duplicated ureters at the ureteropelvic junction.[126] These almost always affect the lower renal pole. Because of their similarity, most problems that affect the ureters of single-system kidneys can affect the lower pole ureters of duplications. The configuration and size of upper pole ureters more closely mimic that of a calyx, making them much less prone to obstruction (Figure 40.61). Ultrasonography demonstrates lower pole hydronephrosis in the absence of ureteral dilatation. Renal scintigraphy is used to assess function and document obstruction (Figure 40.62). When the lower pole is salvageable, its pelvis is anastomosed to the adjacent upper pole ureter (pyeloureterostomy) (Figure 40.63). The remainder of the ureter is ligated above the bifurcation and discarded.

Yo-yo reflux

The phenomenon of yo-yo reflux remains poorly defined and its clinical implications are unclear. Ureteral dilatation of bifurcated ureters was noted in 41% of cases in one series.[127] This raised the question of disordered peristalsis causing partial ureteral obstruction. In theory, antegrade peristalsis that begins in one ureteral limb initiates a reverse peristalsis in the other once it reaches the junction.[128] High-grade obstruction is rare and an increased tendency to infections seems unlikely in most cases (Figure

40.64). In addition, despite altered to-and-fro peristalsis at its junction, the overall direction of urinary flow is still antegrade. In the rare patient in whom a clinically significant yo-yo is suspected, a high ureteroureterostomy is recommended, discarding as much abnormal ureter as possible[129] (Figure 40.65). The preferred option for low-confluence bifurcations is to excise the shared segment and complete a common sheath ureteral reimplantation.

Remnant ureters

A blind-ending branch of a bifid ureter is occasionally found in a child, although they are more often discovered in adults. These occur more commonly in females and on the right side. Most are associated with low-confluence bifurcations that are prone to reflux, although the anomaly can also occur with complete duplications[130,131] (Figure 40.66). Proximally, the ureter ends blindly or may be associated with a small segment of poorly functioning kidney. For larger segments, excision is occasionally warranted. Otherwise, surgery is not indicated unless recurrent infections become problematic, in which case a common sheath reimplantation is recommended. In occasional cases, an unsuspected duplication is discovered at cystoscopy or even during ureteral reimplantation. The ureter can be cannulated and a retrograde ureteropyelogram obtained. In nearly every case, the surgeon should still proceed with reimplantation unless the segment is short and easily excised. Complications from retained renal parenchyma associated with remnant ureters have yet to be described.

Laparoscopic management of duplication anomalies

41

Alberto Lais and Craig A Peters

Introduction

The recent development of laparoscopic techniques applicable to children has presented the opportunity of managing complex renal duplication anomalies using less invasive methods, without compromising surgical efficacy and safety. This chapter reviews the specific laparoscopic methods appropriate to the management of congenital duplication anomalies. Familiarity with the anatomic and functional implications of these anomalies, as well as of their appropriate evaluation, is presumed.

The indications for laparoscopic correction of various duplication anomalies are the same as for open surgery. The principal determinants of the need for surgery as well as the nature of the surgery needed are the status of the affected renal moiety and of the contralateral kidney, and the presence or absence of reflux, obstruction, or incontinence. The options are upper or lower pole heminephrectomy, vesicoureteral reimplant, pyeloureterostomy, and ureteroureterostomy.

Laparoscopic operations in duplicated anomalies

In the setting of duplication anomalies, the most common operation performed is partial nephrectomy, predominantly of the upper pole. The usual indication to perform an upper pole heminephrectomy is an upper pole with minimal or no demonstrable function, typically with a dilated corresponding ureter from distal obstruction, as in an ectopic ureter or ureterocele (UC) or incontinence from an ectopic ureter. In some ectopic ureters with incontinence, there is minimal to no dilation in the affected dysplastic upper pole. Laparoscopy provides excellent exposure to the hilum and this particular operation is carried out more efficiently in laparoscopy than in open surgery.[1]

The approach may be transperitoneal or retroperitoneal. The transperitoneal approach offers a wider operative field and is preferred for nephroureterectomy or when there is need for concomitant abdominal surgery (orchiopexy, reimplant); otherwise, the retroperitoneal approach is preferred. This may be in the prone or lateral position.[2,3]

The instruments required are 5 mm and 3.5 mm cameras, scissors with cautery, a curved fine grasping/dissection instrument, a large grasping instrument for retraction, a clip applier (5 mm), an irrigating/aspirating device, an harmonic scalpel, or a hook cautery. We have used 2 mm instruments, but now feel these do not provide adequate control.[4]

In the prone retroperitoneal approach, the patient is prone and the first incision is at the costovertebral angle (Figure 41.1). Blunt dissection is carried out until Gerota's fascia is exposed and entered. The retroperitoneal working space is developed using a balloon filled with saline. The balloon is created from a finger of a surgical glove tied to a silastic catheter. Developing the retroperitoneal space is accomplished with volumes from 90 ml in an infant to 150 ml in a school-age child. After removal of the balloon, the first trocar is placed, secured, and insufflated to about 12 mmHg. The surgeon is positioned at the ipsilateral side of the patient (affected kidney) or at the feet of the patient in smaller children. Secondary ports are placed under direct vision above the iliac crest lateral to the sacrospinalis muscle and at the posterior axillary line (see Figure 41.1).[4] The prone approach (preferred by the authors) offers excellent exposure of the hilum (Figure 41.2).

The lateral retroperitoneal approach (Figure 41.3) provides easier access to the distal ureter. However, it

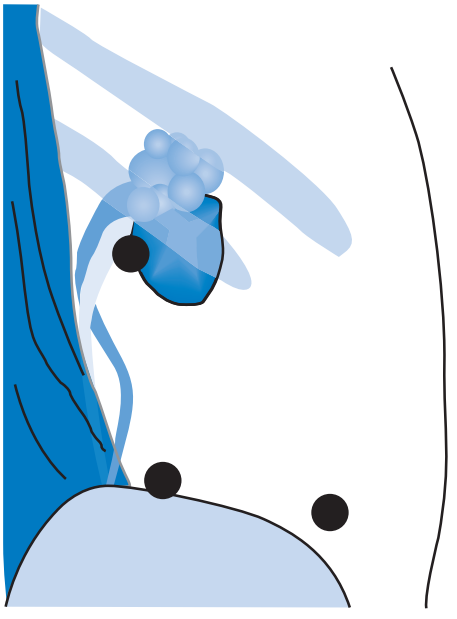

Figure 41.1 Port placement for prone retroperitoneal partial nephrectomy. The camera is usually placed in the port at the costovertebral angle.

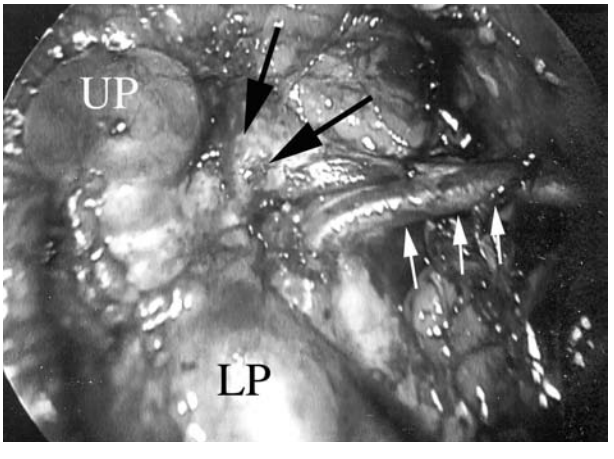

Figure 41.2 Exposure of the hilum afforded by the prone retroperitoneal approach permits efficient access to the renal vessels. The renal artery is marked by the white arrows and the upper pole pelvis by the black arrows. UP, upper pole; LP, lower pole.

requires extensive mobilization of the peritoneum and retraction of the kidney for optimal exposure of the hilum.[5] The patient is positioned in the flank position and the first incision is made at the lower border of the 12th rib. The working space is developed similarly to the prone approach and accessory ports are placed 1 finger width from the top of the iliac crest and posteriorly in front of the lumbosacral muscle. Alternatively, they can be placed in a similar fashion to the prone approach.[6,7]

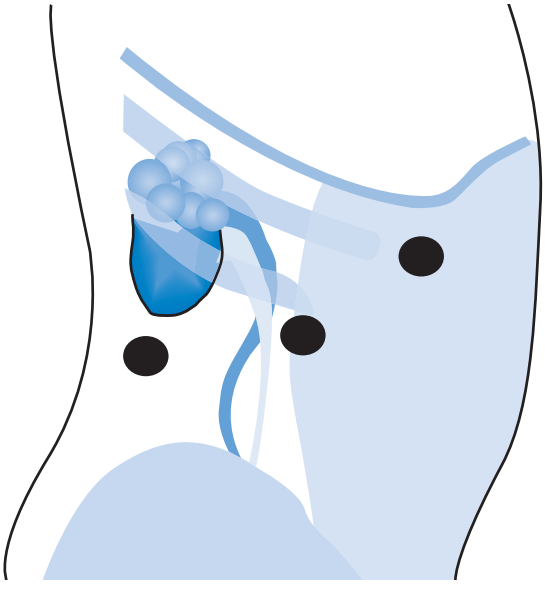

Figure 41.3 Port placement for the lateral retroperitoneal approach to the kidney.

In the transperitoneal approach the patient is supine and the first trocar is placed at the umbilicus with open technique and secured in place. Two additional ports are placed under direct vision on the midclavicular line in the upper and lower quadrant (Figure 41.4). A fourth port for liver retraction may be placed at this time for a right-sided operation. The table is then rotated so that the patient is in an oblique position, which allows the bowel to fall out of the operative field. Access to the retroperitoneum and kidney begins with mobilization of the right or left colon.[8]

Once access to the retroperitoneal space is obtained, the lower pole of the kidney is identified and mobilized until the two ureters can be identified. It is preferable to gain control of the hilum as soon as it may be adequately visualized. In the prone position the kidney tends to fall laterally and anteriorly, exposing the vascular pedicle. The appropriate polar vessels are identified and clipped individually using a 5 mm clip applier. With the patient prone, the artery comes first in view and is taken first (see Figure 41.2). Two clips are used on the proximal side and one on the distal end. Subsequently, the corresponding ureter is mobilized, transected just below the lower pole, and used as a handle to facilitate isolation of the corresponding pole. Occasionally, mobilization of the ureter is required prior to obtaining complete visualization and control of the vessels. Transection of the renal parenchyma is then carried out with the har-

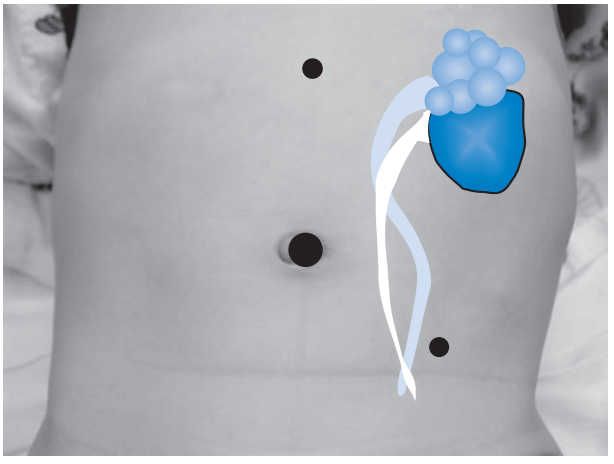

Figure 41.4 Port placement for the transperitoneal approach to the kidney, which provides excellent access to the distal ureter when this must be resected.

monic scalpel or with the bipolar cautery.[9] The remainder of the ureter is then dissected away from the remaining ureter, with care taken to avoid devascularizing it, which is best done by staying very close to the ureter being removed. The distal ureteral stump should be suture-ligated when reflux is present. In the ectopic ureter with both obstruction and reflux, usually those entering the bladder neck, the entire ureter should be removed and the defect closed with sutures. The specimen is removed from the largest port incision. Large cysts in dysplastic upper poles may need to be aspirated before the specimen can be removed.

The typical indication for lower pole heminephrectomy in duplicated anomalies is a severely compromised lower pole as a result of high-grade vesicoureteral reflux (VUR). The procedure can be undertaken, transperitoneal or retroperitoneal, and prone or lateral, in a similar fashion to an upper pole partial nephrectomy. It is best to expose the entire hilum first in order to positively identify the lower pole vessels. In lower pole partial nephrectomy, the plane between the upper and lower pole pelves is not as distinct and may be difficult to develop. Also, the calices of the dilated lower pole often protrude into the upper pole and may be entered during separation of the two moieties. All remnants of the calices and parenchyma must be removed in order to prevent formation of a urinoma (Figure 41.5). If the upper pole collecting system is inadvertently entered, suture closure is recommended as well as drainage.[1] Removal of the lower pole through the initial incision may require morcellation.

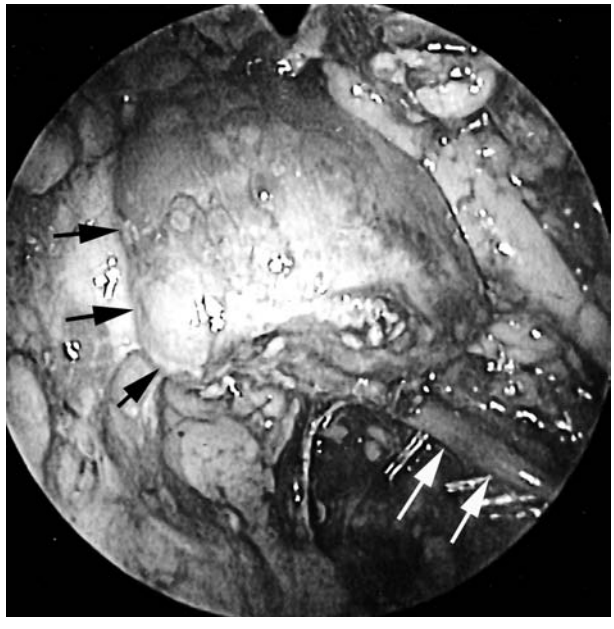

Figure 41.5 Appearance of the remnant upper pole of a left kidney following lower pole nephrectomy. The lateral edge of the upper pole is marked by the dark arrows and the upper pole ureter is marked by the white arrows.

Results of laparoscopic partial nephrectomy

Table 41.1 shows the results of several series of pediatric laparoscopic partial nephrectomy. In general, the operative times are acceptable and the conversion rate to open surgery is low. In comparative studies of transperitoneal and retroperitoneal approaches, there is minimal difference in times or outcomes. In a study from this institution with age-matched open surgical controls, operative times were identical at 3.2 hours, hospital stay was significantly reduced (1.7 vs 4.7 days ($p = 0.001$), and analgesic requirements were significantly less in the retroperitoneal partial nephrectomy group. Even in the infant, laparoscopic approaches for complex renal surgery are both safe and efficient, perhaps even more so than open surgery.

Complications

Possible complications of laparoscopic partial nephrectomy include bowel, liver, and spleen injuries, abdominal wall vessel injuries, and vascular injuries.[16] On the right side, the duodenum can be injured while exposing the upper pole. It is important to recognize that what looks like the renal vein may in fact be the

Table 41.1 Summary data for laparoscopic partial nephrectomy in children, with conversion rates to open surgery

First author	Year	No. of patients	Operative time (hours)	Length of stay (days)	Conversion rate	Conversion rate (% of total)	Comment

vena cava if proper orientation of the camera is lost. It is important to briefly reorient oneself prior to any definitive clip placement. Arterial injuries require prompt control of bleeding and repair. Conversion to open surgery may be necessary, depending upon the severity of the injury and the experience of the surgeon. Although there is less need to manipulate the remnant pole during a laparoscopic partial nephrectomy, the possibility of arterial spasm in the remnant pole must be recognized and anticipated. This is more likely in infants, but can occur at any age. Any tension on the remnant pole vessels should be released and a syringe of papaverine prepared. If the affected pole does not 'pink-up', 0.5 ml of papaverine should be forcefully squirted at the affected artery. If no effect is seen, a second bolus of 0.5 ml should then be instilled. Alternatively, lidocaine (without epinephrine) may be useful to correct the vasospasm.

Postoperative complications have been limited to urinoma formation, although none have been clinically significant. Simple aspiration is usually associated with rapid recurrence. If there is concern about a remnant pole leak, a double-J stent may be placed for several weeks. We have not seen any long-term problems with these and have usually simply observed them without untoward outcomes.

Ureteral surgery associated with duplication anomalies

Laparoscopic vesicoureteral reimplant has limited indications in duplication anomalies. Isolated VUR of the lower pole is best managed by ureteroureterostomy. If the upper pole is also refluxing, typically as a result of previous incision of a UC, a common sheath reimplant is appropriate. An isolated lower pole reimplant is considered when the upper moiety had been previously removed.

In unilateral cases, simple or common sheath reimplant can be accomplished laparoscopically with a Lich–Gregoire extravesical reimplantation.[17–19] The patient is positioned supine, and ports are placed at the umbilicus and symmetrically in the midclavicular lines, 2–3 cm below the umbilicus. The ureter is exposed by incising the peritoneum and a detrusor incision of 2.5–3 cm is made with the hook cautery. A hitch stitch is placed to hold the bladder upwards to aid exposure. The muscle is then brought around the ureter with interrupted sutures. No ureteral stenting is required. In bilateral cases, a laparoscopic intravesical approach has been described by Olsen et al.[20] Laparoscopic ureterocele excision has also been described, including extravesical reimplantation of the remnant ureter.

Associated lower pole ureteropelvic junction (UPJ) obstruction is best treated by creating a wide anastomosis between the lower pole pelvis and the upper pole ureter (pyeloureterostomy). On occasion, however, an isolated lower pole dismembered pyeloplasty can be considered. This is one of the most challenging laparoscopic procedures in pediatric urology, and can be performed transperitoneally or retroperitoneally.[21–23] Ports are placed as in a transabdominal partial nephrectomy, but the retroperitoneal space can be exposed through a transmesenteric incision. The operation is carried out as an open dismembered pyeloplasty, with resection of the stenotic segment, spatulation of the ureter, and reanastomosis. A double-J internal stent is left in the repaired ureter. This operation requires significant skill in laparoscopic suturing and knot tying. For this reason, it can

be more efficiently accomplished by those without the requisite experience by using the da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, CA).[24–26]

Robotic laparoscopy for duplication anomalies

The use of robotics potentially expands the number of laparoscopic cases, enabling surgeons with limited laparoscopic experience to perform complex laparoscopic reconstructions requiring extended suturing skills. Of the different available devices, the da Vinci robotic surgical system seems the more appropriate to pediatric urologic needs. It is composed of three main parts: the robotic unit, with three (or four) robotic arms that hold camera and instruments; the video–insufflation–light source unit, as in conventional laparoscopy; and the remote console from where the surgeon controls the robotic arms.[25] It is equipped with a double camera that facilitates an optimal three-dimensional view. The instruments presently available are 8 and 5 mm in diameter, the larger ones permitting the greatest maneuverability.[27] Whereas robotic laparoscopy presents enormous advantages in terms of visual and fine suturing capabilities, accuracy, and speed of surgery over freehand laparoscopy, it also carries the limitation that once the robot is engaged no further adjustment to patient position is possible without disengaging the robot. Therefore, care must be taken in terms of patient preparation and positioning, set-up, and port placement. A dedicated nursing team is advisable and all members should have had laboratory training on the system.

Extravesical ureteral reimplants, pyeloplasties, and partial nephrectomies have been performed robotically.[25] In pyeloplasties and partial nephrectomies, the approach is currently transperitoneal, whereas retroperitoneal approaches are being investigated.

To perform a ureteral reimplant, the robot is brought in from the feet of the patient and a 30° upangled camera is used. For renal surgery, the robot is brought in from the side and angled from the shoulder, with care being taken to engage it perpendicular to the major longitudinal axis of the kidney. An important point in all robotic laparoscopic procedures is that once the robot is engaged, any adjustment of robot position requires disengaging the system. While the surgeon sits at the console, the assistant will remain scrubbed at the patient's side, taking care of instrument changes. With the da Vinci robot, current instruments include a hook cautery, scissors, DeBakey forceps, larger grasping forceps, and two sizes of needle holder. These instruments are integrated with conventional laparoscopic clip appliers, irrigation/aspiration devices, scissors, and graspers. Dissection is carried out mostly with the hook cautery, as is the parenchymal resection in a partial nephrectomy. Vessels are clipped with a traditional clip applier maneuvered by the assistant. The operations are carried out as previously described. Operation times are usually reduced, compared with conventional freehand laparoscopy, although overall time may be equal due to the set-up time required with the robot. With the use of the da Vinci robotic surgical system, laparoscopic nephrectomies, partial nephrectomies, pyeloplasties, and reimplants may become accessible to a larger number of surgeons with limited experience in conventional laparoscopy.

Vesicoureteral reflux: anatomic and functional basis of etiology

42

John M Park

Vesicoureteral reflux (VUR), a retrograde flow of bladder urine into the upper urinary tract, is one of the most commonly encountered pediatric urologic anomalies. It occurs normally in many animal species but is generally considered abnormal in humans. Traditionally, VUR has been categorized etiologically into primary and secondary. Primary VUR is thought to represent an abnormal anatomy and function of the ureterovesical junction (UVJ), whereas secondary VUR implies an acquired condition as a result of increased intravesical pressure in the setting of neurogenic bladder dysfunction, non-neurogenic bladder dysfunction, or outlet obstruction. The clinical association of VUR and urinary tract infection (UTI) that leads to pyelonephritis, renal scarring, hypertension, and chronic renal insufficiency (reflux nephropathy) has been the primary impetus for diagnostic and therapeutic interventions for VUR during the last three decades. However, various clinical and experimental studies seeking to establish a causal relationship between the pathophysiologic components of VUR, UTI, and other clinical sequelae have led to many contentious debates rather than a unifying consensus. In fact, most pediatric urologists and nephrologists now consider VUR not as a disease in and of itself but rather as a marker of heterogeneous condition of the whole urinary tract. It includes congenital renal hypoplasia and dysplasia (in addition to acquired pyelonephritic renal damage), primary reflux caused by incompetent UVJ, altered lower urinary tract function, and inherent predisposition to UTI. In this chapter, the etiologic components of VUR – both anatomic and functional – are discussed to establish the conceptual framework within which clinical management issues are presented in the subsequent chapters.

Historical perspective

Galen and Leonardo da Vinci were the first to propose that normal UVJ allowed unidirectional flow of urine into the bladder and that VUR might be abnormal in humans.[1,2] In 1893, Pozzi reported that VUR could occur in humans after noting an unexpected urine leakage from the accidentally severed ureter during a pelvic gynecologic procedure.[3] The systematic identification of VUR came as the result of technologic advances in contrast radiography – voiding cystourethrography (VCUG). Initially, VUR was not thought to be a significant clinical problem for humans, although Bumpus speculated in 1924 that VUR was related to UTI and that in children, unlike adults, VUR was not associated with other urinary tract pathology.[4] In 1930, Campbell found VUR in 12% of over 700 VCUGs but assumed that there was other underlying pathology as the cause of VUR.[5] In 1944, Prather proposed that VUR was abnormal in children,[6] and this notion gained increasing acceptance, after accumulating evidence suggested that VUR was typically absent in normal neonates and children. The modern era of clinical VUR management was ushered in by Hutch's observation that VUR and pyelonephritis might be causally related in paraplegic patients.[7] Hodson, applying Hutch's concept to children, noted that VUR was more common in children with UTI and renal parenchymal abnormality.[8,9] Other clinical and experimental observations soon followed, providing the anatomic and functional basis for the UVJ mechanism and the etiology of VUR.

Anatomic features of ureterovesical junction

The UVJ is anatomically and functionally adapted to allow intermittent passage of a urinary bolus from the ureter into the bladder, while preventing the retrograde flow of bladder urine back toward the kidney during storage and micturition. To achieve these functions, the ureter enters the bladder wall with an oblique intramural path (intramural ureter) and

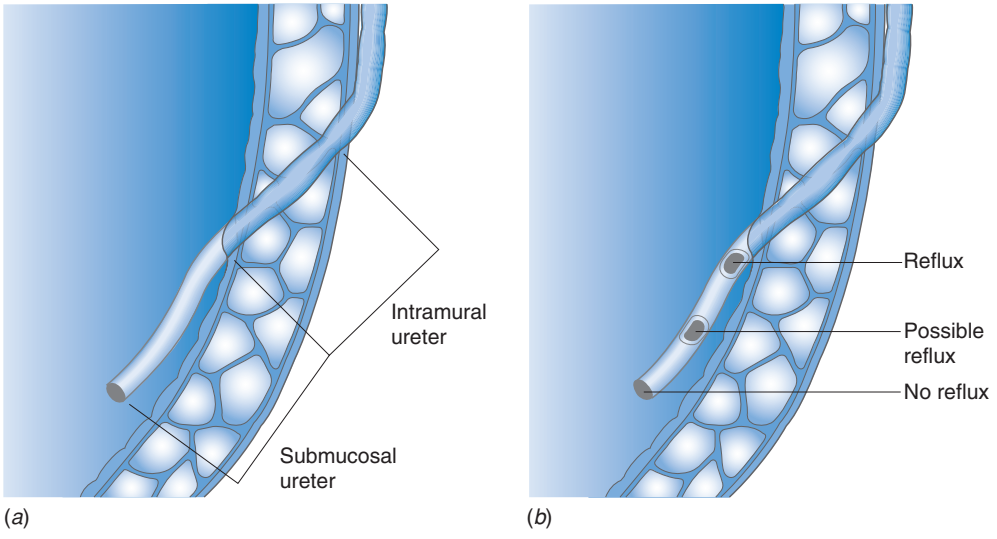

Figure 42.1 (*a*) Normal ureterovesical junction (UVJ): demonstration of the intravesical ureter (intramural + submucosal). (*b*) Refluxing UVJ: unlike a non-refluxing orifice, there is an inadequate length of the intravesical ureter, compromising the 'flap-valve' mechanism. (Modified from Politano,[10] with permission.)

extends through a submucosal tunnel of appropriate length (submucosal ureter) to open onto the trigone in a correct location. This 'flap-valve' configuration causes the intramural and submucosal ureter to be compressed with progressive bladder filling against the detrusor muscle backing, as if one were stepping on compressible straw on the ground (Figure 42.1).

The UVJ mechanism, however, is not entirely passive. It is also active, requiring a functional integration with bladder and trigone. The functional components of the UVJ were first appreciated in 1812 when Bell noted that extension of the ureteral longitudinal muscle fibers into the trigone (Bell's muscle) was important in the preservation of intramural ureter obliquity.[11] Tanagho and Pugh provided an anatomic description of the ureteral muscle fiber extension intravesically.[12] The inner longitudinal ureteral fibers form the superficial trigone, down to the level of verumontanum in males and the dorsal surface of the urethra in females. At the trigone, the muscle fibers extend fanwise, and at the midline of the trigone, they intermingle with those of the contralateral ureter. The middle circular ureteral muscle is not seen beyond the level of the ureteral hiatus. The adventitia of the distal ureter just outside the bladder wall fuses with the fibromuscular sheath that encircles the ureter (known as Waldeyer's sheath). Waldeyer's sheath is thought to anchor the ureter within the hiatus while allowing the intramural ureter to slide freely within the hiatus during bladder filling and emptying (Figure 42.2). In 1972 Elbadawi[14] (later

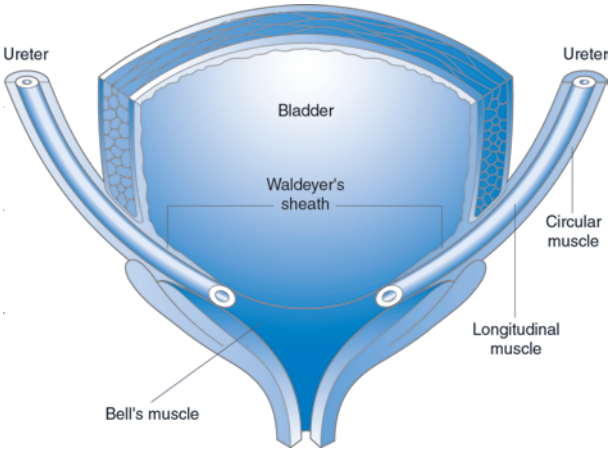

Figure 42.2 Passage of the distal ureter through the ureteral hiatus in the bladder wall. Ureteral inner longitudinal muscle fibers extend into the trigone to form the Bell's muscle. The Waldeyer's sheath anchors the distal ureter at the hiatus. (Modified from Mathisen,[13] with permission.)

confirmed by Stephens[15]) identified a separate intermediate layer extending from the ureter into the deep trigone.

Immunohistochemical studies using antibodies that differentiate the ureteral and bladder embryologic origins have also confirmed these ureteral muscle extensions into the deep trigone, richly innervated by noradrenergic receptors, similar to vas deferens.[16] This intermediate layer may be important in the overall development of ureter and trigone. The ureteral

maldevelopment may be tied together with an abnormal trigonal development, which derives from the common nephric duct (the segment of mesonephric duct distal to the origin of ureteric bud). A recent study of vitamin A signaling-deficient mice demonstrated an abnormal development of trigone, thereby resulting in a high incidence of distal ureteral anomalies.[17]

Despite somewhat conflicting opinions about the precise anatomic details of the ureter–trigone relationship, there is sound physiologic evidence to suggest that a functional integration of ureter and trigone is important in the normal UVJ mechanism. Tanagho et al's series of elegant experiments in dogs defined their roles in preventing VUR.[18] Unilateral sympathectomy at L3–5 uniformly induced reflux. These findings were consistent with earlier observations by Langworthy in 1938, where unilateral sympathectomy in cats induced a unilateral dilated ureter with ipsilateral widening of the ureteric orifice. Additional experiments demonstrated that increasing the trigonal tone and contractility using electrical stimulation, epinephrine injection, bladder distention, and micturition all resulted in functional occlusion of the ureteric orifices. Finally, surgical incision of ureter–trigone continuity below the ureteric orifice resulted in VUR, which then disappeared after healing of the incision.

The anatomic mechanisms of the UVJ can be then summarized as follows. The natural tone of ureteral muscle provides a mild passive closure of the intramural ureter except during the efflux of the urinary bolus. As the bladder fills and becomes distended, there is a progressive obliquity of the intramural and submucosal ureter, creating a 'flap-valve' mechanism, provided that there is a sturdy back-wall support of the detrusor muscle. The tone and contractility of the trigone increases steadily during bladder filling as it becomes stretched, and it provides a secure anchoring of the ureteric orifices, further augmenting the flap-valve mechanism. Micturition also stimulates the trigonal tone, anchoring the ureter and preventing the lateral displacement of the orifice. The critical factor of this flap-valve mechanism is the effective occlusion of the intramural and submucosal ureter as the rising intravesical pressure compresses it against the detrusor muscle. The anatomic and functional integration of ureter and trigone is a remarkable piece of bioengineering that allows an unimpeded unidirectional flow of urine at the UVJ.

In addition to the experimental observations noted above, clinical findings lend further support to the importance of the flap-valve mechanism in preventing VUR. The intravesical ureter (the intramural segment plus the submucosal tunnel) has been estimated to lengthen with age, providing rationale for spontaneous VUR resolution with maturation. In neonates, the average length of the intravesical ureter was 0.5 cm, whereas in adults it was 1.3 cm.[19,20] The mature length was thought to be achieved by 10–12 years of age. In examining other animal species, the variability of VUR incidence was also associated with the length of intravesical ureter. Trigonal competency plays a critical role in maintaining the adequate length and obliquity of the intravesical ureter during bladder distention and micturition. Inadequate trigonal function allows the ureteric orifice to displace laterally and migrate away from the bladder neck during bladder filling, leading to reduction of the intravesical ureteral length.

The lateral displacement of the ureteric orifice and its abnormal appearance in association with VUR are well established (Figure 42.3). The classic explanation proposed by Mackie and Stephens suggests that the lateral displacement may occur as the result of abnormal ureteric bud origin along the developing mesonephric duct.[22] They found a correlation between the lateral displacement of the ureteric orifice and the degree of renal dysplasia and hypoplasia, and postulated that the ectopic origin of the ureteric bud during metanephric development was the primary embryologic error leading to anomalous renal differentiation and an abnormally located ureteric orifice.

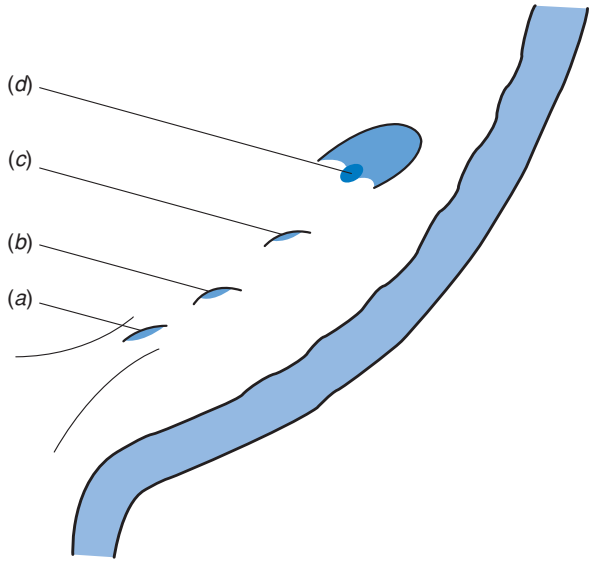

Figure 42.3 Four different ureteric orifice positions: (*a*) normal; (*b*) moderately lateral; (*c*) very lateral; and (*d*) orifice at the mouth of a diverticulum. (Reproduced from Glassberg et al,[21] with permission.)

after presenting with UTI, in which females predominate. Boys tend to present at a younger age, and they tend to have more severe degrees of VUR, especially if diagnosed in infancy.[33] A transient urethral obstruction causing high intravesical pressures has been proposed to explain this phenomenon. Urodynamic studies of infants with VUR suggested that high voiding pressures and small functional capacity are more common in boys.[34]

VUR appears to be an heritable disorder. Identical twins have been observed to have a higher incidence of VUR.[35] It occurs in siblings of affected children at a significantly higher rate than that in the general population. The sibling VUR rate has been estimated to be as high as 40–50%.[36–38] Various studies suggest a dominant inheritance pattern with a variable penetrance. These include an approximately 50% incidence of sibling VUR in the first 2 years of life and a high incidence (about 60%) of parent-to-child transmission.[39] Evidence of genetic heterogeneity has been published, suggesting that different genes act on different families.[40] Furthermore, the incidence of VUR varies among races. Children of Asian and African ancestry have a lower rate of VUR than those of Caucasian genetic background (ratio of 3.4 to 1).[41,42]

Primary versus secondary vesicoureteral reflux

The distinction between primary and secondary VUR is important in the conceptualization of contributing pathophysiology and relevant anatomic/functional etiologies that need to be addressed clinically. In certain cases, the distinction is not entirely clear in that some forms of 'primary' VUR may be associated with bladder anomalies which contribute to the progression of the underlying UVJ malfunction. The clinical reality is that in all patients presenting with VUR, the proper management must include a global view of the entire urinary tract, including UVJ mechanism, bladder dysfunction, predisposition to UTI, and renal anomalies. A short intravesical ureter or a marginally competent ureter–trigone complex may increase the likelihood of VUR in unfavorable conditions such as bladder hypertonicity, high pressure voiding, and UTIs. On the other hand, an extremely competent UVJ may resist VUR even in cases of challenges by an abnormal bladder until there is an irreversible deformation of the UVJ structures.

The concept of 'secondary' VUR is critical in that understanding the dynamic process of reflux will be incomplete without considering the effect of the bladder. In a normal, mature urinary tract, increasing the intravesical pressure alone does not necessarily induce VUR. The clinical association of bladder abnormalities and VUR is well recognized. It is known that VUR can be acquired secondary to bladder anomalies such as neurogenic bladder disorders and various types of bladder outlet obstruction (as in boys with posterior urethral valves). Elevated voiding pressures may have a role in VUR pathophysiology, especially in infants. A higher incidence of high-grade VUR in infant males has been attributed to high voiding pressures caused by transient urethral obstruction, especially when intravesical ureteral tunnels are not fully mature. The chronic elevation of bladder storage pressure and the subsequent distortion of the bladder wall at the UVJ (such as paraureteral diverticulum) may be critical in the formation of secondary VUR. The structural and neurologic perturbation of the trigone in the abnormal bladder is likely to be important as well.

The most common anatomic cause of secondary VUR is seen in boys with posterior urethral valves, which are associated with VUR in over 50% of patients.[43] Anatomic obstructions causing VUR in girls are rare and may occur in the setting of an obstructing ureterocele. Any child with an altered bladder function is at risk for secondary VUR. A poorly compliant bladder, along with its abnormal interaction with dyssynergic urinary sphincters, can lead to increased intravesical pressures, which then weakens and alters the UVJ to cause VUR. A strong correlation was established by McGuire that if the bladder pressures exceed 40 cmH_2O, the incidence of VUR is seen in over 80% of patients with myelodysplasia and neurogenic bladders.[44,45]

Role of urinary tract infection in vesicoureteral reflux

Tanagho and colleagues proposed that lower urinary tract inflammation might affect the mildly deficient UVJ and induce VUR.[18] New VUR was reportedly acquired in 6 out of 7 experimental piglets after *Escherichia coli* infection and bladder inflammation.[46] Some *E. coli* strains have been implicated as affecting the activity of urinary tract smooth muscle directly, rather than via an inflammatory reaction. Bacterial endotoxin was found to inhibit α-adrenergic receptors of trigonal musculature in cats.[47] Similarly, UTI may cause human ureteral dilatation.[48,49] Such a

This view is most plausible when applied to duplex system anomalies but may also be pertinent to the congenital renal anomalies associated with VUR. An alternative embryologic view of VUR may be the concept of primary trigonal disorder. The trigone develops as a result of a common nephric duct and the distal ureter incorporation into the developing bladder, and it is reasonable to postulate that the lateral displacement and the abnormal ureteral anchoring may occur as a result of functional disorganization of the trigone during development.[17]

Endoscopic observations confirm the importance of the flap-valve mechanism in preventing VUR. Specifically, the ratio of the submucosal tunnel length to the ureteral diameter appears to be a critical factor that determines the effectiveness of UVJ function.[19,20] Paquin noted that in children without VUR, the ratio of tunnel length to ureteral diameter was 5 to 1, whereas in children with VUR, the ratio was 1.4 to 1.[19] Cussen documented the relationship among intravesical ureteral length, submucosal ureteral length, and ureteral diameters in normal infants and children[20] (Table 42.1). The relative position and shape of the ureteric orifice also seem to correlate with the length of the intravesical ureter. Orifices that are placed laterally, away from the bladder neck, are associated with a higher incidence of VUR and probably reflect poor trigonal anchoring and short intravesical ureteral length. Lyon and colleagues described four basic orifice shapes that reflect the competency of the UVJ anatomy: cone, stadium, horseshoe, and golf-hole.[23] VUR was seen in 4% of patients with a normal cone configuration, 28% in those with a stadium orifice, 83% in those with a horseshoe orifice, and 100% in those with a golf-hole orifice. Heale confirmed Lyon's observations by reporting a higher prevalence and grade of VUR as well as renal scarring in patients with more laterally placed and abnormal ureteric orifices.[24] Stephens described another orifice configuration – the lateral pillar defect – which probably represents a type of ureter–trigone abnormality between horseshoe and golf-hole orifices.[25] Although endoscopic appearances of ureteric orifices are no longer considered particularly reliable clinical indicators of VUR (especially in low- to moderate-grade situations), these observations provide insight into the overall mechanism of competence of the UVJ (Figure 42.4).

Table 42.1 Mean ureteral tunnel lengths and diameters in children

Age (years)	Intravesical ureteral length (mm)	Submucosal ureteral length (mm)	Ureteral diameter (mm)
1–3	7	3	1.4
3–6	7	3	1.7
6–9	9	4	2.0
9–12	12	6	1.9

Demographic features of vesicoureteral reflux

In most cases, VUR is discovered clinically after investigation of either UTI or antenatal hydronephrosis. In children without UTI or any other urologic problems, the true incidence of VUR is difficult to ascertain but may be in the order of 0.4–1.8% of the overall pediatric population.[26,27] In contrast, the incidence of VUR in children with UTI is typically around 30–50%, with an even higher incidence in infants.[28–30] Hydronephrosis is identified antenatally in about 1 of every 500–1200 live births, and VUR is identified in about 25% of these infants undergoing postnatal evaluation.[31,32] Infants with antenatally detected VUR show a male preponderance in contrast to older children who are diagnosed with VUR

direct effect of bacterial infection on ureteral smooth muscle function could conceivably induce ureter–trigonal dysfunction, thereby facilitating VUR. Since UTI is also known to induce bladder hypercontractility and lower compliance, a combined challenge of both ureter and bladder muscle dysfunction by UTI may well cause VUR in patients with marginally competent UVJ.

Clinically, it had been suggested that VCUG performed at the time of ongoing UTI might 'falsely' demonstrate VUR, which was not present when the urine was sterile. Gross and Lebowitz surveyed over 600 children undergoing cystographic evaluation for VUR and found no evidence of increased VUR in the setting of positive urine cultures.[50] In other words, their data did not support the notion that VUR was caused by UTI.

Role of lower urinary tract function in vesicoureteral reflux

In infants and children, abnormal lower urinary tract function often coexists with VUR without any apparent neurogenic or anatomic pathology. These observations suggest a possible role for lower urinary tract function in the pathogenesis of VUR and its implication in the clinical management of VUR.

Infantile bladder has been shown to have a higher voiding pressure. Urodynamic studies have shown that this may be the result of imperfect coordination between detrusor contraction and sphincter relaxation.[51,52] This pattern of immaturity typically disappears after 2 years, and is thought to result from lack of integration between the bladder, the external urethral sphincter, the brainstem, and the higher cortical centers. Compared with normal infants, those with VUR have even higher voiding pressure and abnormal bladder function, even in the absence of UTI.[51] A discoordinated pattern of voiding was the most common urodynamic abnormality in both male and female infants with VUR. Another urodynamic abnormality – abnormally high voiding pressure with small functional bladder capacity or poor bladder contractility with inadequate emptying – was seen primarily in boys. Other clinicians have also noted an increased incidence of bladder 'hypercontractility' in infant boys with VUR.[53] In a fetal sheep model of VUR, defunctionalization of UVJ (surgical unroofing of the submucosal ureter) was insufficient to produce VUR reliably in females, who also required a partial ligation of the urethra in order to reproduce a similar degree of VUR as seen in males with UVJ unroofing only.[54] Such experimental observation, along with VUR-associated urodynamic abnormality analogous to that seen in boys with posterior urethral valves, led to speculation that transient urethral obstruction may be the cause of infantile VUR in some cases.

The abnormal urodynamics seen in infants with VUR may also imply a global maldevelopment of the trigone and proximal urethral mechanism, which need to funnel open in coordination with detrusor contraction in order to induce efficient, low-pressure emptying. Godley and colleagues studied the clinical outcome of infants with VUR in relation to overall renal status and bladder function and found that those infants with abnormal kidneys were more likely to have abnormal bladder function as well as failure of VUR resolution.[55] These observations further support the notion that the entire spectrum of VUR disorder – reflux, renal anomaly, and bladder dysfunction – may result from the primary maldevelopment of the ureter–trigonal complex.[17,22]

Symptoms of pediatric voiding dysfunction – frequency, urgency, and enuresis – are a manifestation of detrusor instability (DI) and/or detrusor–sphincter dyssynergia (DSD), and they are often found in patients with UTI and VUR. A study of over 360 children with dysfunctional voiding found that 60% of children had UTI and 20% had VUR.[56] The European branch of the International Reflux Study found the presence of dysfunctional voiding in 18% of over 300 children with VUR and UTI.[57] Urodynamic investigation showed that detrusor instability may be found in up to 60% of children with VUR.[58,59] Despite these well-documented associations, it is unlikely that VUR is directly initiated by DI in most cases. Many more children have DI than VUR. There are also reports showing no statistical causal association between DI and VUR.[60] However, in patients with marginally competent UVJ, DI may exaggerate the VUR. It is generally accepted that unrecognized DI can delay the resolution of VUR, and there are reports that the treatment of DI with anticholinergics can facilitate VUR resolution.[58,61] Some studies, however, have not shown any beneficial effect of anticholinergic therapy in the elimination of VUR.[62] Although DI may not induce VUR directly, it plays an important role in the overall pathophysiology of the VUR–UTI–nephropathy complex. The presence and severity of dysfunctional voiding symptoms correlated significantly with the persistence of VUR during medical management and further correlated with UTI recurrence regardless of surgical correction

of VUR.[57] In fact, the mutual association of DI and VUR to UTI may explain its clinical coexistence in many clinical scenarios. Whether the combined challenge of UTI and abnormal bladder dynamics leads to the secondary (or acquired) VUR or merely discloses pre-existent primary VUR, it is clear that they are critical cofactors to contend with in the overall management of patients with VUR.

Concluding remarks

Although VUR remains a significant and commonly encountered clinical problem in pediatric urology, it may be a normal transitory phenomenon in many species and in some humans. It is a dynamic process that involves an anatomic and functional anomaly and maldevelopment of the ureter–trigone complex and the UVJ, as well as the effects of UTI and lower urinary tract dysfunction. The clinical significance of VUR must be interpreted in the context of global urinary tract anomalies, including bladder dysfunction, inherent predisposition to UTI, and congenital/acquired reflux nephropathy.

Non-surgical management of vesicoureteral reflux

43

Jack S Elder

In a child with vesicoureteral reflux (VUR), the primary goal of therapy is to prevent pyelonephritis, because repeated upper urinary tract infection (UTI) can lead to renal scarring, hypertension, reduced somatic growth, renal insufficiency, and end-stage renal disease. In addition, reflux-related complications during pregnancy may occur. If a child already has reduced renal function, then additional treatment may be necessary to preserve existing renal function as the child grows.

Non-surgical therapy is based on the principle that reflux often resolves over time, and that sterile reflux is not harmful to the kidneys and has no significant effect on renal function. In addition, the morbidity or complications of reflux can be prevented by preventing infection. In contrast, the principle of surgical therapy is that the complications of reflux and non-surgical therapy can be prevented with surgical correction of reflux. The benefits and risks of these two approaches must be considered when deciding on a course of therapy.

Non-surgical therapy consists of:

1. Antibiotic prophylaxis:
   - daily
   - intermittent (i.e. treatment of UTIs as they are diagnosed).
2. Bladder training.
3. Treatment of voiding dysfunction:
   - anticholinergic
   - α-blocker
   - treatment of constipation
   - biofeedback.
4. Periodic assessment of reflux and child well-being:
   - serial urinalysis/urine culture
   - serial voiding cystourethrogram (VCUG) or radionuclide cystogram
   - serial upper urinary tract studies
   - serial assessment of blood pressure and renal function.

The approach to each child is individualized and takes into account the child's gender, reflux grade, age, presentation (UTI, sibling screening, antenatal diagnosis), renal status at the beginning of therapy, compliance with treatment, likelihood of reflux resolution, as well as parent and child preferences.

Reflux resolution

The decision to choose non-surgical management in a child with reflux is based on the fact that reflux often resolves, and when it resolves, the risk of upper tract infection is less. The reason that reflux resolves spontaneously is uncertain. Presumably it occurs with bladder growth and with bladder functional maturation. Whether the intramural tunnel length increases is unproved.

There are several difficulties in analyzing reported rates of reflux resolution:

1. The reflux grading scale has been modified over time and has increased from three to five different grades.
2. Some series only report ureteral resolution, whereas others only report patient resolution, which is more relevant.
3. Some centers utilize radionuclide cystography for grading rather than contrast VCUG.
4. Some series combine children with single and duplicated collecting systems, although reflux in the latter may be less likely to resolve spontaneously.
5. Reflux may be intermittent, and show resolution, only to reappear if a VCUG is repeated 1 year later.[1]
6. Follow-up among various case series has been variable, and a significant number are lost to follow-up.

The best data on reflux resolution come from the few randomized prospective trials and a few retrospective

Table 43.1 Reflux resolution of children, by grade

Series	No. of patients	Grade I (%)	Grade II (%)	Grade III (%)	Grade IV (%)
Bellinger and Duckett, 1984[10]	269[a]	87	63	53	33
Goldraich and Goldraich, 1992[2]	202	80(I/II)		50(III/IV)	
Huang et al, 1995[11]	214	92	76	62	32

[b] 10-year data: results disparate for unilateral vs bilateral reflux.

case series from centers with a commitment to nonsurgical management.[1–9]

It is impossible to predict whether a specific child will show spontaneous reflux resolution. In the past, cystoscopy was performed at some centers to try to measure ureteral tunnel length, but in most children cystoscopic findings failed to correlate with likelihood of resolution. The exception, however, was that if the ureteral orifice was patulous or hydrodistended significantly, resolution was uncommon.[10]

Reflux resolution is most likely in younger children and those with lower reflux grades (Table 43.1). The American Urological Association (AUA) Vesicoureteral Reflux Practice Guidelines Committee analyzed the raw data from the series published by Skoog et al,[3] Arant,[1] and the International Reflux Study, European Arm[4] to develop the curves in Figure 43.1.[14,15] In their analysis, at 5 years, approximately 92% with grade I and 81% with grade II showed reflux resolution, irrespective of age at presentation or whether the reflux was unilateral or bilateral. In contrast, in grade III, resolution was highest for unilateral grade III reflux in children <2 years (70%) and lowest for children with bilateral grade III reflux >5 years at diagnosis (12.5%). The data for grade III reflux in children >5 years at diagnosis were based on 27 children. In the series by Greenfield et al, for children with grade III reflux, resolution was similar irrespective of age at presentation.[12] In the combined series, unilateral grade IV reflux resolved in 58% at 5 years, whereas only 10% of those with bilateral grade IV reflux resolved. For grade IV reflux, age was not stratified because of small patient numbers.

Beyond 5 years, few data are available. Reflux can resolve during adolescence, but there are no predictable features. For example, in the series by Lenaghan, reflux resolution was reported in 20%, but their patients were not studied systematically.[16] In a long-term follow-up of the International Reflux Study, at 10 years following study entry, in the children randomized to medical therapy, 73% of those with unilateral grade III or IV reflux had resolved.[6] In

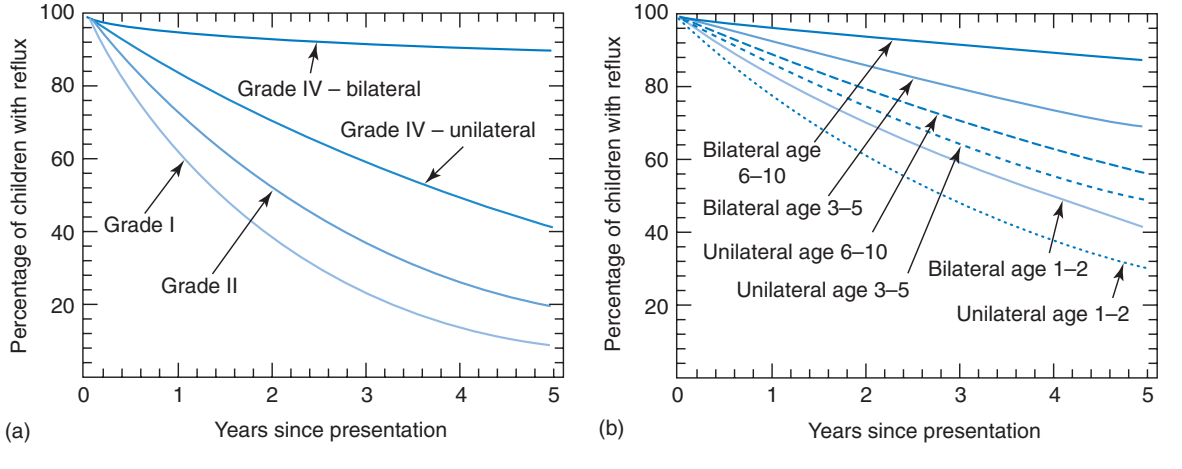

Figure 43.1 Likelihood of spontaneous reflux resolution. The percent chance of reflux persistence for 1–5 years following presentation.[10,12,15] A, grades I, II and IV reflux. B, grade III reflux by patient age at presentation. (Reproduced from Elder.[14])

children with grade III/IV reflux on one side and grade I/II on the other, 49% had resolved, and in those who presented with bilateral grade III/IV reflux, only 39% resolved.

Antibiotic prophylaxis

The cornerstone of UTI prevention is daily antimicrobial prophylaxis. The basis for prophylaxis is that, in the 1960s and 1970s, children with reflux were managed by treating each UTI as it occurred. Lenaghan et al reported that in children with preexisting scars, 66% developed new scars, and in children who had normal kidneys, 21% developed new scars.[16] The average age of boys was 1 year and of girls was 7 years. Most new scars were observed in girls. Lenaghan concluded that intermittent therapy of UTI was associated with an unacceptably high rate of new scar formation in children with reflux. Govan et al reported that 50% of girls with reflux had a UTI during the observation period and 20% had febrile UTI.[17] Scarring was most likely to occur in those with dilating reflux, but 23% with grade I reflux developed new scarring. In a non-randomized study, O'Donnell et al found that 35% of refluxing children followed without prophylaxis developed new scars, compared with 9% who were placed on prophylaxis.[18] From these studies, it was concluded that girls with reflux were more likely to develop renal scars than boys, that scars could occur at any age, children with mild reflux were susceptible to scar formation, and that scarring could occur in normal kidneys.

In contrast, there is a generous body of literature supporting the effectiveness of continuous prophylaxis. In a prospective evaluation of 203 children with all grades of reflux, Goldraich and Goldraich found that only 3% developed new scars, and these were associated with UTI.[2] None of the new scars occurred in children over 4 years. Consequently, they recommended discontinuing prophylaxis after age 5 years. In contrast, in a prospective multicenter trial of children <5 years of age with grades I, II, or III reflux, Arant found that 34% developed a breakthrough UTI and 8% developed new scars.[1] In this series, compliance with the antibiotic regimen was highly variable, ranging from 12% to 75%. Skoog et al retrospectively evalutated 545 children with grades I through IV reflux from 6 months to 10 years on continuous prophylaxis.[3] Overall, only three children (0.5%) developed a new scar and two of the three children had a documented breakthrough UTI.

Although there is general agreement that antibiotic prophylaxis is effective in preventing UTI in children with reflux,[19] the ideal antimicrobial for prophylaxis is uncertain. Typical medications include nitrofurantoin, trimethoprim–sulfamethoxazole, and trimethroprim alone. Generally a dosage that is one-quarter to one-half of the full dose is prescribed and administration at bedtime theoretically yields the optimal benefit. Potential adverse effects of nitrofurantoin suspension include gastric upset, nausea, and a very poor taste to the medication. Use of nitrofurantoin macrocrystals in a capsule can obviate these problems. In young children the capsule may be opened and the macrocrystals can be mixed with food or formula. More serious side effects are rare, with one study documenting only 40 reports out of 8.6 million uses.[20] Trimethoprim–sulfamethoxazole is generally well tolerated, although Uhari et al reported that the medication was changed because of adverse effects in 15% of children receiving sulfonamides and 8% receiving trimethoprim.[21] The most common adverse effect is allergic skin reaction, usually from the sulfa component. This problem may occur following several weeks or months of therapy, but anaphylaxis is rare. Although neutropenia, thrombocytopenia, and/or eosinophilia occur in 12–34% of children receiving full-dose trimethoprim–sulfamethoxazole for only 10 days,[22] the incidence of these side effects in children receiving prophylactic dosages for as long as 1 year is quite low.[23] Photosensitivity is another concern with sulfa-based antimicrobials. Another potential problem is dental caries secondary to the fructose in the liquid preparation, but this problem can be prevented by having the children brush their teeth after taking the drug. The most serious potential side effect is Stevens–Johnson syndrome, but this reaction is extremely rare.

In babies up to 2 months of age, amoxicillin or cephalexin (50–75 mg once or twice daily) should be prescribed instead of a sulfa-based antibiotic, because of potential hepatic toxicity. Nitrofurantoin is also contraindicated in infants <2 months old.

Some have questioned whether antibiotic prophylaxis is necessary. Garin et al recently performed a randomized prospective trial comparing prophylaxis with no prophylaxis in children with vesicoureteral reflux diagnosed following pyelonephritis.[24] The study showed no clinical advantage to administering prophylaxis. However, there were only 45 patients in each treatment group, making it impossible to develop sufficient study power. In addition, patients were only studied for one year. The National Institutes of Health has sponsored a new protocol com-

paring the outcomes in children with and without prophylaxis in Cleveland. Children 6 months to 6 years with grades I through IV will be studied; half will be assigned to antibiotic prophylaxis and half to no prophylaxis.

Breakthrough urinary tract infection

In girls who are receiving antibiotic prophylaxis for recurrent UTI, those with reflux and those with voiding dysfunction are most likely to develop a breakthrough UTI.[25] In boys with reflux, those who are uncircumcised are most likely to develop a breakthrough UTI.[26] In both sexes, children with scarring on a dimercaptosuccinic acid (DMSA) scan are at greatest risk for breakthrough UTI. If the child has a febrile UTI, consideration should be given to obtaining a DMSA renal scan to determine whether there is acute pyelonephritis, which was found in 17% of refluxing children.[27] Children with acute pyelonephritis are at risk of developing new renal scarring, and prompt treatment of these children is necessary.

A breakthrough UTI is an indication of failure of non-surgical management, and surgical therapy should be considered, particularly if the UTI was febrile. In children with a breakthrough UTI with symptoms of cystitis, an alternative is to prescribe an antibiotic to which the breakthrough organism is sensitive, or to use 'double prophylaxis', in which both trimethoprim–sulfamethoxazole and nitrofurantoin are administered daily.[24]

Discontinuing antibiotic prophylaxis (expectant management)

UTI in girls occurs most commonly in those between birth and 5 years and in adulthood. In uncircumcised boys the risk of UTI is greatest in those up to 6 months of age[28] and then it drops off considerably, corresponding to the time of spontaneous retraction of the prepuce. Thereafter, the risk of UTI in uncircumcised boys is slightly higher than in circumcised boys. The risk of UTI in circumcised boys with reflux has not been studied systematically but appears to be lower than in uncircumcised boys.[25]

In selected patients it seems reasonable to discontinue prophylaxis. Cooper et al retrospectively evaluated 51 children, selected from their practice over a period of 14 years, with grades I–IV VUR in whom prophylaxis had been discontinued.[29] All children had a normal voiding pattern and began expectant management at a mean age of 8.6 years. All had an annual renal sonogram and a biannual radionuclide cystogram. These children were followed for a mean of 3.7 years. A UTI occurred in 5/40 girls and 1/11 boys. All of the UTIs in the girls were febrile, and these children underwent ureteral reimplantation. All of the children with UTI had grade III VUR at presentation and four of the six who developed a UTI still had bilateral VUR when the prophylaxis was discontinued. The reflux resolution rate was 20%, and no children developed evidence of new renal scarring on follow-up sonography or underwent DMSA renal scintigraphy. In a similar study, Al Sayyad et al retrospectively reviewed 78 children with VUR (94% grade I or II), in whom prophylaxis was discontinued.[30] All had a normal voiding pattern. The mean age at discontinuation of prophylaxis was 5.7 years. Of the 67 girls, nine developed a UTI, but only one had a febrile UTI. All had a normal renal sonogram on follow-up. Taken together, these two studies suggest that prophylaxis may be unnecessary in some children with VUR, if their voiding pattern is normal. In addition, boys with VUR seem to be at significantly lower risk for febrile UTI, particularly those with lower grades of VUR. It is unresolved whether children with VUR who were detected by sibling screening or screening following detection of a multicystic kidney or renal agenesis have a lower risk of reflux-related complications than children who were diagnosed with reflux following a UTI.

Although antibiotic prophylaxis may be unnecessary in the short term, female patients and their families should understand that if there is ongoing VUR into adulthood, then these women may be at increased risk of clinical pyelonephritis, particularly in association with pregnancy and onset of sexual activity. For example, Smellie et al studied 226 adults with a history of UTI and VUR as children.[5] Of the group, 23% had VUR at most recent follow-up. Overall, 39% of the adults without VUR had UTI in adulthood, compared with 38% of adults who still had VUR. No new scars were observed after age 4 years. However, clinical pyelonephritis occurred in 8/168 (5%) of those without reflux compared with 9/53 (17%) of those who were still refluxing. In a similar study, Martinell et al reported on 107 girls with clinical pyelonephritis at a mean age of 7.1 years and followed for 13–38 years.[31] Using excretory urography, 18 girls developed new scars in previously normal kidneys, and 28 kidneys with scarring developed progressive scarring. The highest risk factors for new or progressive scarring were UTI and clinical pyelonephritis. VUR can be discovered in adult women with a febrile UTI. Kohler

reported on 115 adult women with VUR discovered after 16 years of age;[32] 73% of the refluxing kidneys had evidence of reflux nephropathy, even though the reflux grade was I or II in most cases. This group has also reported that adult women with a history of clinical pyelonephritis and VUR who underwent surgical reflux correction had significantly fewer febrile UTIs than those women who had persistent VUR.[33] Several other studies have demonstrated that women with VUR have a higher risk of febrile UTI compared with those without VUR.[34–36] In most of these cases the reflux grade was low. Taken together, these studies suggest that if there is persistent VUR in a female child, open surgical or endoscopic correction should be considered, even though the child may be doing well on expectant management.

Bladder training

Bladder training refers to regular, volitional, complete emptying of the bladder through behavioral conditioning to achieve balanced, low-pressure voiding with coordinated relaxation of the external sphincter and pelvic floor during voiding. The goal of bladder training is to reduce the likelihood of developing UTI and reduce voiding pressure. Infrequent voiding, detrusor–sphincter dyssynergia, and constipation can increase the likelihood of bacteriuria.[24] Measures include a voiding schedule every 2–3 hours, complete bladder emptying during micturition, re-education in proper voiding dynamics if voiding dysfunction is present, and elimination of constipation. The practice also includes genital and perineal hygiene. Although these recommendations are practical, no firm evidence exists that a specific regimen is beneficial.

Voiding dysfunction

Voiding dysfunction refers to disturbances in normal bladder or bowel function. Many children with VUR and UTI have elements of voiding dysfunction.[37–39] The spinning top deformity of the urethra seen on the voiding film of the VCUG in some girls, and a similar appearance of a dilated prostatic urethra in boys (although the latter could be secondary to posterior urethral valves), may be suggestive signs of voiding dysfunction. Typically, some degree of bladder trabeculation is observed in these children also. 'Dysfunctional elimination' refers to children who have constipation as well as infrequent voiding or difficulty

with overactive bladder contractions. Children with VUR and dysfunctional elimination have a higher rate of breakthrough UTI compared with those without dysfunctional elimination.[39,40] For example, Snodgrass reported 128 children with VUR identified prospectively who answered a questionnaire pertaining to voiding dysfunction.[38] Of the girls, 43% with voiding dysfunction had breakthrough UTI compared with 11% with a normal voiding pattern. Similarly, Koff et al retrospectively studied 143 children with VUR who were old enough to be toilet trained.[39] Breakthrough UTIs were four times more common in children with dysfunctional elimination, and there was a longer time to spontaneous resolution of VUR in affected children. Furthermore, unsuccessful surgical outcomes were observed only in children with voiding dysfunction.

To help assess whether voiding dysfunction is present, Farhat et al reported a validated Dysfunctional Voiding Scoring System (DVSS), which consisted of 10 questions pertaining to urinary and bowel habits (Table 43.2).[40] Subsequently, this group applied the DVSS to children with reflux in a retrospective study. In children with a high symptom score managed with behavioral modification, those with a significant reduction in symptom score were most likely to show reflux resolution or improvement, whereas those with only a minor reduction in symptom score tended to have persistent reflux.[41] Prospective trials of this type of scoring system are necessary.

Anticholinergic therapy

Children with an overactive bladder typically have urgency, frequency, and/or urge incontinence. When girls with this condition sense a sudden bladder contraction, they often cross their legs or squat down on their foot to try to prevent incontinence. In these children, a combination of anticholinergic therapy and timed voiding may be beneficial.[42] The anticholinergic is administered according to the incontinence pattern of the specific child. Most children with an overactive bladder experience incontinence throughout the day and night, and these children should receive the medication so that the effect lasts for 24 hours. Other children may be incontinent only during the day, and these children do not need night-time medication. Typically, oxybutynin chloride 2.5–5 mg tid is prescribed. The medication is available as a tablet or suspension. Typical side effects include xerostomia (dry mouth), facial flushing, reduced sweating, constipation, and, less commonly, blurred vision and drowsiness. Side effects are dose related and may be eliminated with dose reduction. Other antimuscarinics include hyoscyamine, which is available as a sublingual tablet, 0.125–0.25 mg qid or as a capsule taken twice daily; tolterodine, 1–2 mg bid; and trospium, 10–25 mg daily in two doses.[43] These medications have the same potential for side effects as oxybutynin, but their incidence and severity are less. These medications are also available as long-acting tablets taken once daily or as a patch applied twice weekly, and these formulations may be more effective than the shorter-acting drugs.[44] Although these medications are not specifically approved for use in children, they are utilized in many centers, but their dosage and timing of administration need to be individualized and closely monitored. Other antimuscarinics being studied include darifenacin and solifenacin. On the other hand, a recent meta-analysis of the few randomized controlled trials of anticholinergic therapy in children found that there is no evidence that they are beneficial in the treatment of overactive bladder.[45] The beneficial effect attributed to anticholinergic medications may be due in part to a placebo effect.

Anticholinergic therapy may be a beneficial therapeutic modality in children with reflux and an overactive bladder, in that there is an increased likelihood of spontaneous reflux resolution in children treated with anticholinergics.[46,47]

α-blocker therapy

Some children with voiding dysfunction have pelvic floor overactivity and have significant postvoid residual urine volumes. These children may benefit from α-blocker therapy. In a prospective randomized double-blind trial of 38 children, Kramer et al found that doxazosin 0.5 mg resulted in a reduction in incontinence episodes, compared with no change in the placebo group.[48] The differences were not statistically significant, because of small patient numbers. There was significant subjective improvement, however, in the children receiving doxazosin. A larger trial is necessary to determine whether α-blocker therapy is beneficial.

Treatment of constipation

Dysfunctional elimination syndrome is a common component of children with UTIs and reflux.[39] Treatment of constipation is an important component of therapy. Numerous bowel regimens are available. Polyethylene glycol 3350 is a tasteless powder that can be mixed with any liquid and is useful as a single-agent laxative. In a retrospective study of 46 children with voiding dysfunction and constipation treated

with this laxative, 39% became dry and 57% had improved urinary continence.[49] Voided volume increased significantly and postvoid residual urine volume decreased significantly.

Biofeedback

In children with dysfunctional voiding, typically there is inconsistent relaxation of the external sphincter during voiding. This pattern may occur because of repeated unstable bladder contractions that cause the child to tighten his or her sphincter, as opposed to a normal pattern in which the sphincter is relaxed during a detrusor contraction. Many of these children demonstrate a staccato voiding pattern on a uroflow study. Biofeedback may be useful, not only to establish a normal pattern of sphincteric relaxation during voiding but also to reduce or eliminate the need for anticholinergic medication for the overactive bladder. A typical treatment session might include a uroflow study, sonographic evaluation of postvoid residual urine volume, and a 1-hour session with perineal patch electrodes for electromyography (EMG). The child watches the sphincter activity on a television screen, and learns to contract and relax the external sphincter, which are essentially Kegel exercises. In addition to this simple office setup, video games have been developed that help the child coordinate sphincter tone.[50] An alternative is to simply teach the child pelvic floor exercises without using sophisticated urodynamic equipment.[51]

The concept of biofeedback is that children may have difficulty isolating their external sphincter, and biofeedback sessions allow them to learn sphincteric relaxation, which is necessary as a prerequisite to normal bladder emptying. In addition, these pelvic floor exercises may also ameliorate unstable bladder contractions. It is important that children perform these exercises daily, although no definite regimen is used. Several monthly sessions are necessary to reinforce the importance of the treatment, as well as determine whether voiding patterns are improving and whether residual urine volumes are decreasing. Subsequently, the sessions can be spaced further apart.

Most reports of biofeedback for the management of voiding dysfunction have been favorable.[50–55] Some treatments utilize biofeedback in children with symptoms of an overactive bladder that do not respond to anticholinergic therapy and timed voiding, whereas other treatments use it as an alternative to anticholinergic medication. However, it is uncertain how often anticholinergic therapy can be reduced or eliminated in children with an overactive bladder. Some centers have reported that the need for antireflux surgery was eliminated in many cases[50] and that the likelihood of reflux resolution was higher in children submitted to biofeedback.[56]

Follow-up assessment

Screening for urinary tract infection

In a child with VUR, periodic surveillance is generally recommended to monitor for UTI, because the complications of reflux often occur when infection is present. However, no guidelines exist for frequency of monitoring (e.g. monthly, every 3 months), or type of surveillance (urine dipstick, dipstick with microscopy, urine culture, or a combination).[14] Most children with a UTI are symptomatic, with fever and abdominal/flank pain for an upper tract infection, or they experience dysuria, urgency, frequency, and possibly incontinence and malodorous urine with a lower tract infection. There is no evidence that periodic screening of asymptomatic children with VUR for a UTI is beneficial. Consequently, if the child is suspected of having a UTI, a urine culture should be obtained. If the child has symptoms of upper tract infection, approximately 17% will have evidence of acute pyelonephritis on a DMSA renal scan.[27]

Follow-up cystography

In a child receiving medical therapy, follow-up cystography is generally performed every 12–18 months. Some prefer a radionuclide cystogram, because the radiation dose to the gonads is significantly less than with a standard contrast cystogram.[57] Unfavorable prognostic factors include demonstration of reflux at less than 60% of bladder capacity and reflux volume >2% of bladder capacity.[58,59] Demonstration of intermittent reflux is common. However, the assessment of reflux grade or severity is not entirely comparable with a contrast cystogram. With digital fluoroscopy equipment and a tailored contrast cystogram performed by a pediatric radiologist, the radiation exposure can be kept to a minimum.[60]

Non-compliance with follow-up visits is common; in one large study it was 33%.[61] Seeing the patient at least annually allows the clinician to reassess the child's voiding and bowel habits, dosage of medication, and status of the kidneys and reflux. One reason for non-compliance in children who are doing well on

antibiotic prophylaxis is the trauma of the VCUG.[62,63] There are several other potential strategies to consider.

First, a children's hospital is more likely to provide the support services, such as Child Life, as well as radiologic personnel who recognize a child's special needs.[64] Zelikovsky et al found that coping skills training and parent coaching were beneficial.[65]

One option is to reduce the frequency of VCUG in children with reflux. In 1992, the AUA Vesicoureteral Practice Guidelines Committee reported a survey of various specialists in their practice patterns pertaining to reflux, and found that general urologists recommended performing a VCUG as often as every 6 months.[66] However, the likelihood that grade II reflux will resolve is only 18% per year, and for unilateral grade IV reflux the chance is only 8% per year. Thompson et al used the AUA Reflux Guidelines data for reflux resolution and proposed that a VCUG be performed every other year for children with mild reflux and every 3 years for children with moderate or severe reflux.[67] This practice would significantly reduce the number of VCUGs and medical costs of treatment. Whether long-term compliance would be maintained is questionable.

An alternative to the standard VCUG is to administer either oral or nasal midazolam in selected children undergoing a VCUG, because it provides anxiolysis and anterograde amnesia. The medication takes effect in 10–20 minutes, and no anesthesiologist or anesthetist is present. A registered nurse checks vital signs every 10–15 minutes. In this author's initial report, 60% remembered none of the study, whereas 31% remembered part or all of the procedure but did not have a negative experience.[68] No child had a change in vital signs or oxygen saturation. More recently, the benefit of midazolam before VCUG was demonstrated in prospective randomized trials.[69,70]

Several other options include the use of lidocaine jelly to lubricate the catheter,[71] the use of continuous-flow 50% nitrous oxide before catheterization,[72] and self-hypnosis.[73]

Upper tract imaging

Regular upper tract imaging with sonography or a DMSA renal scan allow the clinician to assess renal size and development of renal scarring. There are no standards regarding the timing of follow-up or type of imaging. However, if there has not been a symptomatic UTI, it is highly unlikely that a new scar will develop. In a retrospective study of 64 consecutive children with low- and medium-grade reflux and a normal renal sonogram, Lowe et al found that all 128 renal units remained normal in follow-up.[74] In contrast, with a febrile UTI, in a prospective trial, Szlyk et al reported that 17% had changes of acute pyelonephritis on a DMSA renal scan,[27] and these patients are those at risk for developing new renal scars.

Other assessment

The AUA Practice Guidelines Committee recommended that follow-up evaluation be performed at least annually, at which time the patient's height and weight should be recorded. If the child has renal scarring, the blood pressure should also be monitored.[14,15] There are no guidelines regarding measurement of renal function, but if there is significant reflux nephropathy, serum creatinine should be assessed regularly.

Surgery for vesicoureteral reflux

44

John W Brock III and Romano T DeMarco

Introduction

Multiple techniques for the open surgical repair of vesicoureteral reflux (VUR) have been described since Hutch first reported the successful correction of VUR in 1952.[1] Although many methods have been proposed, most of these techniques have become footnotes in the evolution of the surgical management of VUR. Today, most surgeons employ only a handful of the previously described repairs.

The surgical correction of VUR has as its goal, the restoration of the flap-valve mechanism absent in children with reflux. Success using any of the described open techniques involves the general surgical principles of tissue handling with the preservation of tissue vascularity. Specific surgical tenets of ureteral reimplantation surgery include the establishment of an adequate submucosal tunnel, a smooth course for the intravesical ureter, and an adequate posterior bladder wall for submucosal tunnel backing. Whereas newer, less-invasive, and novel alternatives to antireflux surgery exist, open surgical repair of VUR remains the gold standard against which all other methods are measured.

Historical background

The earliest descriptions of ureteral reimplantation surgery appeared in the medical literature near the turn of the 20th century. The first reported ureteroneocystostomy is credited to Tauffer in 1877 by Bovee in a review article on ureteral surgery in 1900.[2] Bovee described 80 cases of ureteral reimplant surgeries, the vast majority performed following accidental division of the ureter at the time of laparotomy for ureteral fistulae resulting from prolonged labor or forceps delivery. Subsequently, other innovative procedures for reimplanting the ureter were described in the early part of the 20th century unrelated to the treatment of VUR.[3–9]

In 1952, Hutch reported the successful correction of VUR in 7 out of 9 paraplegic patients with a combined extravesical and intravesical dissection.[1] Hodson followed with his findings that VUR was more common in children with urinary tract infections (UTIs), and that there was a high correlation between VUR and chronic pyelonephritis on intravenous pyelography (IVP).[10] These landmark papers led to further investigations into the treatment of VUR and played a pivotal role in the development of pediatric urology as a separate subspecialty.

Following Hutch's seminal paper, many surgical techniques were described. Landmark refinements of Hutch's operation included Politano and Leadbetter's technique of intravesical mobilization of the terminal ureter, with subsequent reimplantation through a new vesical hiatus and submucosal tunnel.[11] Paquin's method summarized several fundamental requirements of successful VUR surgery, including the creation of a tension-free ureteral anastomosis and a submucosal tunnel length five times longer than the diameter of the ureter.[12] An extravesical approach soon followed, with almost simultaneously reported techniques described by Lich and colleagues in the United States and Grégoir and Van Regemorter in France in the early 1960s.[13,14] Glenn and Anderson reported success using their modified ureteral advancement technique without creating a new muscular hiatus in the mid-1960s.[15] Cohen subsequently modified the ureteral advancement procedure and achieved adequate submucosal tunnel length by using the posterior aspect of the bladder for cross-trigonal tunneling.[16] These descriptions, in addition to contributions by other surgeons over the past 50 years, have made open surgical correction of VUR an effective and durable surgical treatment.

Indications

The surgical indications for VUR should be tailored to the individual patient. Absolute indications for

surgery include breakthrough UTIs despite prophylactic antibiotics or because of medical non-compliance. Relative indications for reimplant surgery include the following: persistent grade IV or V reflux; VUR associated with congenital abnormalities at the ureterovesical junction; renal growth retardation or the presence of new renal scars; and dilating reflux persisting in girls who have reached full somatic growth potential.

At Vanderbilt Children's Hospital (VCH), counseling is initiated at the first clinic visit for those patients referred to our office with UTIs and VUR. Good voiding mechanics, adherence to daily antibiotic suppression, and avoidance of dysfunctional elimination issues are repeatedly stressed to both the patient and parents. If indications for surgical intervention are present, other complicating factors, including the nature of the infections while on medical therapy, possible neurologic or non-neurologic bladder dysfunction, and the presence of dysfunctional elimination, are taken into account. Informed operative consent and expectations following surgery are explained in detail to both parents and child.

Presurgical techniques

Cystoscopy

Cystoscopy can be performed prior to open ureteral reimplantation surgery following induction of general anesthesia. Cystoscopy should take only a few minutes from positioning to completion. It alerts the surgeon to unexpected anatomic findings not found on preoperative imaging studies. Duplication anomalies, the presence of small ureteroceles, or evidence of posterior urethral valves or other urethral abnormalities may be found. Bladder trabeculae are seen well during cystoscopy and may be related to voiding dysfunction. Additionally, acute cystitis (if found during endoscopy) delays open surgery until an appropriate course of antibiotic therapy has been completed.

However, cystoscopy is not mandatory in all patients and, with the improvement in diagnostic imaging techniques, typically adds little information. Male patients, those with unclear radiographic findings, or patients with anatomic abnormalities found on preoperative imaging studies are a few of the select group of patients who may benefit from endoscopy.

Positioning

If cystoscopy is performed, the bladder is left moderately distended. The child is then positioned supine with either a rolled towel placed at the level of the upper sacrum or a slight break in the table used to raise the lower pelvis and hips (Figure 44.1). All pressure points are appropriately padded and a wide surgical prep is performed with the perineum draped and exposed within the surgical field.

Intravesical techniques

Exposure/initial dissection

Exposure for all of the intravesical repairs involves a series of similar steps before the individual techniques diverge during ureteral reimplantation. A Pfannenstiel skin incision is made along an appropriate skin crease about one finger breadth above the pubic symphysis (Figure 44.2a). The subcutaneous tissue and Scarpa's fascia are incised the length of the skin incision. The anterior rectus sheath is then opened in a horizontal fashion with superior and inferior rectus flaps created (Figure 44.2b). The rectus muscle bellies are then incised in the midline through the linea alba, separating the rectus and the pyramidalis muscle. Alternatively, the anterior rectus fascia can be opened in a vertical fashion, extending the incision posteriorly through the linea alba (Figure 44.2c).

Following the fascial incision, the space of Retzius is entered bluntly. The peritoneal reflection is displaced superiorly, the bladder is visualized, and full-thickness bladder wall stay sutures are placed on either side of the midline of the bladder. The Denis

Figure 44.1 A child positioned for ureteral reimplant. The legs are gently abducted. A towel placed under the sacrum provides a slight rise of the pelvis.

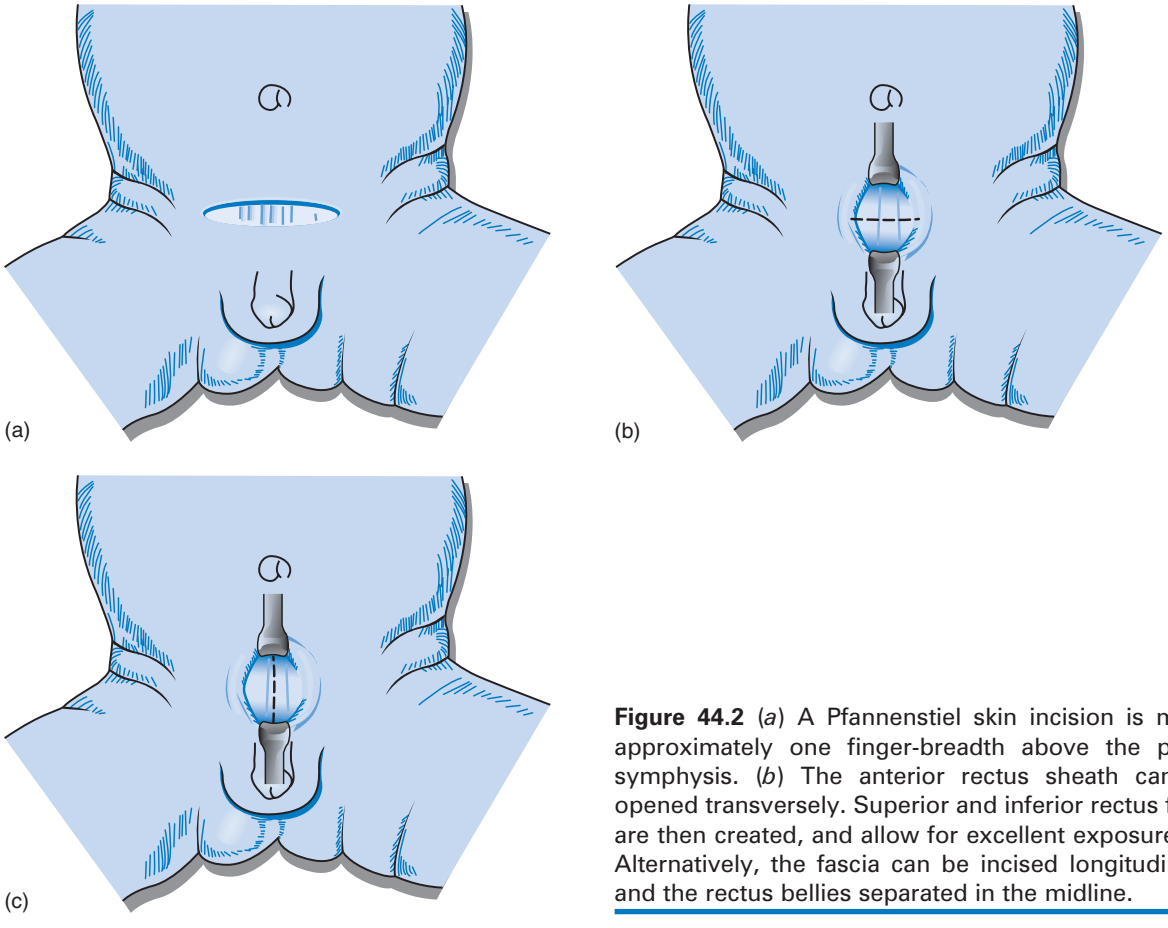

Figure 44.2 (*a*) A Pfannenstiel skin incision is made approximately one finger-breadth above the pubic symphysis. (*b*) The anterior rectus sheath can be opened transversely. Superior and inferior rectus flaps are then created, and allow for excellent exposure. (*c*) Alternatively, the fascia can be incised longitudinally and the rectus bellies separated in the midline.

Brown retractor is a helpful aid in allowing for sustained exposure. The anterior bladder wall is then incised longitudinally, and the inferior edges of the bladder wall are sewn to the lower abdominal skin edges, immobilizing the inferior aspect of the bladder. Moist sponges are packed in the dome of the bladder behind the cephalad blade retractor to flatten the posterior bladder wall and elevate the entire bladder in the pelvis, bringing the ureteral orifices into the middle of the operative field. Lateral blades are secured to the Denis Brown retractor to obtain further exposure. These maneuvers ensure optimal exposure of the posterior aspect of the bladder and trigone. Care must be taken during positioning of the Denis Brown retractor to prevent tearing of the bladder incision through the bladder neck region. Also, excessive touching, suctioning, or rubbing of the bladder mucosa are avoided to prevent edema or inflammation of the mucosa, which can lead to bleeding and difficult mucosal dissection.

Ureteral dissection begins with intubation of the ureter with either a 5 or 3 Fr feeding tube, depending on the size of the ureteral orifice. The tube is secured to the ureter with a 4–0 silk suture placed in a transverse fashion just inferior to the ureteral orifice, and then through the feeding tube which maintains orientation of the ureter throughout mobilization (Figure 44.3a). The mucosa is then circumferentially incised around the ureteral orifice with an electrocautery device in the cutting mode, leaving a several-millimeter cuff of bladder mucosa (Figure 44.3b). The muscular attachments of the ureter to the bladder are then carefully divided with the electrocautery device, using the coagulation mode. This dissection involves gentle countertraction of the ureter away from the periureteral tissue using the feeding tube, in concert with judicious use of the cautery device (Figure 44.3c). Care is taken to avoid both devascularization and injury to the continuity of the ureter. The appropriate plane of dissection is achieved if the shiny, reflective ureteral wall in Waldeyer's sheath is seen. As dissection proceeds proximally, division of the ureteral attachments is taken down further from the ureter to avoid devascularization. Ureteral dissection is completed after an adequate distance of the ureter has been mobilized. A good measure of this distance is for the ureter to have enough length to reach the contralateral bladder wall. An additional clue is the subtle feel-

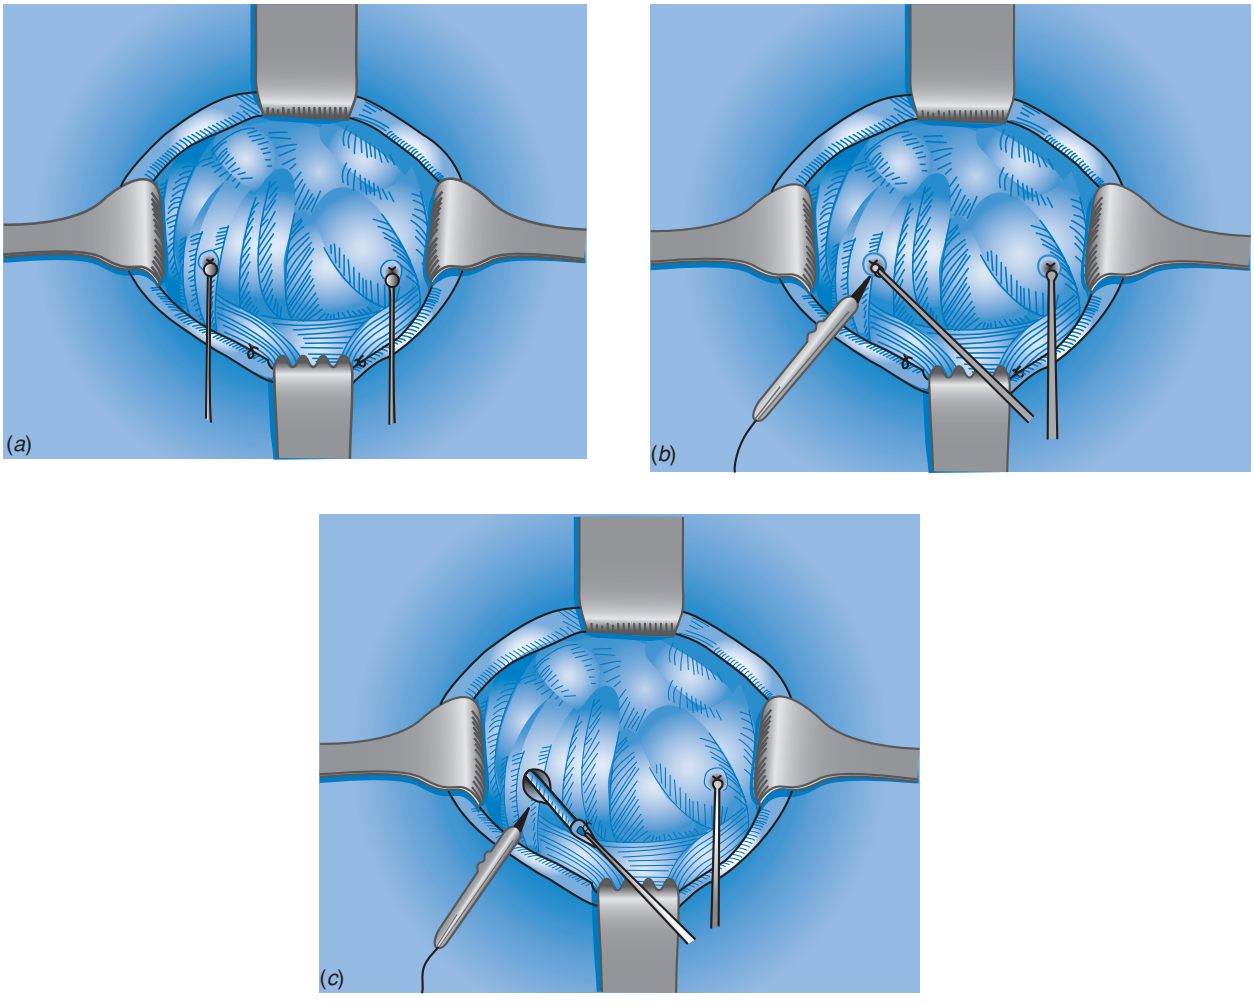

Figure 44.3 (*a*) The refluxing ureter(s) are intubated with an appropriate-sized feeding tube. The feeding tube is secured with a silk stay suture. (*b*) The mucosa is incised circumferentially around the ureteral orifice with an electrocautery device. (*c*) The ureteral attachments are carefully divided, and an adequate ureteral length for reimplant is obtained.

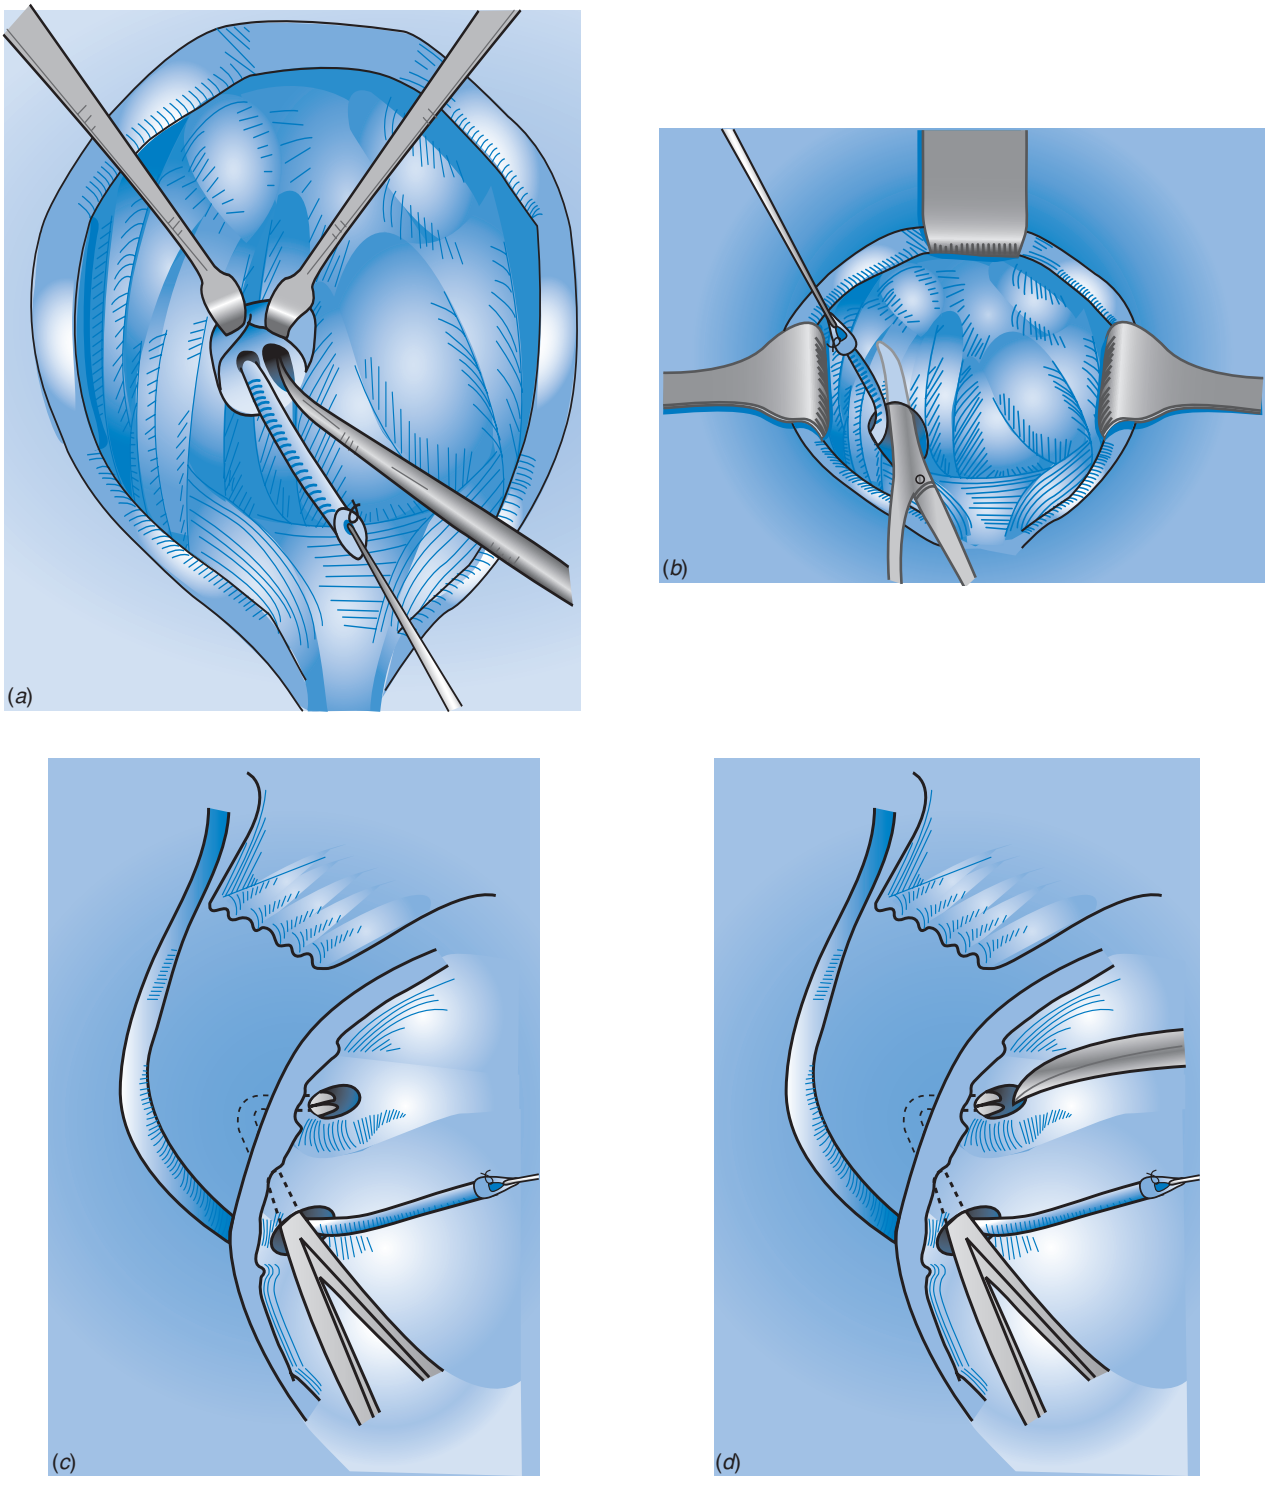
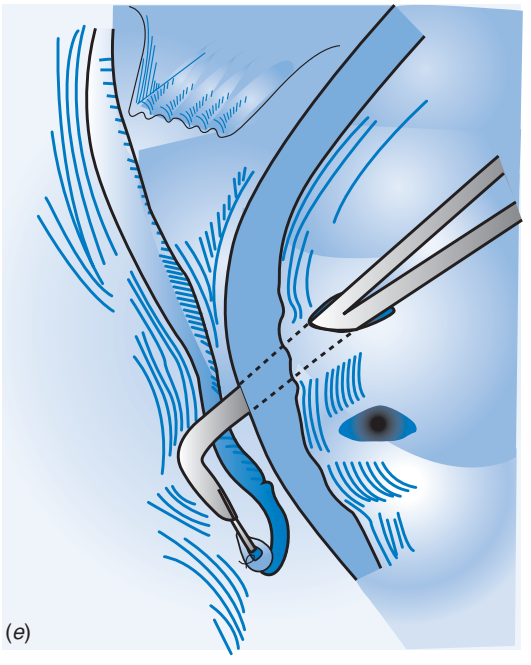
ing of ureteral release the experienced surgeon is alert to, which allows the redundant ureter to easily slide back and forth in the muscular hiatus (Figure 44.4).

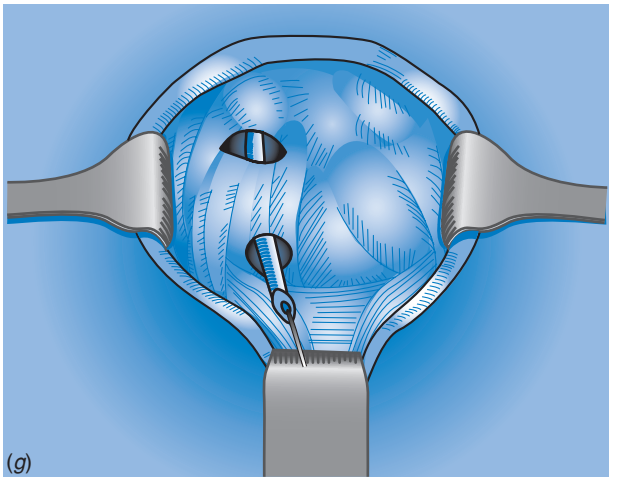
Figure 44.4 Following ureteral dissection, adequate mobilization of the ureters for reimplantation is demonstrated.

Politano–Leadbetter repair

The original Politano–Leadbetter technique described in 1958 involved the blind creation of a new suprahiatal muscular location for the ureter.[11] Following adequate ureteral mobilization as described above, the peritoneum is reflected superiorly away from the posterior aspect of the bladder using the original muscular hiatus as a window in which to work through (Figure 44.5a). If the muscular opening is not adequate for exposure, the posterior bladder wall may be incised superiorly to allow for better visualization. Perivesical crossing vessels, when encountered during







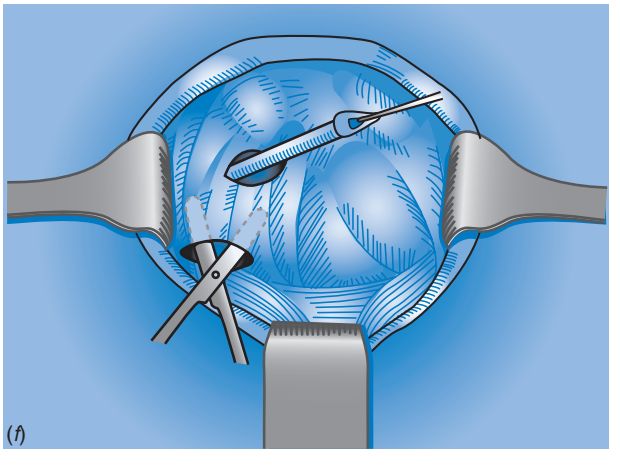


Figure 44.5 (*a*) Following adequate ureteral mobilization, the peritoneum and other structures (vas deferens or vagina) are displaced under direct vision. The posterior aspect of the bladder may be opened to allow for better visualization during this dissection. (*b*) Once the peritoneum is swept away, a right angle clamp is passed from the original hiatus, indenting a region superior and medial to the native hiatus. The electrocautery device incises the bladder tissue indented by the clamp. (*c*) The new hiatus is opened widely with the tip of the right angle clamp to allow for accommodation of the ureter. (*d*) A second right angle clamp is passed from the new hiatus down through the original hiatus.

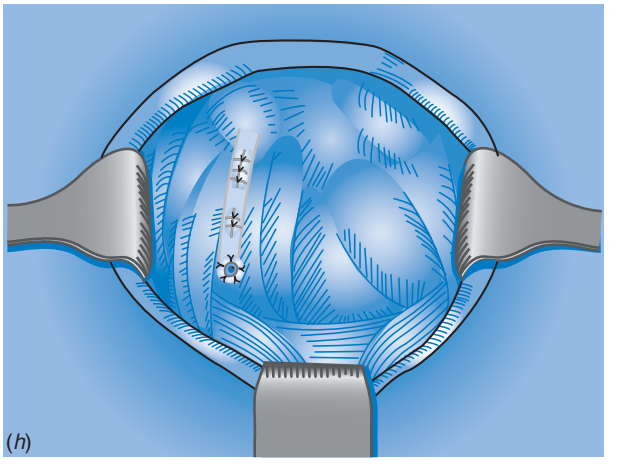

Figure 44.5 *continued* (*e*) The ureter is then grasped by the second clamp after amputating the distal aspect of the feeding tube. (*f*) The ureter is transferred to the new hiatus and an appropriate submucosal tunnel is created. (*g*) The ureter is brought through the tunnel and secured distally to the new mucosal hiatus. (*h*) Completed ureteral reimplant.

division of the bladder wall, are fulgurated. The posterior bladder wall dissection is performed under direct visualization. Blind passage of instruments behind the bladder is forbidden because of the risk of unrecognized entry into the peritoneum or injury to the bowel, vagina, or vas deferens.

Once the posterior bladder wall is freed from the peritoneal reflection, a right angle clamp is passed through the original hiatus superiorly under direct vision, hugging the posterior wall and indenting the bladder wall superiorly, marking the new muscular entrance for the ureter (Figure 44.5b). The location of the new hiatus is slightly medial and cephalad, typically 2–3 cm above the original hiatus. Excessive lateral placement allows for potential kinking and J-hooking of the ureter during bladder filling. The mucosa and muscle are incised directly on the right angle clamp with the electrocautery device, and the right angle tip is delivered into the bladder, dilating the opening carefully (Figure 44.5c). A second right angle clamp is passed through the newly made hiatus inferiorly, and the ureter is then transferred to its new muscular hiatus, using the amputated feeding tube as a handle (Figure 44.5c–f). Careful relocation of the ureter involves ensuring a relatively smooth entrance of the ureter without acute angulations or kinks. The original muscular opening is then closed with 3–0 interrupted chromic sutures in a buried fashion. Adequate room for the ureter to emerge through the new hiatus is measured by the gentle insertion of the tip of a Schnidt clamp.

A submucosal tunnel or mucosal flaps are created from the new entrance of the ureter inferomedially towards the bladder neck, which is marked with the electrocautery device. A modification of Politano and Leadbetter's original method involves increasing the submucosal tunnel length by extending the tunnel past the native ureteral orifice toward the bladder neck. Submucosal dissection is performed carefully with tenotomy scissors or the electrocautery device, and should proceed with ease through a bloodless field if in the correct plane (Figure 44.5f). Once an adequate submucosal tunnel has been made, the ureter is transferred through the tunnel (Figure 44.5g). The feeding tube is then removed, and the ureter is spatulated if needed. If excessive ureteral redundancy is present, the distal tip of the ureter may be excised. Three 6–0 Vicryl sutures are placed through the posterior apex of the distal ureter and through both bladder mucosa and muscle to secure the ureter distally and prevent it from retracting back into the tunnel. Then, 6–0 Vicryl mucosal sutures are placed circumferentially around the ureteral orifice, completing the mucosal anastomosis. The original mucosal opening is closed with a fine absorbable suture, and if mucosal flaps were created they are approximated with a running fine absorbable suture (Figure 44h). The bladder is then closed in two layers with 3–0 chromic suture in a running fashion.

Cohen's cross-trigonal repair

Arguably, today's most popular open technique for ureteral reimplantation is the cross-trigonal repair described by Cohen in 1975.[16] Ureteral dissection is performed as described above; however, this method typically requires less ureteral mobilization than the Politano–Leadbetter technique. The submucosal tunnel is created along the posterior bladder wall without transferring the ureter to a new muscular hiatus, virtually eliminating kinking of the distal ureter. The major drawback to this operation is the subsequent difficult intubation of the ureteral orifices related to their transtrigonal location.

Following ureteral mobilization, the muscular hiatus may need approximation if a patulous opening is present. Cinching of the hiatus with a 3–0 chromic suture should bring the muscle together tightly but allow for the tip of a Schnidt clamp to pass between the bladder and ureter. Aggressive closure of the muscular hiatus can cause kinking with angulation of the ureter and possible distal ureteral obstruction. In contrast, too lax of a muscular approximation may lead to diverticulum formation.

During unilateral ureteral reimplantation, a submucosal tunnel is developed across the posterior bladder wall in a cross-trigonal fashion. The new mucosal hiatus is created above the contralateral ureteral orifice. This ureteral position allows for an adequate submucosal tunnel. Once the submucosal tunnel is created, the ureter is transferred through the tunnel using the shortened feeding tube and stay suture as a handle. The feeding tube is then removed from the ureter. The ureter is spatulated, as indicated, and three fine absorbable sutures are placed through the lateral, posterior apex of the ureter and the bladder mucosa and muscle. Placement of these tacking sutures in the correct position creates an appropriate lateral vector force on the ureter, preventing medial regression of the ureter and loss of the effective submucosal tunnel. The newly created ureteral orifice is then matured with circumferential fine absorbable sutures. The mucosal defect from the old ureteral orifice is then closed with interrupted fine absorbable sutures (Figure 44.6a and b). Prior to closing the bladder, the free, smooth passage of a small feeding tube rules out excessive ureteral kinking.

When both ureters are reimplanted, the submucosal tunnel for the most superior ureter is made with the mucosal hiatus located just above the contralateral ureter. Subsequently, the other ureter is brought across the posterior bladder wall, with the new ureteral orifice positioned close to the inferior portion of the old contralateral hiatus. Visual inspection of the anatomy of the trigone and posterior bladder wall aids the surgeon in deciding how to orient the ureters with regard to superior and inferior location. At times, proper positioning of the submucosal tunnels dictates carefully incising the posterior bladder wall following peritoneal displacement in a superolateral fashion (Figure 44.6b). This leads to a cephalad shift of the ureter at the muscular hiatus, and allows for a smoother course across the posterior bladder wall for the superior-most ureter. Additionally, a lateral, muscular incision may be performed to recess the ureter laterally and can be used to increase the tunnel length in small bladders. Following ureteral reimplantation, the bladder is closed in two layers using 3–0 chromic suture.

Glenn–Anderson repair

In 1967, Glenn and Anderson refined and popularized the intravesical ureteral advancement procedure

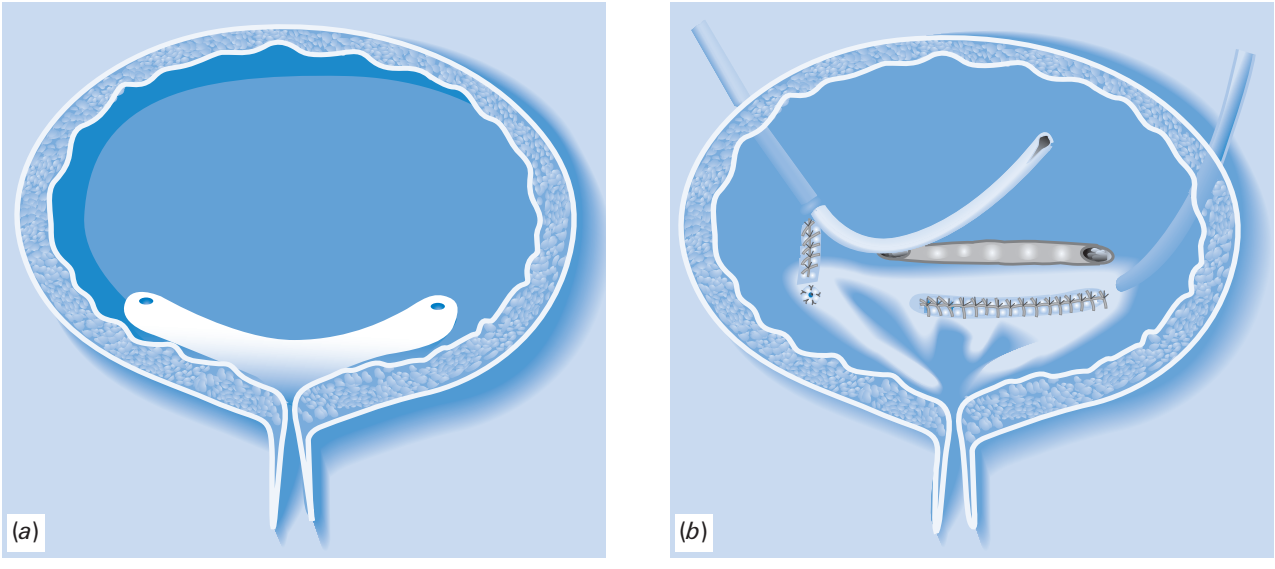

Figure 44.6 (*a*) Laterally displaced, refluxing ureteral orifices with an adequate posterior bladder wall for cross-trigonal reimplantation. (*b*) The left ureter was reimplanted using this technique. The native right ureteral orifice becomes the new left orifice after reimplant. The right ureteral muscular hiatus is incised superiorly to shift the ureter in a cephalad fashion, allowing a smooth tunnel for cross-trigonal reimplant.

that had been reported by several other authors.[15,17,18] Patients in whom this technique is used are selected based upon the location of their refluxing ureteral orifice(s) (Figure 44.7a). Those patients with laterally displaced ureters and a sufficient posterior bladder wall are good candidates for this procedure.

Ureteral dissection is performed in a fashion as described previously. If the muscular hiatus is gaping, the muscle edges are approximated with a buried, 3–0 chromic suture allowing for an adequate, smooth entrance for the ureter (Figure 44.7b). Following ureteral mobilization, a mucosal tunnel or mucosal flaps are developed from the original mucosal hiatus and extended in a caudal fashion to a point marked superior to the bladder neck. Once the tunnel or flaps are created, the ureter is transferred either through the tunnel or placed in the mucosal trough. The ureter is then secured distally to the newly created mucosal hiatus in a manner similar to the Poli-

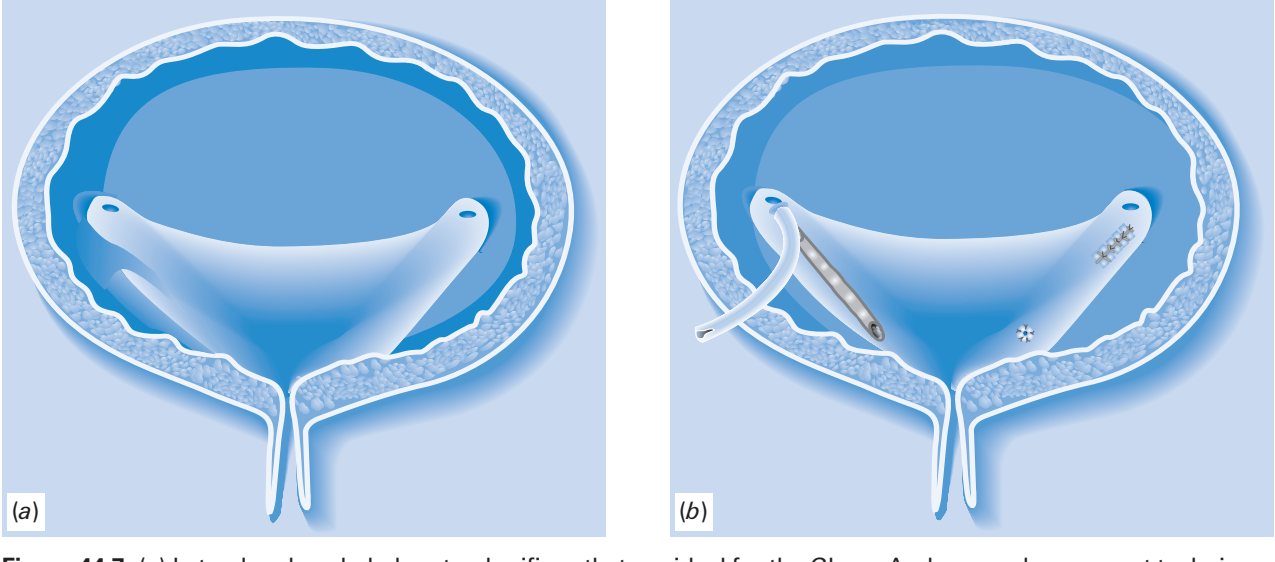

Figure 44.7 (*a*) Lateral and cephalad ureteral orifices that are ideal for the Glenn–Anderson advancement technique. (*b*) The ureters are advanced to an area superior to the bladder neck with an adequate submucosal tunnel.

tano–Leadbetter technique. The mucosal hiatus is then matured circumferentially with interrupted absorbable sutures or the mucosal trough is closed with a running fine, absorbable suture (Figure 44.7b). The bladder is then closed in a similar fashion to the other repairs.

Gil-Vernet repair

A simple, advancement technique for those patients with lateral ectopia and a widened, 'mega-trigone' was described by Gil-Vernet in 1984.[19] Exposure of the ureters is similar as in the other open procedures; however, minimal ureteral dissection is needed. A traction suture is placed at the medial aspect of the ureteral orifice and adequate mobility of the distal ureter and intrinsic muscular fibers of the terminal ureter is demonstrated by the ability of the ureter to be pulled towards the midline (Figure 44.8a and b).

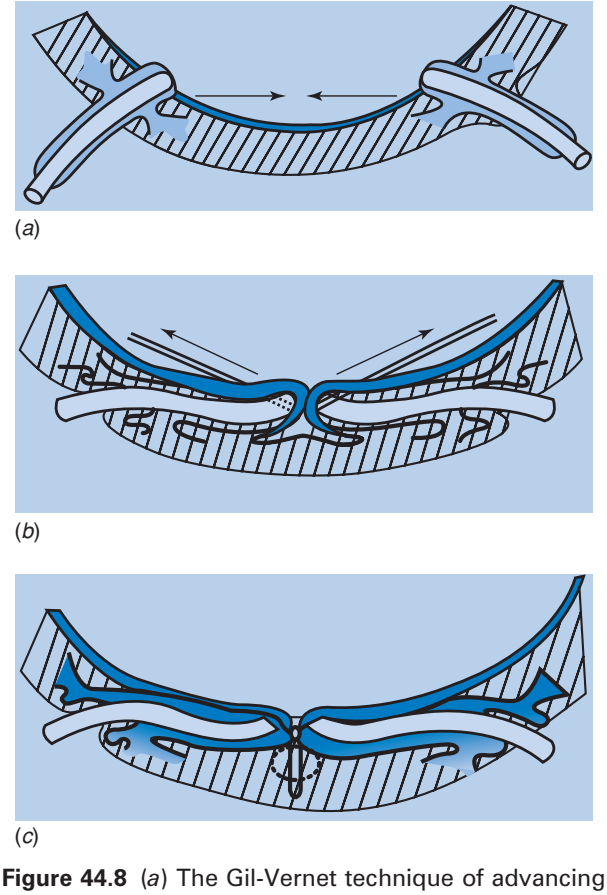

Figure 44.8 (*a*) The Gil-Vernet technique of advancing mobile ureters across the trigone. (*b*) Traction sutures are placed at the medial aspect of the ureteral orifices to test mobility. (*c*) Mattress sutures advance the ureters towards the midline, increasing their submucosal tunnel length. (Modified from Gil-Vernet,[19] with permission.)

If mobility of the distal ureter is found to be adequate, a transverse incision is made through the mucosa across the superior aspect of the trigone between the ureteral orifices. The mucosa is then elevated off the bladder wall muscle. The classic description by Gil-Vernet uses a single 3–0 nylon or Prolene suture placed in a mattress fashion at the base of each ureter encompassing the periureteral sheath and muscle. This suture advances the ureters toward the midline, increasing their intramural length. The permanent suture is then buried by approximating the bladder muscle with 3–0 chromic sutures. The mucosa is then closed vertically with interrupted, fine absorbable sutures (Figure 44.8c). A modification of this technique using absorbable suture for the medial advancement has been described, and that is our practice at VCH.[20] The bladder and the overlying incision are then closed in a routine fashion.

Extravesical techniques

Lich–Grégoir repair

An extravesical approach to the correction of VUR was almost simultaneously described here in the United States and in Europe by Lich and colleagues and Grégoir and Van Regemorter in the early 1960s.[13,14] This technique, commonly referred to as Lich–Grégoir, is similar to previous methods published by other surgeons around the turn of the 20th century.[4,21] Despite its popularity in Europe, US surgeons were less enthused following Hendren's disappointing initial results using a modification of this repair.[22] Subsequent studies with minor modifications have found this technique to be both durable and reliable.[23,24]

Because the bladder is not opened during the repair, cystoscopy is performed following induction of anesthesia to rule out any bladder abnormalities. Once cystoscopy is complete, a Foley catheter is placed, clamped, and the bladder is left moderately full. Bladder exposure is obtained in a fashion similar to the intravesical repairs. The bladder volume is then emptied, and the bladder is retracted medially to expose the refluxing ureter. The peritoneum is reflected superiorly away from the posterior bladder wall, and the obliterated hypogastric artery is identified and ligated. The ureter is then found, mobilized, and freed of attachments distally to the posterior aspect of the bladder (Figure 44.9a) A network of small vessels typically congregates near the

ureterovesical junction, and they need to be divided carefully with an electrocautery device.

Following ureteral mobilization, the serosal and muscular layers of the detrusor are incised superiorly for a distance of 4–5 cm to create a trough for the ureter. The bulging bladder mucosa is seen following muscular division and ensures adequate mucosal exposure. Distention of the bladder during this step makes this dissection easier. Mucosal rents made during this step are closed with fine absorbable suture. The muscular division continues in a caudal direction 1–2 cm past the ureterovesical junction. The ureterovesical junction is freed circumferentially. Mobility of the ureterovesical junction is needed for ureteral advancement. Two or three 4–0 chromic vest-type sutures are placed through the bladder wall and ureter to advance and anchor the ureter to the distal aspect of the trough (Figure 44.9b–d). The ureter is then placed in the trough, and the detrusor is closed over it with interrupted 3–0 chromic sutures (Figure 44.9e). Approximation of the muscle edges proximally should be loose, and able to accommodate the tip of a Schnidt clamp at the muscular hiatus. Although no perivesical drain is typically used, an indwelling Foley catheter is left overnight and removed on postoperative day 1. If bilateral extravesical reimplants are performed, a voiding trial is initiated prior to discharge because of the risk of transient postoperative urinary retention.

Postoperative evaluation

The majority of children following simple ureteroneocystostomy are managed without indwelling urethral catheterization or perivesical drainage at VCH. Surgical repair of VUR via a catheterless ureteroneocystostomy at our institution was found to reduce hospital stay for patients when compared with those patients undergoing ureteral reimplantation with a

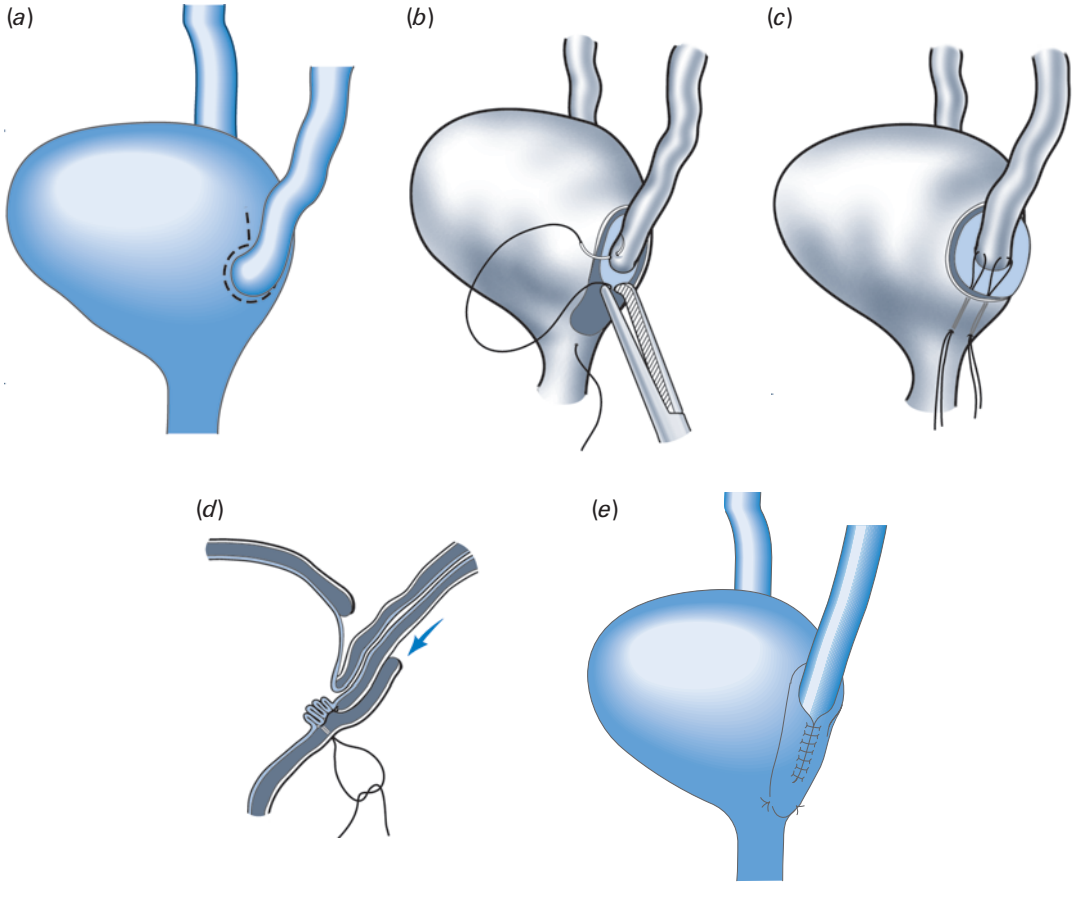

Figure 44.9 (*a*) The extravesical approach begins with ureteral mobilization followed by detrusorrhaphy. (*b*) After mobilization of the mucosa off the bladder muscle, two or three vest sutures are placed in an appropriate fashion. (*c*) Tying of the sutures advances the ureter down toward the inferior aspect of the trough. (*d*) A sagittal view following ureteral advancement. (*e*) The detrusor is loosely closed over the ureter once secured in the trough.

urethral catheter, without increasing complication rates.[25] Most children are discharged on postoperative day 1: i.e. once the child demonstrates adequate oral intake and postoperative pain is controlled with oral medications.

Standard postsurgical management includes a renal ultrasound at the first postoperative visit at 1 month to assess for the presence of hydronephrosis. Mild, transient hydronephrosis is commonly seen and usually resolves within the first several postoperative months. Management of persistent severe hydronephrosis will be discussed later in the chapter.

Voiding and stooling habits are reviewed during all postoperative clinic visits, and dysfunctional elimination issues are treated aggressively with educational reinforcement and medications. Suppressive antibiotic therapy is continued for 3–6 months following surgery. The child's preventive antibiotics are discontinued on an individual basis. Factors considered in the cessation of antimicrobial therapy include the demonstration of good elimination habits, a consistent UTI-free state, and evidence of resolved hydronephrosis. Routine voiding cystourethrography (VCUG) in patients undergoing simple ureteroneocystostomy is not performed at our institution, and this approach has been supported by others.[26,27] Following the early postoperative clinic visits, annual or semi-annual appointments are made to follow the child's voiding history and check the blood pressure, urine (with a urinalysis), and kidneys (with ultrasonography). Later in adult life, periodic evaluation should continue as indicated.

Results

The open surgical treatment of VUR has a long record of impressive correction rates. Initial and follow-up series of accepted surgical methods have success rates of 94–99%. The American Urological Association (AUA) Pediatric Vesicoureteral Reflux Guidelines Panel, released in 1997, analyzed 86 publications with respect to failure rate after ureteroneocystostomy, and found an overall success rate of 95.9% in 8061 open surgically treated ureters.[28] Reimplanted ureters with grade I–IV VUR had surgical correction rates of 98–99%, independent of technique, and these findings hold true at VCH.[29] However, patients with grade V VUR were found to have a persistent but lower grade of VUR 19% of the time following surgery.[28] With improvements in instrumentation and suture material, modifications of techniques, proper performance, and appropriate selection of patients, success nears 99% in those patients undergoing simple ureteral reimplantation with low to moderate grade reflux.

Complications

Ureteral obstruction

Postoperative complications are rare following ureteroneocystostomy. Mild hydronephrosis is not unusual in the early recovery period. In our series of patients who underwent ureteral reimplantation surgery, 8% of patients had grade I hydronephrosis that resolved over a period of several months.[26] Severe, persistent hydronephrosis is uncommon and is probably related to ureteral obstruction. Fortunately, ureteral obstruction is rare, with an occurrence rate of around 1%.[26,27,30] In cases of ureteral obstruction, initial management includes the placement of a percutaneous nephrostomy tube or indwelling stent in the hope that the obstruction is transient and will resolve over time. In patients with persistent ureteral obstruction, a repeat ureteral reimplant is required. This procedure may necessitate significantly more ureteral mobilization than the initial surgery, requiring both an intravesical and extravesical approach. A viable ureter is identified and the distal fibrotic ureter is discarded. A psoas hitch or Boari flap may be required if a significant length of distal ureter is lost. In rare instances, a transureteroureterostomy or ileal ureter is required for reconstruction.

Persistent reflux

Persistent reflux following ureteroneocystostomy is rare. The success rate, as noted previously, exceeds 98% in those patients with a non-dilating VUR. Poor selection of patients for specific operative techniques may have led to early reports of persistent reflux following surgery using specific methods.[22] The creation of an adequate submucosal tunnel in children with severe, dilating VUR is challenging. Ureteral tapering is often required; this increases the complexity of the surgery and the risk for postoperative morbidity and is discussed in detail in Chapter 39. Fortunately, in most patients with persistent VUR, their reflux is downgraded substantially following surgery and may resolve with growth and good voiding mechanics. One unusual cause of persistent VUR is the development of a ureterovesical fistula postoperatively. This complication does not typically resolve with expectant management. If problematic, surgical correction is indicated.

New contralateral reflux

The development of new contralateral VUR following unilateral ureteral reimplantation is uncommon. Occurrence rates vary from 1 to 18%.[31,32] Possible factors associated with de-novo contralateral VUR include a prior history of resolved contralateral reflux, correction of grade V VUR, or VUR into a duplicated system.[31,33] Contralateral VUR is usually low grade, causes no sequelae, and resolves within 1–2 years if the child adheres to a good voiding regimen. The need for surgical correction of new-onset, contralateral VUR following surgery is a rare event.

Conclusions

The open surgical repair for the correction of VUR is both a safe and effective management option. Classically described methods, such as the Politano–Leadbetter and the Cohen cross-trigonal techniques, are successful, durable repairs and continue to be used today. Whereas laparoscopic and endourologic techniques are being performed in greater numbers, the ease and success of the open surgical repair is the standard by which all other repairs should continue to be judged.

Key points

1 The open surgical correction of vesicoureteral reflux is highly effective, has few complications, and is the current gold standard of treatment.
2 The appropriate intravesical surgical technique is determined by trigonal anatomy.
3 The modified Politano–Leadbetter repair involves the creation of a new suprahiatal location of the ureter under direct vision.
4 When creating a new suprahiatal location for the ureter during the modified Politano–Leadbetter repair, it is important to avoid lateral placement to prevent J-hooking of the ureter.
5 The cross-trigonal method of ureteral reimplantation results in less potential for kinking because of its use of the original muscular hiatus.
6 The major drawback to the cross-trigonal method is the subsequent difficult intubation of the ureteral orifice due to its position following surgery.
7 The Glenn–Anderson technique is highly successful when used in those patients with laterally displaced ureters, allowing for sufficient ureteral advancement and tunnel length.
8 For experienced surgeons, routine postoperative VCUG is not mandatory in all patients following reimplant surgery.

Minimally invasive approaches to correct vesicoureteral reflux

45

Patrick Cartwright and Brent W Snow

The narrow bony pelvis of the child leads to the bladder occupying a more intra-abdominal position than in the adult. This creates relatively easy access to the bladder and perivesical space. Percutaneous bladder access is quite familiar to pediatric urologists, with suprapubic aspiration for culture being a standard practice for many years. In addition, placing a needle or port directly into the distended bladder may allow access for other procedures, including:

- placement of a suprapubic catheter
- antegrade ablation of a posterior urethral valve
- injection of bulking agents at the bladder neck
- catheterization of ureteral orifices with an unusual orientation (such as after Cohen's reimplant).

This background and a growing expertise with transperitoneal laparoscopy has inevitably led pediatric urologists to approach the common problem of vesicoureteral reflux laparoscopically; both intravesical and extravesical approaches have been reported and continue to be pursued.

Extravesical laparoscopic ureteral reimplantation

To assess the feasibility of this approach, early research work included creating reflux in a porcine model by incising the roof of the ureteral tunnel intravesically and subsequently creating a new submucosal tunnel via a transperitoneal, laparoscopic extravesical approach similar to the Lich–Grégoir repair.[1] Repair proved to be achievable with good reflux resolution rates but involved 1–2 hours per reimplant with bladder perforation and ureteral obstruction noted among the complications.[2–4] The procedure described involved splitting detrusor fibers superolaterally from the ureteral hiatus to expose urothelium, laying the ureter into this trough, and then closing detrusor edges together over the ureter to create a longer submucosal tunnel. This basic surgical approach is very similar to what has been undertaken clinically.

In 1994, the initial clinical report of transperitoneal, extravesical laparoscopic reflux correction was made and included patients aged 2 and 5 years with successful outcomes and long but acceptable operating times.[5] Janetschek and coworkers followed this shortly with a report on six patients, one of whom required ureteral stenting for 6 weeks.[6] These authors were impressed that the procedure was unwieldy and seemed to offer little recovery advantage to patients. While some surgeons may have been dissuaded by these reports, others have continued to pursue improvements.

Four significant series of transperitoneal, laparoscopic extravesical reimplantation studies have been reported over the past several years. In 2000, Lakshmanan and Fung reported on 26 patients (36 ureters), utilizing a technique with four ports, having an operative time of 1.5 hours/ureter and resulting in only one failure (follow-up of 3 months).[7] This series was updated in 2001 with 53 patients (83 ureters) accumulated in a period 'beyond the learning curve'. In these patients, there was failure of resolution in only one ureter (1.1%) and obstruction in another (1.1%), with each requiring open revision.[8] Shu et al have taken a similar approach, using four ports, and have recently documented excellent results and recovery, particularly in postpubertal patients.[9] Finally, Peters and associates have recently (2005) applied robotic technology to reimplantation in 24 children. Their initial results at 19.5 months mean follow-up include no obstruction in any patient, with resolution of reflux in 18/20 patients (90%) undergoing cystography. Mean operative times were 2.5 hours for unilateral and 3.5 hours for bilateral cases, with variable catheter usage and hospital stays of 0.25–3 days.[10] It

is unclear whether a robotic approach will allow for reduction in the problematic postoperative voiding dysfunction sometimes seen in open bilateral extravesical reimplantation. Of interest, this group has pursued and reported robotic reimplant approaches both intravesically and extravesically; they suspect that the greatest benefit may lie with extravesical approaches. To summarize all these reports, creating good exposure of the posterior bladder wall and avoiding injury to both the ureter and urothelium seem to be crucial advantages of this transperitoneal, extravesical approach.

Intravesical (transvesical) laparoscopic ureteral reimplantation

It has been shown by many groups that the intravesical space can be accessed with percutaneous laparoscopic ports and that carbon dioxide insufflation can create a 'pneumovesicum' appropriate for surgical procedures. With such an approach, authors differ as to how many ports they place, which port holds the camera, and whether there is a working instrument via the urethra or just a balloon catheter to prevent desufflation.

Initial attempts at intravesical reimplantation were reported by Okamura, Tsuji, and coworkers, replicating the Gil-Vernet technique of medial orifice advancement.[11] This innovative group accessed the bladder with two ports and used the urethra as a third access site to perform 'endoscopic trigonoplasty'. They were able to make an incision along the trigonal ridge and draw the ureters medially to the midline with sequential suturing. Their original experience (mostly adults), published in 1997, documented resolution in 95% of patients at 1–3 months, but this fell to 79% at 12 months.[12] They concluded from follow-up evaluation that progressive separation or splitting of the trigone, with lateral drift of the orifices to their original position, was often the cause of failure.[13] Cartwright et al reported on a variation of this same concept (percutaneous endoscopic trigonoplasty) shortly after this initial report[14] (Figure 45.1). This series of 23 children had reasonable initial resolution rates that fell significantly, with long-term follow-up of 30–37 months, to an unimpressive 47%.

The Japanese group has continued to assess technical changes to their procedure. In 2003, they reported on a procedure involving incision around the orifice in a U-shaped fashion, thus making a more significant flap of ureter and bladder muscle.[15] This flap is advanced distally onto the dissected trigone after the muscular hiatus is repaired to be certain that effective tunnel length is maximized. Reflux resolved in 12/14 ureters (86%) operated upon with mean operative time of 4 hours. We (Cartwright and Snow) also changed our original approach seeking better results. In 1999, we reported an intravesical cross-trigonal (Cohen) reimplant performed with the same two transvesical ports and a cystoscope[16] (Figure 45.2). This was performed in eight patients, with 83% long-term resolution. These results were more encouraging but are still significantly inferior to open approaches.

More recently, there have been three reports on intravesical laparoscopic approaches to reimplantation. Gill et al documented a cross-trigonal reimplant technique in three patients with operative times of 2.5–4.5 hours and no reflux postoperatively in two of the three patients.[17] Yeung and colleagues, as well, have reported on a laparoscopic Cohen reimplant done inside the bladder in 16 children (23 ureters).[18]

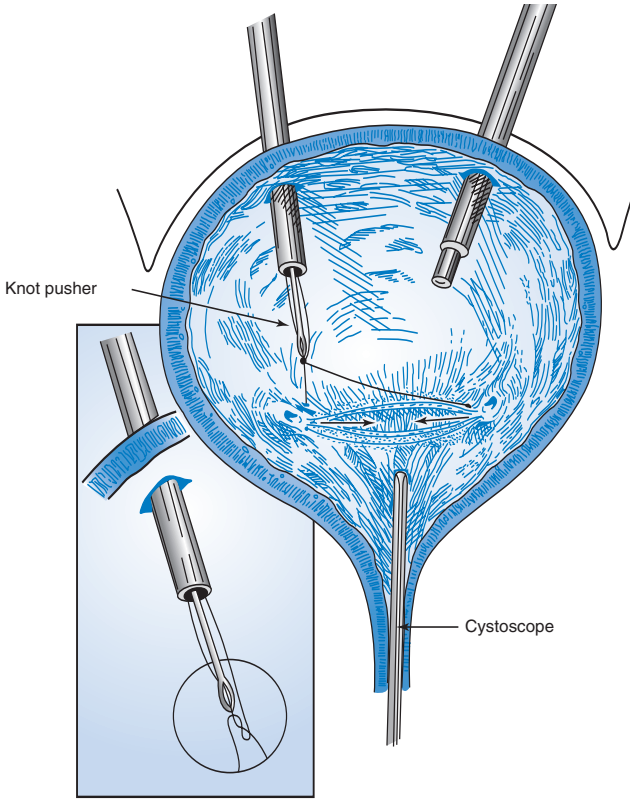

Figure 45.1 Percutaneous endoscopic trigonoplasty (PET): note the two working ports placed through the bladder wall superolaterally, and the cystoscope being used to assist and suction. Urothelium has been dissected, creating a muscular trough between the orifices; the suture being tied will advance each orifice toward the midline.

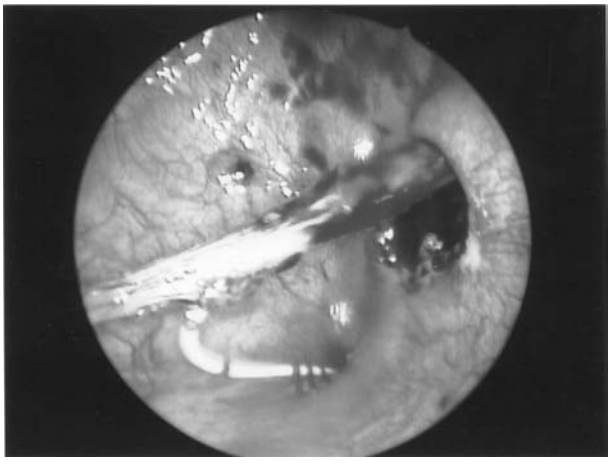

Figure 45.2 Intravesical view of a ureter mobilized via transvesical ports. The stent is coming through the bladder neck to enter the ureteral orifice; 3–4 cm of ureteral mobility can be achieved.

They report operative times of 1.9–3 hours for bilateral cases and had one conversion to open for trocar displacement from the bladder. They found minimal long-term complications, and patients had a mean hospital stay of 1.9 days, with a Foley catheter in place for 1–2 days.[19] The resolution rate was 96% at 3–4 month follow-up cystogram. Peters and Woo very recently added their experience with the da Vinci surgical robot in performing intravesical reimplantation. The ports required are 10–12 mm, with the sites dissected enough to place a suture into the bladder wall to prevent perivesical insufflation and to facilitate closure once the port is removed. Operating on 6 children with no open conversion, 2–4 day hospital stay, and 24-hour catheterization, they had 1 bladder leak from a port-site closure, and 5/6 with resolved reflux on early follow-up and no ureteral obstruction. For many of these authors, one challenge was getting secure closure at the bladder wall level once a port was removed; this was probably the cause for at least overnight catheter drainage in many cases. Another challenge noted by two of the authors was eventual accumulation of carbon dioxide within the perivesical space and a resultant decrease in intravesical working space as bladder walls were forced inward.

Future direction

Optics, instruments, and our own understanding and technical abilities with laparoscopic ureteral reimplantation will all undoubtedly improve over time. Smaller scars, less pain, and quicker recovery are all potential benefits of laparoscopic reimplantation, but these seem most pronounced in older children, adolescents, and adults and may be less apparent in younger children. Our own recent experience with open, unilateral, extravesical reimplantation is that 93% of children can be managed as outpatients, with a mean total hospital stay of just over 6 hours.[20] It seems likely that laparoscopic reimplants will need to be routinely achievable on an outpatient basis and without stents or catheters if they are to become mainstream in our management of reflux for the younger group of children that we most commonly treat.

Injection therapy for vesicoureteral reflux

46

Anthony A Caldamone

Introduction

Vesicoureteral reflux (VUR), the most common urologic abnormality in children, occurs in 0.4–1% of the general population and in 30–50% of those children who present with urinary tract infections (UTIs).[1] When correction of VUR is determined to be necessary, historically open ureteral reimplantation by a variety of techniques has been the mainstay of treatment. This approach is justified because surgical correction affords a very high success rate, approaching 99% in experienced hands, and a low complication rate.[2]

The search for a less-invasive approach to the correction of reflux, however, dates back to 1981 when Matouschek[3] first described the injection of polytetrafluoroethylene (PTFE) at the ureteral orifice to correct VUR. Reports then followed by McDonald and McDonald.[4] Following reports of the use of PTFE for incontinence, Politano reported on its use in VUR.[5–8] Puri and O'Donnell brought this clinical concept to the laboratory and demonstrated the successful correction of experimentally produced VUR in a piglet model by the intravesical injection of PTFE.[9] In their classic article in 1986, they reported on the successful endoscopic correction of primary VUR in 103 ureters, achieving a success rate of 75% after a single injection.[10] They termed this technique the STING.

This approach earned widespread international acceptance but only sporadic usage in the United States because of the lack of Food and Drug Administration (FDA) approval. It was quite apparent, however, that the potential for revolutionizing the management of children with VUR was real. Although the procedure requires general anesthesia and possible repeat injections, the ease of treatment, lack of open surgery, and minimal hospitalization were extremely attractive in the pediatric population. However, the lack of demonstrated long-term safety and concerns raised in experimental and clinical settings on the potential migration of PTFE particles prohibited its widespread acceptance in the United States. It was quite clear, however, that while the material had its drawbacks, the technique itself was reproducible and reliable. The search was on, therefore, for a substance that would fulfill the following characteristics: ease of injection, maintenance of injected volume, minimal host response, no evidence of distant migration of material particles, maintenance of the injected mound without shifting, and biocompatibility. The mechanism for the endoscopic correction of VUR involves one or more of the following effects: (1) improved backing of the intramural ureter, (2) fixation of the ureterovesical junction (UVJ) to the trigone by spot welding, or (3) decreased caliber of the distal ureter.

In this chapter we will review the substances that have been used both experimentally and clinically for the endoscopic correction of reflux. In addition to the use of this technique for primary VUR, the applicability of the endoscopic correction technique to other reflux variations will also be discussed. Finally, as with any new technology, one must address the issue of whether this new technology changes the indications for surgical correction of VUR.

Technique of endoscopic injection

The technique of endoscopic injection for correction of VUR has changed little since it was first described by O'Donnell and Puri.[11] The technique is relatively independent of the material used, although variations in material properties do exist, which result in minor modifications in technique, as will be described. The technique is often referred to as the STING, an acronym for subtrigonal injection (Figure 46.1).

Under cystoscopic control, the orifices and bladder mucosa are inspected. Whereas the type of cystoscope

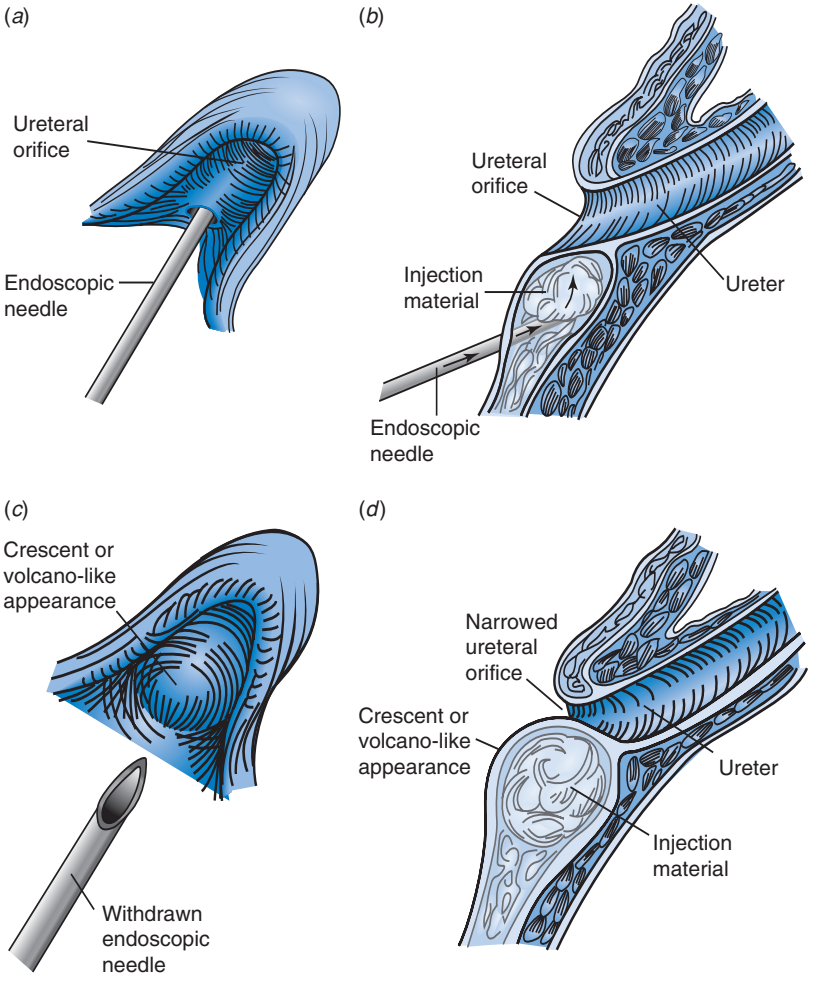

Figure 46.1 (*a*) Needle placed at 6 o'clock position, bevel upward. (*b*) Slow injection in subureteric space. (*c*) Postinjection appearance. (*d*) Appropriate position of injected material. (Reproduced from Russinko and Tackett,[12] with permission.)

Figure 46.2 Offset lens 'STINGER' scope, allowing for a straight 4 Fr channel to pass a rigid or flexible needle for injection of material.

is not critical, an offset lens system allows for a straight route for the needle through the scope, which is helpful if using a metal needle (Figure 46.2). The degree of bladder filling is critical, as a full bladder may make it more difficult to accurately place the material behind the ureter and still be in the wall of

Figure 46.3 Needle in 6 o'clock position at left ureteral orifice.

the bladder. Either a rigid metal needle or a malleable needle may be used, most commonly 3.7–4 Fr in size. A syringe of material is fixed to the needle and, depending on the thickness of the material, a ratcheted metal syringe holder may be needed. This is necessary for PTFE and silicone, in particular. The needle is introduced through a cystoscope using a 0° or 30° lens. Under direct vision the needle is advanced bevel-up and introduced submucosally at the 6 o'clock position of the UVJ (Figure 46.3). Puri and O'Donnell originally reported piercing the mucosa 2–3 mm distal to the UVJ and advancing the needle 4–5 mm into the lamina propria of the submucosal portion of the ureter. Alternatively, for more gaping orifices, the needle can be placed directly through the mucosa at the UVJ. This can be facilitated by hydrodistention of the ureter, by having irrigation flowing through the cystoscope at the time of the injection and thus dilat-

ing the ureteral orifice.[13] The critical step of the procedure is observing the effect from injection of 0.1–0.2 ml. One should carefully assess the positioning of the mound with this minimal initial injection. A 'volcanic' bulge should be observed, raising the ureteral meatus onto the dome of the mound. Minor adjustments in the direction of the bevel or the depth of the needle can be made based on the initial 0.1–0.2 ml injection volume. Once the appropriate effect is obtained, more material can be injected to achieve a volcanic mound with a crescent-shaped orifice at the dome (Figure 46.4).

Depending on the material injected, there is a variable degree of leakage from around the needle or through the needle track once the needle is removed. For PTFE or silicone, the needle should be left in place for 30–60 seconds prior to removal to avoid extrusion. At the conclusion of the injection(s), the bladder is then drained; viscous 2% lidocaine can be injected into the bladder if desired, prior to cystoscope removal. The patient is discharged from the recovery room on a therapeutic dosage of antibiotics for 3 days, followed by prophylaxis until a postoperative ultrasound and voiding cystourethrogram (VCUG) are done at 3 months. The presence of a well-positioned mound on ultrasound, while reassuring, does not predict successful correction of VUR (Figure 46.5). If reflux is resolved, antibiotic prophylaxis is discontinued and a follow-up ultrasound is done at 1 year.

Postinjection catheter drainage is generally not necessary. Most clinicians recommend antibiotic prophylaxis for 3 months until a follow-up ultrasound and VCUG are performed. If there is persistent VUR, a second endoscopic injection can be performed, especially if improvement has been demonstrated after the initial treatment. If failure occurs again, most clinicians would recommend open surgery. All studies to date have demonstrated the same high success rate of open ureteral reimplantation following endoscopic injection, regardless of the agent used, compared with a primary ureteral reimplantation.[14]

It is apparent to most surgeons who have performed endoscopic injection procedures for VUR that, whereas the procedure is relatively straightforward, there are subtle aspects of the technique that are learned over time. Kirsch et al demonstrated a learning curve over their first 180 cases. The success rate after a single injection for their first 20 patients was 60%, compared with 80% for the last 20 patients in this series.[15]

Kirsch et al reported on a variation in the Puri and O'Donnell technique in which material is implanted submucosally within the intramural ureter.[13] In a comparative study, they found the success rate with the modified technique to be significantly greater than the standard technique, 97% vs 79% (Figure 46.6).

Materials

Many materials have been used over the past 25 years of endoscopic treatment for VUR. Whereas success rates vary little from material to material, other properties – such as ease of injection, particle size and migration, inflammation response, longevity, and biocompatibility – vary greatly (Table 46.1). Materials may be divided into non-autologous and autologous.

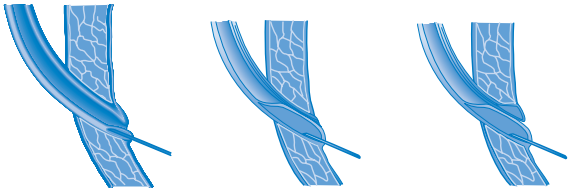

Figure 46.6 Modification of the STING procedure places implant material along the entire subureteral tunnel and leads to greater ureteral wall coaptation. (*a*) The needle is placed within the ureteral submucosa to the level of the mid-ureteral tunnel. (*b*) Initial injection causes the floor of the ureteral tunnel to rise up to meet ceiling of the tunnel. (*c*) Further injection leads to tracking of implant circumferentially within the ureteral tunnel, resulting in complete coaptation.[13]

Non-autologous materials

Polytetrafluoroethylene

In 1973 Berg reported a method for the correction of urinary incontinence using an injectable form of PTFE paste.[16] In 1981 Matouschek injected PTFE at the UVJ for the correction of VUR.[3] This was then first studied in an animal model by Puri and O'Donnell,[9] and then in human subjects.[11,17]

PTFE, a polymer composed of large molecules formed by chemical combinations of smaller ones into chains, has been used in the manufacture of plastic materials for medical devices for many years, including vascular grafts, cardiac valves/implants, stents, cartilage or bone replacement, sutures, and patches. The paste form of PTFE is a suspension of inert PTFE particles in a glycerin carrier. The glycerin, which represents 50% of the weight, is absorbed by the tissues after injection. The size of the particles ranges from 4 to 100 μm, with approximately 90% <40 μm. Because of its high viscosity, PTFE requires a ratcheted syringe mechanism for injection. Upon injection, a foreign-body giant cell reaction occurs with the infiltration of histiocytes, which is followed by a fibrous encapsulation.[10,18–20] The material is not biodegradable, and, therefore, should persist throughout a lifetime. Results of endoscopic correction of VUR with PTFE approach 90% after a single injection in some series and 94% after subsequent injections.[21,22] Long-term follow-up in a multicentered report indicate sustained effect for up to 10

Table 46.1 Characteristics of available injection materials

Product	Material composition	Particle size (μm)
Teflon, Polytef	Polytetrafluorethylene (PTFE) particles, which are inert and suspended in glycerin 50% by weight	4–100
Deflux	Dextranomer microspheres cross-linked in 1% sodium hyaluronan solution	80–120
Zyderm, Zyplast, Contigen	Derived from bovine dermis, cross-linked to glutaraldehyde: GAX 35, 35 mg/ml collagen; GAX 65, 65 mg/ml collagen suspended in pH neutral saline	–
Macroplastique	Polydimethylsiloxane (PDMS), a biphasic copolymer polymerized and vulcanized polydimethylsiloxane in polyvinylpyrrolidone (PVP) hydrogel	35–540; mean maximal diameter, 209 μm
Coaptite	Calcium hydroxylapatite spheres suspended in water and glycerin mixture with cellulose gel former	75–125
Urocol	50% microporous hydroxyapatite ceramic suspended in gel with 4% collagen in glycerin	100–400
Chondrocytes	Auricular chondrocytes suspended in an alginate solution with calcium salt	20×10^6 chondrocytes/ml
Fat	Suprapubic adipose tissue obtained by microliposuction	–
Autologous collagen	Extracted from dermis	–
Autologous blood	Extracted from patient	–
Autologous bladder muscle	Extracted from animal	–

Modified from Russinko and Tackett.[12]

years.[23,24] In this multicentered study the overall success rate in 6216 ureters and 4166 children treated at 18 European centers demonstrated a cure rate of 86% after 1–4 injections, with an obstruction rate of 0.0003%. In a 17-year follow-up of 247 patients treated with PTFE, Chertin et al demonstrated a sustained 95% success rate after 1–4 injections and a 5% recurrence rate, with 1.8% requiring open surgery.[25] In the meta-analysis review by Elder et al of 33 studies reporting on the results of PTFE, the overall success rate after a single injection was 67%.[26]

Experimental studies done shortly after the introduction of PTFE in clinical reports demonstrated the migratory property of PTFE as a result of a significant percentage of particles being <80 μm.[27,28] These particles become phagocytized and carried to regional lymph nodes or enter into capillaries directly upon injection. Experimental studies by Malizia et al have found particles in lymph nodes and distant organs.[29,30] Particle migration has also been reported in humans,[28,31–33] including, in a speculative report, to a child's cerebral microcirculation and associated with an ischemic stroke.[34] Some clinicians have argued that particle migration is at least partially related to the volume of injection; however, clinical reports indicate that particle migration has occurred with small volumes of 0.5 ml of PTFE.[35]

The potential of carcinogenesis with PTFE and other non-autologous substances has been of concern. Although there has not been direct evidence of carcinogenesis with PTFE in an experimental model,[36] there has been experimental evidence linking injected foreign substances of large particulate size to potential carcinogenesis.[37]

Cross-linked bovine collagen

Cross-linked bovine collagen has been used for multiple medical purposes such as cardiac valves, hemostatic agents, sutures, and as a soft tissue substitute. It is harvested from bovine hide and treated with pepsin to reduce its antigenicity associated with the telopeptides of the collagen helix. It is composed of 95% type I collagen and 5% type III collagen. It is cross-linked with glutaraldehyde to reduce breakdown after implantation by human collagenases. For human implantation, several products have become available (Contigen, Zyplast, Zyderm, GAX 35, GAX 65).

Upon injection, collagen causes very little local tissue reaction and no granuloma formation. To variable degrees, there is an ingrowth of fibroblasts and eventual replacement with native collagen.[38–40] The degree to which native collagen ingrowth occurs is thought to determine the potential for long-term cure.

Table 46.2 Results of endoscopic treatment of vesicoureteral reflux with collagen

Authors	No. of ureters treated	Percent success, after one injection

Modified from Läckgren et al.[53]

Collagen is injected easily with finger pressure, with no special device required. However, as a result of this relatively low viscosity, precise injection may be more difficult. Preinjection skin testing is necessary, as 3% have a hypersensitivity reaction to collagen, although a negative reaction does not completely eliminate the risk of an allergic reaction.[41] As noted in Table 46.2, the initial success with the endoscopic injection of collagen is similar to that of other materials. However, several reports indicate poor sustained results. Haferkamp et al reported an initial success of 92% after a single injection in 36 children, with a recurrence of reflux in 91% after 37 months.[47] In a similar study, the recurrence rate was 63%.[48] The use of a more concentrated mixture of 65 mg collagen/ml (GAX 65) has shown promise of a more sustained cure in a report by Frey et al, where a 6-month evaluation postinjection demonstrated more retained volume, 26.9% vs 0.1% for GAX 35.[52] Reunanen et al reported on 197 ureters treated with endoscopically implanted collagen in which 84% remained without reflux at 4 years follow-up.[43] De Grazia and Cimador reported a 16.8% recurrence rate in 129 refluxing ureters injected, with higher rates of recurrence in the higher initial grades of VUR.[49]

Polydimethylsiloxane

This bulking agent is composed of particulate silicone in an injectable mixture of fully vulcanized polydimethyl-

siloxane (40%) suspended in a water-soluble polyvinylpyrrolidone (60%). The particulate size ranges from 35 to 540 μm (average 209 μm) with 28% <80 μm and 7% <50 μm.[53] It is not surprising, therefore, that studies by Buckley et al[54,55] and Henly et al[56] found particle migration to the lungs, kidneys, brain, and lymph nodes after injection in animal models. It has been shown that particulate size <80 μm facilitates particle migration.[29] Shedding of silicone particles with migration has been reported from implanted medical devices.[57] The advantage of particulate silicone is there appears to be less inflammatory response and granuloma formation, although those findings have not been consistent. Silicone is non-biodegradable and, therefore, should be permanent once injected at the UVJ. Similar to PTFE, a ratcheted mechanism is required for injection. The injection of silicone induces an inflammatory response with macrophages and fibroblasts and later ingrowth of collagen.[58]

Silicone has been implicated in autoimmune reactions[27,56] and associated with a possible risk of malignancy,[38,59–61] although the data for the latter have been inconsistent.[62] Multiple studies have demonstrated the reproduced effectiveness of injected particulate silicone to correct reflux.[53] Herz et al demonstrated a success rate of 81% after a single injection and 90% of ureters after repeated injection with a 12-month follow-up.[63] In a 1-year follow-up study from two centers, van Capelle et al reported success with the endoscopic implantation of silicone in 155/195 children treated, representing 82.3% of ureters injected one or more times.[64] Aboutaleb et al compared particulate silicone injection versus extravesical ureteral reimplantation for primary low-grade reflux (grades I–III) in 180 patients, 74 silicone injections and 106 extravesical reimplantations.[65] Of the injected group, 81% were cured at 3 months and 92% at last follow-up compared with 96% at 3 months and 99% at 1 year in the reimplantation group. There were no complications in the injected population, whereas 7% of the reimplanted group had postoperative complications, including 3.3% (2 patients) with transient urinary retention. In summary, silicone appears to be an effective agent for the treatment of VUR. Concerns remain regarding its particle size, and, therefore, its migratory potential, as noted in experimental studies.

Dextranomer/hyaluronic acid copolymer

Dextranomer microspheres were first introduced by Stenberg and Lackgren in experimental models in which 1 ml was placed into the abdominal wall of rats and into the bladder wall of piglets.[66] At 3 months, the implants became encapsulated, with a 23% reduction of the injected volume. Repeat studies performed with radiolabeled dextranomer spheres demonstrated no evidence of distant migration, lymphadenopathy, mutagenic effect, DNA changes, or tumor development.[67] The larger particulate size of the dextranomer/hyaluronic acid (Dx/HA) copolymer compared with PTFE and silicone is thought to account for the fact that it is not phagocytized, and, therefore, its lack of particulate migration to distant organs.

The Dx/HA copolymer is a solution of cross-linked dextranomer microspheres (80–250 μm in diameter) suspended in a carrier gel of stabilized sodium hyaluronate.[51] Dextranomers have found previous uses in medicine for wound healing, and sodium hyaluronate has been used for eye surgery and joint injection. The Dx/HA copolymer differs from other non-autologous materials such as PTFE and silicone in that it is biodegradable. Its volume stability over time results from fibroblast migration and collagen ingrowth between the dextranomer microspheres (Figure 46.7), as the hyaluronate dissipates 12 weeks after implantation.[68] It is injected with a standard syringe mounted on an endoscopic needle with finger pressure. In animal studies, carried out for 3 years, the durability of the spheres has been demonstrated without granuloma formation or calcification.[66,69]

The overall results with Dx/HA copolymer compare favorably with that of PTFE and silicone, as

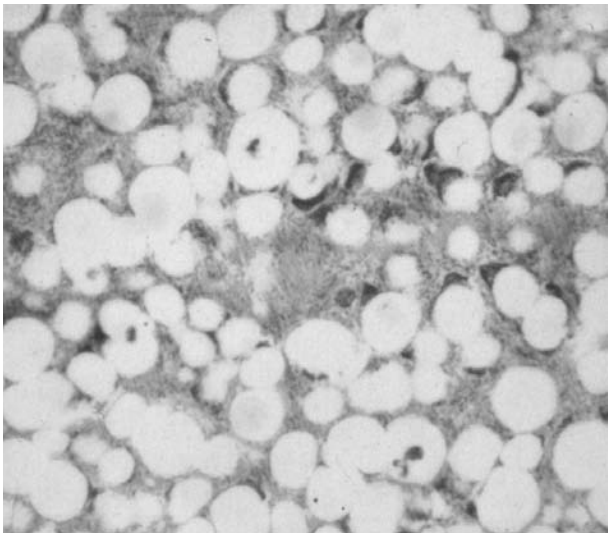

Figure 46.7 Ingrowth of native fibroblasts around dextranomer microspheres. (Reproduced from Stenberg et al,[68] with permission.)

Table 46.3 Results of the endoscopic treatment of vesicoureteral reflux with the dextranomer/hyaluronic acid (Dx/HA) copolymer

Authors	No. of ureters treated	Percent success, after one injection
Stenberg and Läckgren[66]	115	69
Capozza et al[70]	52	71
Oswald[71]	55	77

Puri[72]	166	>86
Kirsch[15]	134	72
Capozza et al[46]	1050	82[a]

[a] Reported only after multiple injections.

noted in Table 46.3, which lists the results after a single injection. In a long-term follow-up study by Läckgren et al of 221 children followed for a mean of 5 years, 68% of patients (75% ureters) maintained grade 1 VUR or less and 81% (85% ureters) grade 2 VUR or less at the last VCUG done. Of 49 patients who had a VCUG at 3–12 months, reflux recurred in 13%, 4% of which were grade 3 or greater.[14] No long-term adverse effects were noted, with 2% developing postoperative UTIs, and early mild postoperative hydronephrosis occurring in 4 patients, none of whom developed signs of ureteral obstruction. In a study comparing Dx/HA copolymer and silicone, Oswald et al reported a slightly higher success rate with silicone, but the difference was not statistically significant.[71]

Coaptite

Calcium hydroxylapatite is composed of calcium hydroxylapatite spheres suspended in a water and glycerin mixture with 3% methylcellulose gel. Calcium hydroxylapatite particles are synthetic, and, therefore, a uniform spherical shape with a narrow range of 75–125 μm. This material represents synthetic bone, and, therefore, as a subureteric bulking agent, theoretically it should have a limited local reaction and a very durable long-term effect. A clinical trial by Mevorach et al on 98 patients and 155 ureters with grade II–IV reflux demonstrated reflux resolution in 67% of patients and 75% of ureters, and improvement was noted in 77% of patients and 84% of ureters.[73] Interestingly 5 patients in this particular subgroup demonstrated progression, from improvement in reflux grade postinjection at 1 year to reflux resolution when evaluated with a VCUG at 2 years. The procedure was tolerated well by all patients and there were no significant safety issues disclosed. Calcium hydroxylapatite, therefore, is determined to be a safe, durable, and effective material for the endoscopic treatment of reflux, although at this time clinical trials are still being evaluated by the FDA.

Autologous materials

Autologous materials have the appeal of not having the concern of a foreign body reaction to the injected mound. The disadvantage, however, is the need for a harvesting step, which, with all materials tried to date in the pediatric population, requires an additional anesthetic. These autologous materials must behave as free grafts, and, therefore, are subject to the physiology of graft survival. To date, the autologous materials that have been tried are chondrocytes, collagen, and fat.

Chondrocytes

Following demonstration that the harvesting and subsequent implantation of autologous chondrocytes resulted in viable chondrocytes, first in the mouse model and later in the pig model by Atala,[74,75] Diamond and Caldamone used harvested chondrocytes in the human model.[76,77] Chondrocytes were harvested from the posterior auricular cartilage, grown in culture for 6 weeks, suspended in an aqueous mixture of alginate and calcium salts, and subsequently injected at the UVJ. Long-term results of 47 ureters with grade II–IV VUR demonstrated an 80% cure rate at 3 months and an 86% cure rate at 1 year following one or more implantations. In those children requiring a subsequent open ureteral reimplantation, no viable chondrocytes were identified, however. It was unclear whether the failure to correct the reflux was attributed to a failure of chondrocytes survival, or whether this was a more universal effect. In those children who underwent a second injection or open reimplantation after a failed injection, the most common findings were shifting of the materials and a loss of material volume.[77]

Fat

Autologous fat has been used as an implant for correction of reflux. It was initially reported in an experimental model by Matthews in 1994, followed by clinical reports by Palma and Chancellor.[78–80] In

Table 46.4 Overall resolution rate after single injection based on ureter and material

Agent	Number in studies	Sample	Percent resolution

3	22	477	72.3
4	17	172	62.6[a]
5	9	25	50.9[a]

[a] Grade 4 and 5 significantly decreased with respect to grades 1 and 2.
From Elder et al.[26]

follow-up studies at 3 months postimplantation, reflux persisted in 70% of Chancellor's study group and 83% of Palma's group. Viability appears to rely on vascular ingrowth to the injected cells and, therefore, small volumes injected appear to be more effective in survival. In the rabbit model by Matthews, there was a 25–100% loss of volume postinjection in 47% of sites injected.[78]

Collagen

Cendron et al reported on the use of autologous collagen as an injectable material for correction of VUR.[81] The rationale for the use of autologous collagen is to improve on the longevity of bovine collagen preparations, as well as to avoid the hypersensitivity potential. Collagen fibers were isolated by centrifuge from the dermis. In an experimental study, collagen integrity was demonstrated at 50 days.

Muscle

Autologous bladder muscle cells have been used in an experimental study to correct reflux.[82] Muscle cells were harvested from the bladder, coupled with an alginate mixture, and reinjected through a 21-gauge needle. Cell survival was demonstrated in a short-duration study.

Cumulative results

Endoscopic treatment for VUR in children has a high success rate (Table 46.4). The success rate is universally proportional to the grade of reflux treated (Table 46.5). Multiple injections are advantageous in increasing the success rate and prior endoscopic material implantation does not appear to significantly alter the open surgical success rate.

Special considerations

Neuropathic bladder

A significant number of patients, upwards of 50%, with spina bifida have associated VUR. This can be a cause of significant morbidity and renal damage in this population. The mainstay of management of VUR in association with a neurogenic bladder has been modulation of bladder pressures and frequent complete emptying. This is usually accomplished by a combination of intermittent catheterization with or without the addition of anticholinergic therapy and/or suppressive antibiotics. When children fail this regimen, treatment has been bladder augmentation with or without ureteral reimplantation. Some articles

Table 46.6 Results of reported series of the endoscopic treatment of vesicoureteral reflux in children with neuropathic bladder

Authors	Material	No. of ureters	Success rate after one or more injections	Recurrence rate per corrected ureter
Haferkamp et al[48]	Collagen	26	24/26	15%
Granata et al[83]	Polytetrafluoroethylene	40	72.5%	2/29
Engel et al[84]	Polytetrafluoroethylene	60	56.7%	–
Misra et al[85]	Polydimethylsiloxane	69	82%	4/57
Yokoyama et al[86]	Collagen	13	100%	5/13
Sugiyama et al[87]	Polytetrafluoroethylene	4	75%	–
Kaminetsky and Hanna[88]	Polytetrafluoroethylene	20	70%	–
Dewan and Guiney[89]	Polytetrafluoroethylene	29	23/29	4/23
Puri and Guiney[90]	Polytetrafluoroethylene	15	12/15	–
Perez-Brayfield et al[91]	Dextranomer	9	78%	–

have advocated the addition of endoscopic correction of reflux to the armamentarium for management of VUR in the setting of the neurogenic bladder (Table 46.6). Technically, this can be more difficult to perform because of the trabeculation of the bladder, and a ureteral catheter in the orifice at the time may facilitate injection. However, in spite of these difficulties, success has been reported in up to 90% of cases after multiple injections.[85,90,92,93] Engel et al reported success in 57% of reflux in ureters after a single injection of PTFE and 62% after a second injection.[84] They compared this to their open surgical population, in which they were able to achieve an 84% success rate in 30 patients undergoing ureteral reimplantation. Haferkamp et al found that the long-term success rate using collagen (GAX 35) was only 15% of treated units after 24 months.[48] Part of that fall off in success rate could be a result of the degeneration of collagen, but also may result from the inherent neuropathic disorder. It is imperative that, once these children are treated endoscopically or with open surgery, continued bladder management is carried out in order to prevent long-term complications such as the recurrence of reflux or functional UVJ obstruction. Similarly, Dewan and Guiney reported 4 of 23 successfully treated ureters recurred after initial treatment was successful.[89] Granata et al reported a comparative study on surgical and endoscopic correction of reflux in children with a neuropathic bladder.[83] They found an overall success rate of 72.5% using PTFE, compared with 95.5% when a Cohen cross-trigonal ureteroneocystotomy was performed. They found that 2 of their 29 ureters that were cured with the endoscopic approach reccurred with VUR; however, both were treated successfully by a repeat endoscopic procedure. There were no recurrences observed in the patients cured by open reimplantation. In a meta-analysis recorded by Elder et al of 10 articles, there was a significantly lower rate of success of the endoscopic approach in the neuropathic bladder (53.5%) vs the non-neuropathic bladder (74.2%).[26]

Dysfunctional voiding

Studies by Frey,[38] Trsinar,[94] and Capozza[44,95] have implicated undisclosed dysfunctional voiding as a cause of failure of endoscopic correction of VUR. In each of these cases the authors found displacement of the mound, a common occurrence using either collagen or dextranomer microspheres. In each of these studies, however, the diagnosis of dysfunctional voiding was based on clinical history and not urodynamic findings, representing some limitation to their conclusion. The implication from these studies, therefore, would be to control or at least stabilize the dysfunctional voiding prior to the endoscopic correction of the reflux. Several studies have pointed out that management of dysfunctional voiding in refluxers improves the spontaneous resolution rate and decreases the need for ureteral reimplantation.[96,97] Lackgren and Stenberg noted, however, that when the endoscopic correction of reflux in children with dysfunctional elimination syndrome was undertaken, they found an overall cure rate of 65% across all grades of reflux, indicating no particular difference as to whether or not preinjection bladder retraining had been undertaken.[98] Of 35 patients that were cured of their reflux on a single injection, 8 continued to have

evidence of minor bladder dysfunction, whereas 27 appeared to have completely resolved their symptoms of bladder dysfunction. This may indicate a potential role of the reflux in either the causation or the promotion of bladder dysfunction in this particular population.

Duplicated systems

More experience is being gained in the use of injectable materials for duplicated systems. At one time, a duplicated system was considered to be a relative contraindication to the use of injectable material;[99] however, several reports have now indicated that, with experience, the success rate for the endoscopic correction of reflux in the duplicated system approaches that of a single system. Miyakita et al[101] reported on their results with the use of PTFE in both partial and complete duplication. Their success rates were 87% in partial duplication and 59% in complete duplication. Similarly, Steinbrecher et al reported a cure rate of 68% in completely duplicated systems using PTFE.[101] Dewan and O'Donnell reported on 32 children with duplex systems and VUR treated endoscopically with PTFE.[102] They were able to cure VUR in 21/32 patients. In the meta-analysis by Elder et al, the success rate of endoscopic correction for duplicated systems was 50% compared with 73% for non-duplicated systems.[26] Perez-Brayfield et al reported a 73% success rate in using dextranomer microspheres for the endoscopic correction of reflux and completely duplicated systems.[91] Lackgren et al reported on the use of Dx/HA copolymer and duplicated systems, and found a 63% success rate, defined by improvement to grade 0–1.[103]

It should be pointed out, however, that the technique of the injection varies with the anatomy. For those completely duplicated systems in which there is wide separation of the ureteral orifices, and, therefore, more likely to reflux just to the lower pole, separate injections under each orifice are recommended. However, for those duplicated systems where the orifices are closely approximated, a single injection may suffice (Figure 46.8).

Aboutaleb et al compared the results with polydimethylsiloxane injection vs open surgery for the treatment of VUR in duplex systems.[104] The open surgical approach for reflux in this study was extravesical common sheath ureteral reimplantation. The endoscopic injection of polydimethylsiloxane was performed in 15 patients with 22 refluxing units. The success rate for the endoscopic correction was 68% at 3 months, 82% at 12 months, with 1 patient developing contralateral VUR. There were no cases of de-novo hydronephrosis or UTIs postoperatively. This compared with the success rate of extravesical common sheath ureteral reimplantation of 96% at 3 months and 97% at 15 months. The authors concluded that whereas injection therapy was highly successful in patients with low-grade VUR in duplex systems, it still fell short of the open surgical cure rate.

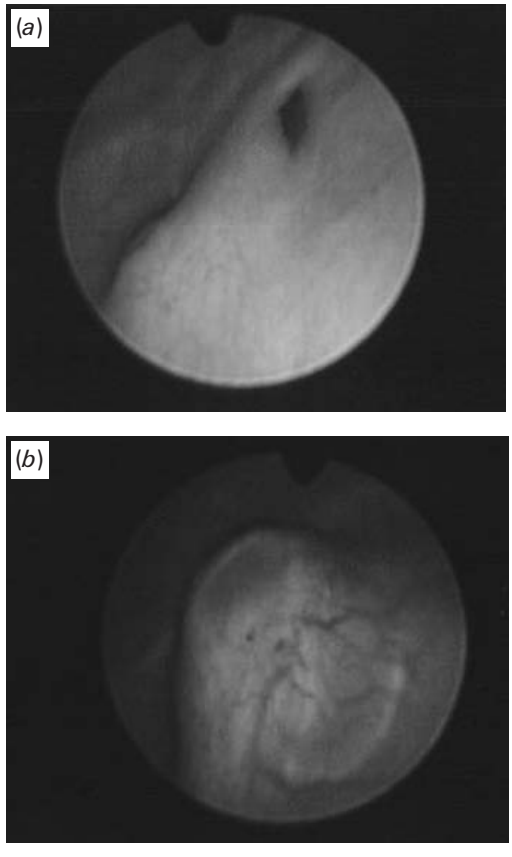

Figure 46.8 (*a*) Duplicated left ureters with lower pole reflux. (*b*) Mound under lower pole refluxing orifice.

Paraureteric diverticulum with VUR

Bladder diverticulum can be found in association with VUR. Whereas those diverticulae which are small have a similar spontaneous resolution rate as primary VUR, moderate to large diverticulae, which usually lie lateral and cephalad to the ureteric orifice, will often drag the orifice into the diverticula on filling or voiding. This relationship portends a poor spontaneous resolution rate. The presence of a paraureteric diverticulum that is associated with reflux presents a significant challenge to the accurate placement of material at the UVJ endoscopically. Perez-Brayfield et al[91] report on six such cases, with a respectable success

rate of 67% using the Dx/HA copolymer. It appears that with experience, therefore, the presence of a paraureteric diverticulum represents only a relative contraindication to endoscopic treatment. Puri and Lackgren (pers comm) have stated that a modified technique to this anatomy is needed, in which the material is injected beneath the ureteric orifice for a longer length into the diverticulum.

The refluxing ureteral stump

There have been isolated reports of success using the endoscopic approach for the refluxing ectopic ureter, refluxing ureteral stump, and reflux after transurethral ureterocele incision.[91,105,106] The results in the ectopic ureter, however, have been very disappointing to date.[92] This may also be true for the refluxing stump, which is often ectopic at or below the bladder neck, although there have only been a few reported cases.[106,107]

Failed ureteral reimplantation

From the report of the American Urological Association Pediatric Vesicoureteral Reflux Guidelines Panel, the success rate for correction of reflux by open ureteral reimplantation ranges from 80 to 99%, based on the grade of reflux.[107] Overall, the incidence of persistent reflux is generally 2% and the incidence of ureteral obstruction is 2%. Reoperation for the failed ureteral reimplantation can be a difficult procedure, with a significant complication rate.[108] There have been reports on the use of the endoscopic approach to reflux correction for the failed ureteral reimplantation.[91,109–111]

Kumar and Puri reported on 31 children with persistent reflux with 40 persistently refluxing units after failed ureteral reimplantation.[109] These patients represented a diverse group of refluxers, including primary refluxers, duplicated systems, reflux secondary to neuropathic bladder, posterior urethral valves, ureterocele, bladder exstrophy, and UVJ obstruction. Twenty-seven of 40 persistently refluxing units were cured after a single injection of PTFE, 7 refluxing units required two injections, and 4 required three injections for correction of the reflux. Failure to correct reflux by endoscopic correction was noted in 2 ureters of one patient with bladder exstrophy. In the report by Gaschignard et al, 1 of 12 patients developed a late meatal stricture, occurring 2 years after endoscopic correction following a failed ureteral reimplantation.[111] Perez-Brayfield et al reported on 17 patients who had failed open surgical correction of reflux. The success rate with endoscopic correction in this group was 88%.[91] Capozza et al reported success in 12 of 18 ureters with endoscopic treatment after failed ureteral reimplantation.[44] In a review of 9 studies and 80 ureters, Elder et al reported a cumulative success rate of 65% for endoscopic injection after failed ureteral reimplantation, compared with 74% in the non-reimplanted ureter.[26]

Complications

The risk/benefit ratio for endoscopic correction of reflux remains very low. Specific complications related to inherent material properties have been mentioned, such as particle migration with PTFE and with polydimethylsiloxane. Other specific concerns have been raised, such as malignant degeneration with PTFE or the development of connective tissue disorders with polydimethylsiloxane.[61,112–115]

More generic complications, such as ureteric obstruction, have been reported infrequently. Engel et al reported obstruction in a single ureter after the endoscopic implantation of PTFE in their series of 60 injected ureters.[84] In the reported series by Capozza et al of 1244 patients injected with a variety of materials, 8 (0.006%) developed temporary obstruction, 2 requiring a double-J stent.[44] In their meta-analysis, Elder et al noted a very low incidence of post-injection hydronephrosis (Table 46.7).[26] Other outcomes such as UTIs, febrile or not, do not appear to occur with an increased frequency over that seen with open ureteral reimplantations: 6.4% in a meta-analysis of 11 studies, 0.7% for febrile UTI, and 6% for cystitis.[26]

The development of contralateral denovo VUR following reflux correction may be troublesome.[116] Studies by Ross et al indicate a 35% risk of contralateral VUR after unilateral open correction if there has been a remote history of contralateral VUR.[117] Hoenig et al reported an incidence of contralateral VUR occurring in 17% of cases after unilateral open correction similar to that reported by other surgeons.[116,118–120] Following the endoscopic correction of reflux with PTFE, Kumar and Puri reported the contralateral denovo VUR rate to be much lower, at 7%.[121] Similarly, Kirsch et al reported its occurrence in 4.5% with Dx/HA copolymer.[15] This would led credence to the theory of trigonal distortion during open reimplantation rather than a pop-off mechanism theory as the etiology for denovo postoperative VUR.[122]

Table 46.7 De-novo postinjection hydronephrosis based on material used: a meta-analysis

Material	Denovo hydronephrosis/total number[a]	No. requiring intervention[a]
Polytetrafluoroethylene	34/3616	19
Collagen	2/947	0
Polydimethylsiloxane	4/347	3
Dextranomer	2/385	2

[a] From Elder et al.[26]

Recurrence of vesicoureteral reflux

Recurrence after proven correction of reflux remains an issue with certain materials. The difficulty is determining a firm and reliable figure for this, as only selected series have performed a VCUG beyond the initial negative study. In addition, one must distinguish between a maintained clinical cure (i.e. no febrile UTIs) and a proven long-term cure by a negative VCUG. Chertin et al reported on 247 patients who were treated for VUR with PTFE and followed for 17 years.[25] They reported a recurrence rate of 5%, with 1.8% requiring open ureteral reimplantation. Capozza et al reported on their long-term experiences with bulking agents – specifically PTFE, collagen, and dextranomer – in 1244 patients, all of whom had a VCUG at 3 and 12 months postinjection. They found that a significant percentage of those patients who relapsed had evidence of voiding dysfunction by micturation questionnaire.[44] Lackgren et al reported their long-term results with the use of Dx/HA copolymer in 221 children who had a VCUG at 3 and 12 months postinjection.[14] In addition, a later VCUG was performed in 49 patients 2–5 years after initial treatment. Reflux on the late VCUG occurred in 13% of those previously cured. It is unclear how many, if any, of those late recurrences were symptomatic.

Haferkamp et al reported on the use of a second collagen injection in 16 children with 21 ureters, with a failed first injection.[48] They found that the reflux was cured after a second injection in 17/21 ureters. Of those cured with a second injection, a repeat VCUG was performed every 6 months, with a mean follow-up of 11 months. Of these patients, 8 ureters remained reflux free, whereas in 9 units the reflux recurred. The authors noted that the interval to recurrence of reflux was longer after the second injection compared with the first injection. In a similar report, Haferkamp et al found that of 55 renal units successfully treated with collagen, only 5 (9%) remained reflux free after 37 months of follow-up.[48] Other studies have shown a more modest recurrence rate of 11–16%.[49] In a report of 132 children, Frey et al reported late reflux recurrence in 11.3% of 204 renal units treated with GAX 35 collagen.[42] In the meta-analysis study by Elder et al, the probability of recurrence for all agents used was 8%.[26] Overall, it appears that collagen carries a higher recurrence rate than other bulking agents that have been followed with a VCUG beyond 1 year postinjection, with the lowest recurrence rate from PTFE.

Reasons for failure of endoscopic treatment

Whereas most series have demonstrated a high success rate for the endoscopic subureteric injection for the treatment of VUR, very few have discussed the reasons for failure. The mechanisms of failure of endoscopic correction of reflux can be divided into three categories:

- technical factors
- bladder dynamics issues
- individual physical properties of the particular material used.

Technical factors include anatomic abnormalities of the UVJ or bladder, including duplicated systems, paraureteric diverticulum, a trabeculated bladder, either from neuropathic origin, or obstructive origin, be it functional or anatomic, or a previously reimplanted ureter. In addition, the position of the orifice can certainly be influenced by the degree of fullness of the bladder, making the injection zone for the material larger or smaller. It is also theoretically possible that – with the bladder relatively empty at the time of the injection, as is the standard recommendation – when the bladder fills, the mound and orifice may not have the same relationship to each other.

Factors relative to bladder dynamics include scenarios where elevated bladder pressure is present, such as seen in the neuropathic bladder, the previously obstructed bladder, or in dysfunctional voiding. It is theoretically possible that in the face of elevated bladder pressures from whatever etiology, the shifting of the mound may be possible from the pressure itself. Capozza et al implied that voiding dysfunction could contribute to endoscopic injection failure.[44] They theorized that elevated intravesical pressures could displace or shift the injection mound or cause migration from the original site of implantation. They found, in retrospect, that a high percentage of those patients that had failed initial endoscopic treatment had evidence of voiding dysfunction on clinical evaluation. Therefore they advocated that voiding dysfunction be addressed prior to undertaking the endoscopic treatment for reflux. Trsinar et al also observed displacement of failed injection mounds and theorized that this was due to voiding dysfunction, although there were no urodynamic studies or voiding diaries presented.[94]

Specific material properties may also play a role in the failure of endoscopic correction of reflux. Materials that have been utilized have a variable degree of longevity. Loss of material can occur either by absorption of the carrier substance that is used for the specific material, as seen with glycerol for PTFE, hyaluronic acid with dextranomer particles, alginate solution with chondrocytes, or aqueous gel with calcium hydroxylapatite. These materials will be absorbed in a variable amount of time from the implant site, decrease the site of the injection mound, and, therefore, possibly hinder the mechanism for ureteral closure or insufficient support of the intramural ureter. In addition, there is an intrinsic material biodegradability that plays a role with certain substances. Collagen is known to have a significant loss of volume over time and its long-term success is thought to be due to the development of natural collagen to replace the resorbed injected collagen. Haferkamp et al[49] demonstrated a low rate of long-term success with collagen in that after 37 months only 5 out of 57 ureters previously corrected with a single injection remained cured. Similarly, dextranomer microspheres have some degree of biodegradability, which eventually should be replaced by the ingrowth of native fibroblasts.

The ability of a particular material to weld at the injection site may be a factor in the long-term success as well. Materials that tend to create an inflammatory response may be more likely to stick to the site of the injection. The viscosity of the material may also be a factor that may or may not allow it to easily leak through the needle track of the injection site.

When dealing with autologous materials, as previously mentioned, free graft issues come into play. The ability of fat, collagen, muscle, or chondrocytes to grow in their new location may require some of the same principles of imbibition and inosculation as with larger tissue graft physiology. This was shown in the report by Diamond et al on autologous chondrocytes in which those mounds that were explanted at the time of ureteral reimplantation failed to demonstrate viable chondrocytes.[123]

Several studies have documented that in those cases where observation of the injection site was possible after a failed implantation, displacement appeared to occur quite frequently (Figure 46.9). In a series reported by Diamond et al on cystoscopic examina-

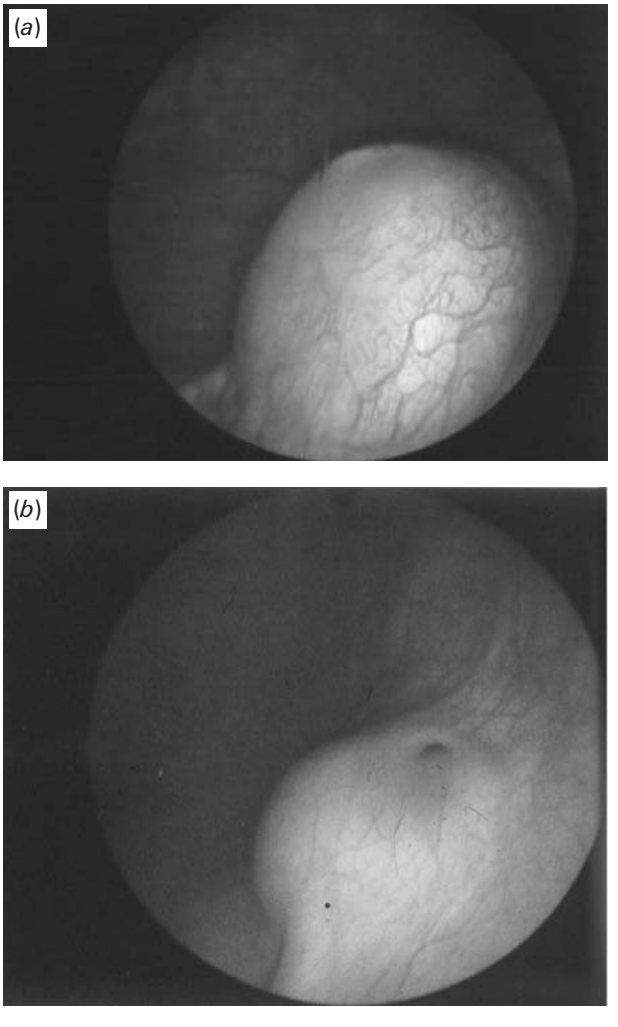

Figure 46.9 Mound shifting or displacement. (*a*) Appearance of mound and left ureteral orifice at time of initial injection. (*b*) Appearance at time of reinspection for persistent VUR on VCUG.

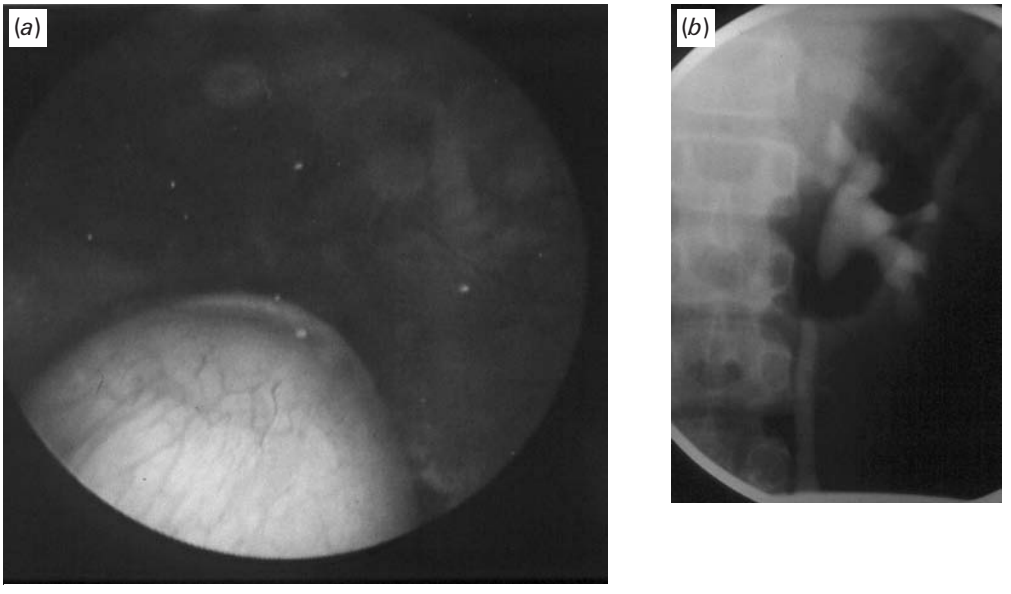

Figure 46.10 Perfectly injected mound with persistent VUR on VCUG classified as an indeterminate failure. (*a*) Mound on recystoscopy. (*b*) VCUG demonstrating left VUR.

tion of patients who had failed subureteric injection with autologous chondrocytes, it was noted that 35% had mound shifting, 25% had shifting and volume loss, and 13% had isolated volume loss. It appeared that the most frequent direction of mound shifting was distally and medially towards the bladder neck from the original injection site.[123] Eleven percent of their population, however, were classified as indeterminate: i.e. there was failure on postoperative VCUG to resolve the reflux but the appearance of the mound on cystoscopic or intraoperative inspection was perfectly normal (Figure 46.10). Other studies also found that either mound displacement or absence of a mound were the most common causes of failures on reinspection either cystoscopically or by open surgery of failed primary injections.[63,124–126]

Few studies have focused on failures from the injection of the dextranomer microspheres. Capozza et al reported on 45 failures with Dx/HA copolymer, and found 60% had mound displacement and 33% had absence of the mound on reinspection.[127] They reported a high percentage of their cases with failed dextranomer microspheres and suspected high intravesical pressures noted by voiding diaries. In 2 cases, however, there was a unilateral cure and contralateral mound displacement. It is uncertain as to whether this represented a technical failure or an anatomic failure. However, it is unlikely that they represented abnormal bladder physiology. Kirsch et al[15] reported on 18 patients who underwent reinjection for primary failures, and found that 61% had shifting of the mound away from the injection site. In the remainder of patients, the mound was either absent or present, and, therefore, indeterminate.

Conclusion

With a technology that is reproducible and at least a single agent that is widely available for endoscopic correction of reflux that appears safe, the obvious question that is raised is where does this fit in the management of children with VUR? This question must be addressed in light of the present day concerns for the use of long-term antibiotics with growing patterns of resistance. Studies have questioned the effectiveness of long-term antibiotic prophylaxis,[128] and the potential for long-term complications.[129] In this regard, Stenberg et al have proposed an algorithm which includes a shorter term of antibiotic prophylaxis, based on the child's age and grade of VUR, with endoscopic treatment with Dx/HA copolymer, as seen in Figure 46.11.[130] The use of Dx/HA copolymer has been shown to be a cost-effective alternative to open surgery for persistent VUR in children on a prophylactic antibiotic program.[131]

The effectiveness of endoscopic therapy requires that its approach be presented to parents as an upfront treatment in lieu of antibiotics. However, there has been a paucity of studies looking at long-term outcomes in a comparative analysis between antibiotic therapy and endoscopic correction. Studies

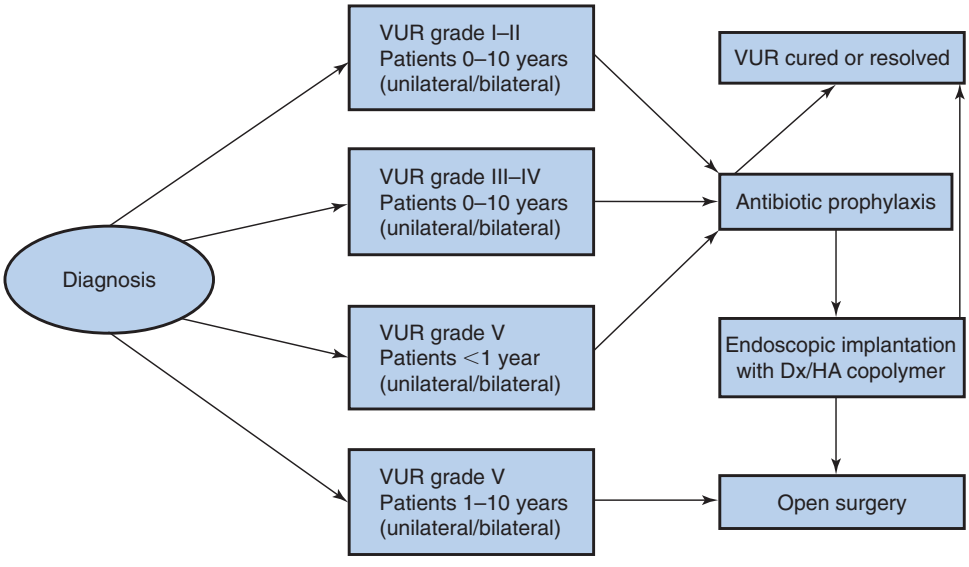

Figure 46.11 Algorithm proposed by Läckgren et al for the management of VUR in children, incorporating an endoscopic correction into the treatment plan. (Reproduced from Läckgren et al,[51] with permission.)

which have shown endoscopic treatment with Dx/HA copolymer to be more effective than antibiotic prophylaxis have often been of relatively short duration, raising the criticism of an adequate clinical trial. Additionally, is the outcome of VUR resolution the only outcome we should be concerned with? These questions will only be answered with multivariant prospective trials, which are difficult to perform in children. It is possible that endoscopic correction may change our approach to children with secondary reflux as well. Traditionally, children with neurogenic bladders or dysfunctional voiding and VUR are approached by managing the bladder dysfunction initially and reserving correction of VUR for those children with upper tract deterioration or breakthrough pyelonephritis. One could argue, however, as this population has a high rate of breakthrough UTIs and renal scarring,[132] for correcting the VUR endoscopically while ongoing and often tedious efforts at bladder rehabilitation are undertaken, thus protecting the upper tracts from pyelonephritis and potential scarring. This approach may have merit in light of the observation of Läckgren and Stenberg on the improvement in dysfunctional voiding in children treated primarily with endoscopic injection of Dx/HA copolymer without bladder management, implying that the reflux itself may contribute in some way to the abnormal bladder function.[98] Clinical trials in these scenarios would be most valuable.

In the integration of new technology and new concerns in the management of children with VUR, it would be helpful if we were better able to identify groups at high and low risk for renal scarring and tailor our management accordingly. With further progress in clinical research of VUR, we may be able to withhold therapy for certain low-risk groups, while taking a very aggressive approach, by either endoscopic correction or open ureteral reimplantation, for patients at high risk of renal scarring from VUR and infection.

Key points

1 Technique of endoscopic injection:
   - an incompletely filled bladder improves the accuracy of the injection
   - the needle is introduced with the bevel up
   - the assessment of the mound position should be made after an injection of 0.1–0.2 ml.
2 Key characteristics of commonly used materials:
   - polytetrafluoroethylene demonstrated a high success rate, with tendency for particular migration and foreign body reaction
   - cross-linked bovine collagen demonstrated an early success rate, with lack of durability
   - polydimethylsiloxane demonstrated an excellent success rate, with the potential for particulate migration
   - dextranomer microspheres demonstrated excellent success rate, with no evidence of migration.
3 Complications:
   - malignant degeneration or the development of connective tissue disorders is material dependent

- ureteral obstruction has been reported infrequently with most materials
- development of contralateral denovo VUR occurs less commonly with injection therapy than with ureteral reimplantation.

4 Reasons for failure of endoscopic treatment:
- specific material properties play a significant role in the failure rate of endoscopic correction as well as durability
- bladder dynamic factors may play a role in success rate insofar as they may result in mounds shifting within the bladder
- the most common finding in failed endoscopic correction has been mound shifting towards the bladder neck.

Section V

The Bladder and Prostate

Basic science of the urinary bladder

47

Armando J Lorenzo and Darius J Bägli

Introduction

The urinary bladder is a unique organ. As a hollow structure, it demonstrates a remarkable integration of neuromuscular, mechanical, and physical properties that are crucial for its normal function. No other organ is evolutionarily programmed to fill with fluid over hours at low pressures, and then contract on demand to evacuate its contents. The bladder is the only autonomic organ under voluntary control. Indeed, the sociobiologic etiology and reasons for the existence of this unique behavior have been argued for decades. Although the ability to accommodate a fluid volume (filling) is thought to represent largely a passive phenomenon, this is not entirely the case. Recruitment of active neuromechanical properties is crucial for maintenance of low intravesical pressures during filling, and to this end the character of the surrounding cellular elements and extracellular matrix (ECM) can either facilitate or compromise this function. Bladder contraction (emptying), on the other hand, is largely an active neuromuscular process, although it is also influenced by the physicochemical nature of the ECM, and obviously depends on the overall mass and optimal functional status of bladder smooth muscle cells (bSMCs). This chapter reviews some of the biologic concepts related to normal bladder development and function, a complex orchestration of events that, if disturbed, can lead to a significant functional disharmony that places both continence and renal function at risk.

Bladder development

The urogenital sinus develops to form the bulk of the urinary bladder, with its endoderm giving rise to the urothelium and the surrounding mesenchyme to the lamina propria and smooth muscle layer. A smaller, albeit crucial, part of this organ – the trigone – originates from the gradual incorporation of the mesonephric ducts and ureteric buds into the caudal aspect of the bladder wall.[1] Early in gestation the undifferentiated mesenchymal cells are highly proliferative[2] and differentiate into smooth muscle cells with ample spatiotemporal opportunity for interaction with the surrounding primitive urothelium.[3] As differentiation occurs, fetal bSMCs begin to express markers that will come to signify their smooth muscle lineage – α-smooth muscle actin, desmin, and smooth muscle myosin[4] – in a process that coincides with changes in expression of specific ECM proteins such as collagen, fibronectin, and laminin.[5] Although the significance of these temporal associations is still not completely understood, they highlight the early molecular interactions between different developing cell types and their surrounding environment. Evidence to date indicates that specific epithelial–mesenchymal–ECM interactions are necessary for orderly differentiation and development. For example, laminins and fibronectin have been found in the basal lamina during development, and are probably important in mediating interactions between the developing urothelium and its underlying mesenchyme.[1] Other ECM molecules, such as the structural collagens, whose different types are expressed differently between the lamina propria and detrusor muscle fibers,[6] interact with adjacent cells via specific cell-surface receptors, the most important of which are believed to be the integrins.[7] The cell–matrix transduction of different stimuli through different mechanoreceptors (integrins, cell adhesion molecules, and selectins) probably regulates cellular proliferation and differentiation, as well as modulates ECM synthesis.[7] Consequently, normal prenatal bladder development not only results from a complex interaction of ECM and developing cells but also depends on appropriate mechanical stimulation. As gestation progresses, this type of stimulation varies as a result of the multiple factors regulating the mechanical distention stimulus. Compliance appears to increase gradually,[8] the bladder wall thickness and composition

changes,[9] and urine production increases as the fetus grows. Later, the bladder acquires a pattern of cyclical emptying.

Contraction and relaxation

As storage and emptying alternate, the complex function of the detrusor muscle demands integrated control of perhaps its most important cellular component, the smooth muscle cell. During filling, bSMCs must relax and elongate over a considerable length of time (hours) to accommodate the urine volume at low pressures. Conversely, during micturition a rapid change occurs, leading to coordinated and synchronized force generation and cell shortening. By means of dense innervation and abundant intercellular communications (gap junctions), these activities – contraction and relaxation – respond to various transmitters and modulators that activate different cellular pathways.[10]

Contraction of bSMCs is mainly the result of interaction between the contractile proteins actin and myosin, in a similar manner to other muscle cells in the body. In an energy-dependent process, a multistep enzymatic reaction allows for the cross-bridging and attachment of these two proteins in a cyclical fashion, following the same general scheme proposed for skeletal muscle. ATP is the immediate energy substrate, and is crucial for membrane pump Ca^{2+} handling, phosphorylation events, and cross-bridge cycling. The cellular concentration of ATP is therefore essential, and is maintained by mitochondrial respiration, glycolysis, and conversion of the high-energy compound phosphocreatine. Successful regulation of free Ca^{2+} in the cytosol is a highly energy-dependent process. Activation of the contractile apparatus by phosphorylation of the myosin light-chain kinase is modulated by cytosolic Ca^{2+}, whose concentration is regulated by Ca^{2+} channel pumps in the sarcoplasmic reticulum and plasma membrane. Thus, significant energy expenditures are required to maintain these Ca^{2+} gradients. Therefore, mitochondrial function is yet another factor essential for the normal generation of the contractile force by bSMCs.[11]

Even though different isoforms have been described for both actin and myosin, their functional significance remains unclear. Smooth muscle myosin is composed of a pair of heavy chains and two pairs of myosin light chains. Through alternative splicing, the mRNA that encodes vertebrate smooth muscle myosin heavy chains can produce two C-terminal isoforms (SM1 and SM2) and two N-terminal isoforms (SMA and SMB). Some studies suggest that the SM1 isoform forms better contractile filaments than SM2, and that SMB is associated with increased ATPase activity, increased shortening velocity, and more phasic contractions than the SMA isoform.[12–14] Although it remains possible that the presence and relative concentrations of actin and myosin vary with developmental state and in response to obstruction or other pathologic processes,[14,15] their function not only supports the contractile apparatus but also helps to define the cytoskeleton.[16] Indeed, the cytoskeletal framework of the bSMC forms a dynamic structure, with linkages to the ECM. At the same time, these points of linkage, or adhesion complexes with the ECM, mediate intracellular signaling that leads to gene expression, cell migration, cell growth, apoptosis, and adaptation.[10,17,18] Although a relatively novel finding in urology, this paradigm has been appreciated in other biologic systems where it governs cell–matrix relationships in a multitude of ways. Nevertheless, it should be pointed out that, at this time, a coherent picture of the molecular nature of bladder outlet obstruction remains elusive. The question is a difficult one, as bladder outlet obstruction seems to be remarkably heterogeneous.

Mechanotransduction

Cycling between filling and emptying continually exposes the bladder to mechanical stimulation, with force transduction to the cells and their surrounding environment. As a conditioning and modifying process, forcible changes in cell shape induced by various combinations of stretching, contraction, pressure, and membrane and cytoskeletal deformation eventually lead to alterations in gene expression (Figure 47.1). The macroscopic changes often appreciated in the bladder wall are thus the result of genetically mediated tissue remodeling and activation of different molecular pathways. The process of converting physical forces into biochemical signals and integrating these signals into a cellular response, also known as mechanotransduction,[19] is an important concept in bladder development and response to different pathologic stimuli. The bladder, among other mechanosensitive organs, derives essential mitogenic stimuli from mechanical stimulation through the activation of members of the mitogen-activated protein kinase (MAPK) family – the c-Jun N-terminal kinase

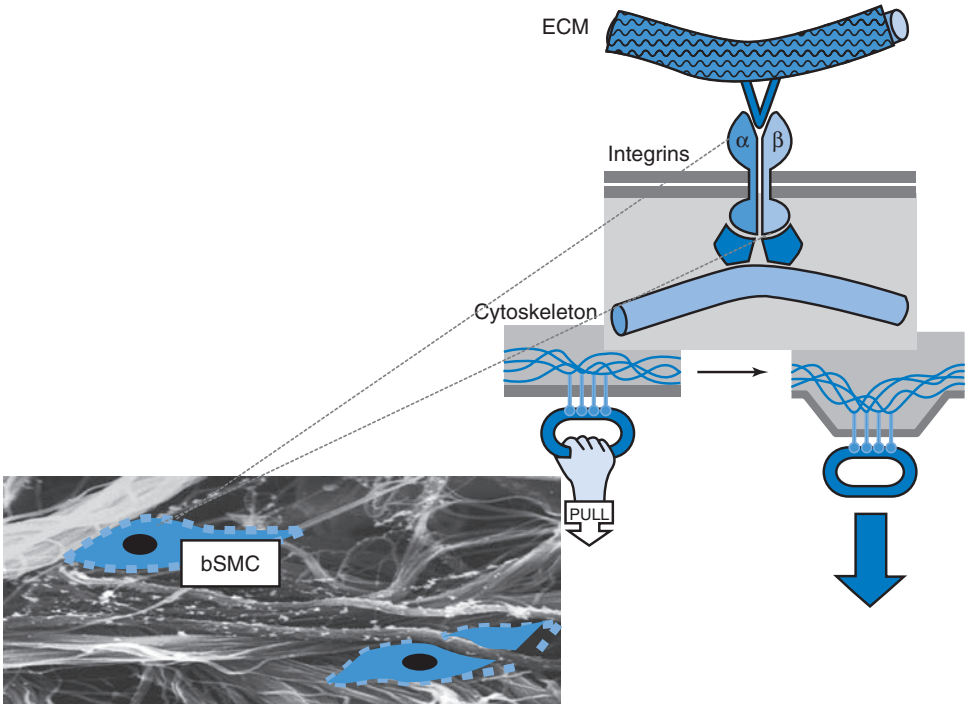

Figure 47.1 Mechanotransduction: schematic representation of conditioning forces (depicted as action over handle on the cytoskeleton), leading to changes in cell shape. This can be induced by various combinations of stretching, contraction, pressure, and membrane and cytoskeletal deformation, eventually leading to alterations in gene expression. Note that the integrins are shown as important mediators of such a process. ECM, extracellular matrix; bSMC, bladder smooth muscle cells.

(JNK), p38, and extracellular signal-regulated kinase (ERK)[20,21] – and other pathways (such as the phosphoinositide 3-kinase (PI3K)/Akt pathway),[22] that in turn up-regulate and activate transcription factors responsible for cell growth and survival.

A key factor in this process is the signaling system that mediates this mechanotransduction. It is probable that the pathways are multiple and perhaps redundant; however, it is currently believed that the integrin receptors, along with stretch-activated ion channels, play an important role in these series of events.[23] These linkage molecules are almost ubiquitous, acting as a relay between the matrix and different cells. Individual tissues thus display different complex responses to mechanical stimulation, the eventual response modulated by the type of mechanical stimulation as well as the signaling molecules and transcription factors expressed by that particular tissue.[19] As a group, these ECM receptor molecules provide a physical link between cell membranes and surrounding structural ECM proteins, such as collagen, laminins, vitronectin, and fibronectin. In particular, the integrins represent a large and versatile family of heterodimeric transmembrane mechanoreceptors capable of transducing a wide range of alterations in the cell microenvironment.[24] Growth factors can further stimulate cell responses through integrins by either mutual interaction, or integrin clustering with growth factor receptors. This process is tightly regulated and expression of different integrin subunits may be specifically modulated by different growth factors and/or ECM molecules under different developmental and pathologic situations. Even though much of the current knowledge about these molecules remains to be revealed in relation to the bladder, their importance in response to bladder distention and dynamic alterations in ECM expression has been demonstrated.[7]

Smooth muscle growth

The generation of contractile force is one of the principal roles for bSMC. Beyond the immediate effect of recruitment and longer contraction times, bladder response to increased work demand (i.e. increased outlet resistance) results in an increase in bSMC mass through hypertrophy (increase in cell number) and hyperplasia (increase in cell size). Bladder SMC growth is mediated by growth factors such as basic

fibroblast growth factor (bFGF), platelet-derived growth factor-BB (PDGF-BB),[25] and heparin-binding EGF-like growth factor (HBEGF),[26] along with other mitogenic signals. In many instances, the transcription of specific genes eventually leads to increase in cell mass and/or number, and is mediated through MAPKs,[27] as previously mentioned, although other kinase signaling families are probably involved (Figure 47.2). These bioactive peptides contribute to tissue expansion through autocrine and paracrine signaling mechanisms. It has become increasingly clear that diverse signals can participate in a number of positive and negative feedback loops which may amplify or reduce the initial stimulus, differentially contributing to specific DNA transcription, protein synthesis, and inactivation of proapoptotic pathways. There exists considerable interest in the modulation of the bSMC mitogenic response, as it is believed that progressive increase in smooth muscle mass is a key component of bladder dysfunction. Currently, management of bladder wall thickening is based on the use of anticholinergics, such as oxybutynin and tolterodine. Interestingly, besides its well-described antimuscarinic effect, oxybutynin appears to inhibit bSMC proliferation and gene expression in vitro, giving us another potential explanation for its proven clinical efficacy.[29] Once the pathways mediating a mitogenic response are better elucidated, specific inhibitors may lead to clinical trials. As an example, a recent area of interest has been regulating compensatory bladder hypertrophy with calcineurin inhibitors such as cyclosporine and FK506 (tacrolimus). Initial evidence suggesting modulation of cardiac muscle hypertrophy has been described in a transgenic model of murine cardiac hypertrophy,[30] and more recently in a bladder outlet obstruction animal model.[31] Ideally, translational research would be the venue for new pharmacologic therapies to be developed; however, molecules such as botulinum toxin have appeared in experimental clinical use based

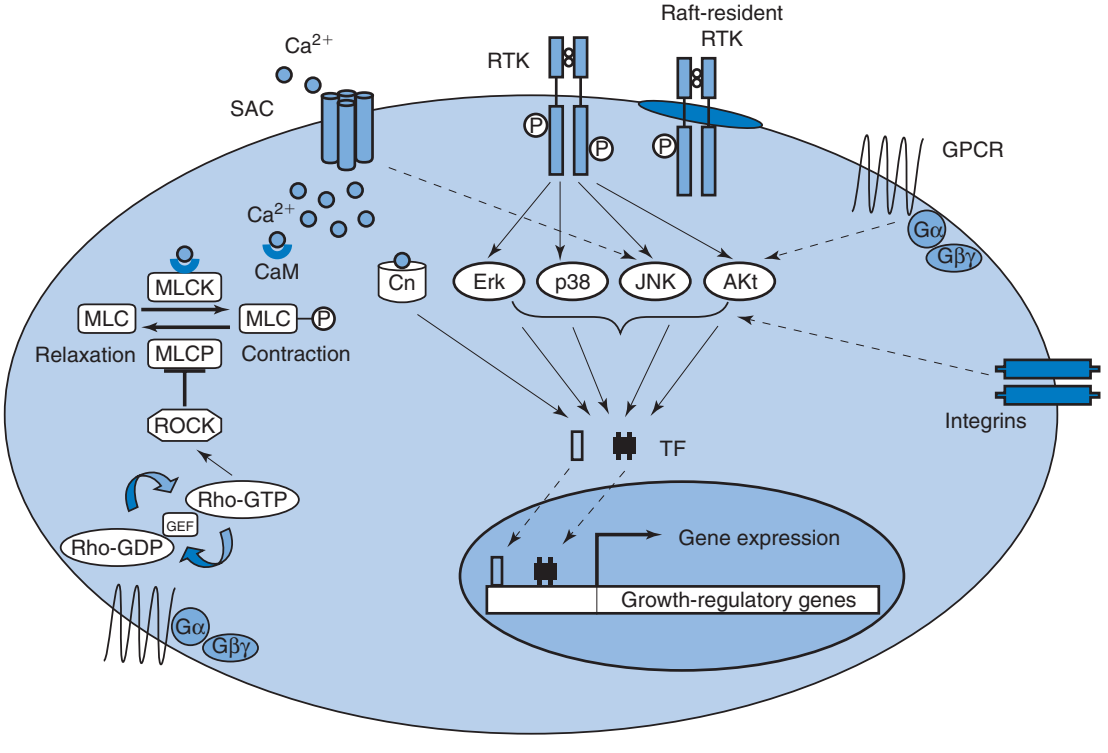

Figure 47.2 Signaling cascades in bladder smooth muscle cells: external stimuli are transduced by stretch-activated ion channels (SAC), receptor tyrosine kinases (RTK), G-protein coupled receptors (GPCR), and integrin subunits. SAC-mediated calcium (Ca^{2+}) entry promotes calmodulin (CaM) binding and activation of myosin light-chain kinase (MLCK), leading to MLC phosphorylation and initiation of smooth muscle contraction. MLC phosphatase (MLCP)-induced relaxation is inhibited by Rho-associated kinase (ROCK). Ca^{2+} influx also activates calcineurin (Cn), leading to dephosphorylation and nuclear translocation of transcription factors (TF). RTK activation promotes activation of the mitogen-activated protein kinases (MAPKs) Erk, p38 stress-activated protein kinase 2 (SAPK2), and c-Jun N-terminal kinase (JNK), and Akt. These signaling intermediates in turn promote activation and nuclear translocation of TF, and alterations in gene expression. (Adapted from Adam,[28] with permission.)

on an acceptable clinical response in other conditions.[32–34] Known to have a chemodenervating effect based on skeletal muscle studies, the different toxin serotypes (BTX A-G) target different proteins involved in the SNARE [soluble N-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor] proteins complex[32] (Figure 47.3). The mechanism of action in smooth muscle, however, may be more complex, as new evidence suggest an antinociceptive and neuromodulating effect.[34]

Even though several elegant studies have suggested that different growth factors contribute to bladder impedance pathology, these proteins are by no means the exclusive mediators of bSMC mechanical responses. For instance, studies of the cyclooxygenase (COX) pathway have suggested that COX-2 expression – active during bladder development[36] – is re-expressed during bladder distention[37] (making COX-2 inhibitors potential pharmacologic inhibitors of stretch-induced bSMC proliferation). These observations suggest that obstruction responses may reactivate mechanisms employed during development itself. Teleologically, this may represent an effort to restore the function originally intended during development. Convergence of these protein and enzymatic pathways in the regulation of bladder obstruction has yet to be demonstrated.

Extracellular matrix remodeling

As the bladder develops, or adapts to different stimuli, the extracellular matrix also remodels in concert with the changes described for bSMCs. An important group of enzymes – the matrix metalloproteinases (MMPs) – are crucial in this process of altering the ECM structure and function. They are multifunctional proteases that degrade ECM proteins, liberate or modulate the bioactivity of growth factors, cytokines or other proteases, as well as alter the bio-

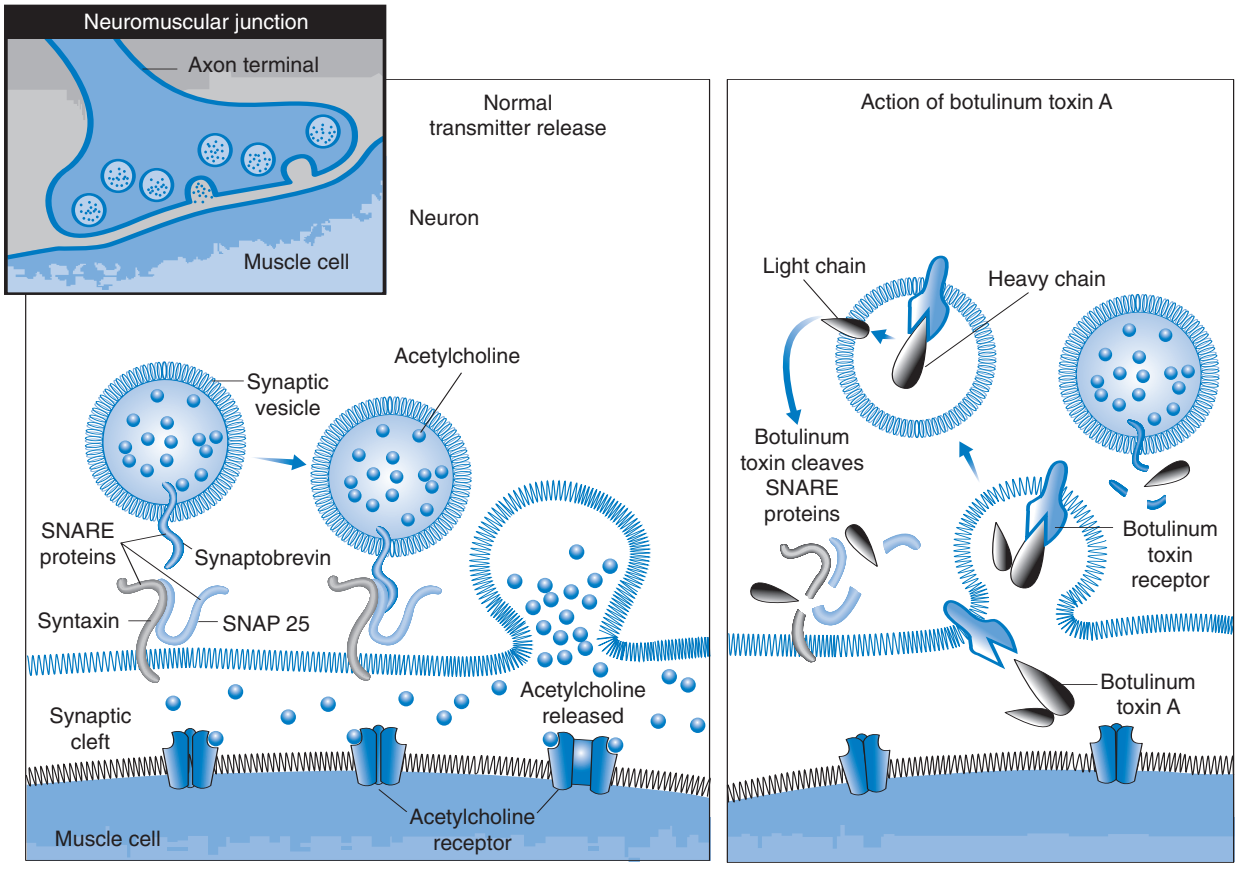

Figure 47.3 Under normal conditions, acetylcholine is packaged in vesicles that fuse with those of the nerve terminals, releasing the transmitter into the synaptic cleft. This process is mediated by a series of proteins, collectively called the SNARE proteins. Botulinum toxin cleaves the SNARE proteins, preventing assembly of the fusion complex and thus blocking the release of acetylcholine (Adapted from Rowland,[35] with permission.)

physical characteristics of the matrix. A cascade of events is initiated in the setting of excessive distention or high-pressure emptying, grossly resulting in thickening of the bladder wall. In conjunction with bSMC hyperplasia and hypertrophy, there is an increase in collagen synthesis, with deposition of collagens I and III,[38] associated with increased expression of MMP-2 and MMP-9, which are MMPs known to have an active role in matrix turnover in animal models.[39]

While the bladder matrix contributes to the physicomechanical characteristics of bladder dysfunction, it is proving to directly orchestrate bSMC biologic responses as well. The prototypical matrix protein in the bladder is fibrillar collagen. Stretching bSMCs promotes collagen production, and bladder obstruction models have demonstrated the new expression of both protein and collagen mRNA within the muscle bundles. Mostly, type I and type III are associated with the detrusor, although 19 different collagen types have been identified so far in other tissues, some with structural roles and others that associate with the structural types. For example, type XII collagen contributes to cross-linking type I fibrils during fiber assembly and may contribute to stiffness of tissues. Furthermore, type XII mRNA expression increases during mechanical distention of the whole bladder.[40] Diverse matrix alterations (accumulation, breakdown, redistribution, and structural rearrangements) are all occurring when tissues are remodeled during development as well as during response-to-injury or wound repair. In fact, many biologic mechanisms in development are recapitulated during repair. MMPs are substances with the ability to edit matrix collagen as well as many of the other ECM proteins. Although MMPs are now known to perform a variety of functions, they are best known for their originally described ability to break down (proteolyse) the ECM during morphogenesis, cell (tumor) invasion, and wound repair. Increased MMP activity or production has been described during bladder development and bladder obstruction in animal models. However, it now appears that the alterations in collagen may directly stimulate bSMC growth. When collagen is denatured experimentally, it elicits a strong proliferative response in bSMCs. Similarly, when collagen is chemically proteolysed by MMPs, bSMC growth is stimulated.[41] The proteolytic fragments released from the degradation of fibrillar collagen generate different signals than intact collagen, and potentially modulate bladder remodeling and bSMC growth by differential signaling pathways.[42]

It is likely that the receptors on the surface of all cells, including bSMCs, which permit cell-matrix attachment, are recognizing new epitopes in ECM macromolecules exposed as a result of protease activity. Inhibition of matrix receptors, such as the integrins, can potentially prevent bSMC proliferation in response to proteolysed matrix. Since bSMCs themselves are producing the enzymes (MMPs) responsible for matrix rearrangement, a powerful dynamic reciprocity is being revealed wherein bSMCs cause matrix alterations, which can then directly stimulate bSMC growth. Since natural regulators or inhibitors of these molecules also exist in the bladder (tissue inhibitors of MMPs, or TIMPs), we begin to appreciate a complex set of balanced mechanisms that depend on cell–matrix interactions. These processes are probably disturbed during bladder obstruction responses.

Finally, an integral, yet poorly understood and sometimes overlooked, part of the ECM is composed of proteoglycans and glycosaminoglycans. For instance, they may serve as ligands for some of the collagens present in the bladder wall and mediate response to injury or hyperdistention.[40] Most of the current research regarding these molecules has been directed towards the urothelium and the protection of this layer against noxious stimuli, which is probably disrupted in conditions such as interstitial cystitis.[43] The accumulation of ECM proteoglycans and glycosaminoglycans is a known integral part of the early phases of tissue response to injury response, conditioning changes in the ECM that may serve to direct the later deposition of the structural collagens. Evidence for a role in bladder wall remodeling comes from studies on the receptors for the ubiquitous glycosaminoglycan hyaluronic acid, a molecule that appears to play a role in bSMC collagen gene expression and regulation during distention.[40,44]

Neurotransmitters and modulators

Bladder function is tightly regulated, mainly under the influence of nervous and hormonal control systems. To date, the muscarinic receptors seem to be the most important ones in regards to activation of detrusor contractions;[45] however, the relative importance of others – such as the purinergic (P2X) and adrenergic receptors – gains relevance, depending on the species studied and the presence of a pathologic process. The human bladder can express all of the known cholinergic muscarinic receptors (M_1–M_5),[46] with well-described predominance of the M_2 and M_3

subtypes.[47] Even though the M_3 receptor has been clearly linked to detrusor contraction stimulation through activation of phosphoinositide hydrolysis and generation of inositol triphosphate, it is the M_2 receptor that predominates in the human bladder by a ratio of at least 3:1 over the M_3 subtype. Notwithstanding the unclear functional role of the M_2 receptor, it is interesting to note that its expression further increases in experimental pathologic states, potentially facilitating bladder contractions and muscle hypertrophy.[48,49] Beyond the evidence for adenylyl cyclase inhibition after M_2 or M_4 activation, other ill-defined signaling pathways may be involved, such as modulation of purine-evoked relaxation and activation of non-specific cation channels.[10,45,50,51] Interest in this topic has been rekindled after the recent introduction of subtype selective pharmacologic agents: i.e. M_3 specific antagonists solifenacin and darifenacin.[52]

In regard to congenital disorders, the issue is compounded by the limited understanding of neural control and maturation during development. Fetal human studies have shown variation in some receptor subtype expression when compared with adults, as is the case for P2X receptors.[53] In contrast, most reports describe little difference in cholinergic innervation or response to stimulation of muscarinic receptors, suggesting functional capacity early in life.[54] Abnormalities in receptor expression and function are probable in disorders that affect the bladder during its organogenesis. However, the role of these receptors in terms of detrusor functional alterations remains to be established.

Posterior urethral valves as a model of congenital bladder outflow obstruction

How the underlying molecular signaling cascades mediate survival and cell death can help lay the foundations for understanding how extrinsic pathologies mediate intrinsic bladder responses. Posterior urethral valves (PUV) represent an archetypical form of increased resistance to urinary flow in humans. In the pediatric sphere, this is somewhat analogous to the impedance generated by benign prostatic enlargement in the adult male. Whereas similar clinical bladder responses are noted between these two pathologies, multiple factors probably differentiate childhood from adult obstructive uropathies. PUV bladder trabeculation and altered function represents a spectrum of pathology which may derive as much from its timing during gestation as it does from the degree of impedance. Experimental observations on extrinsic manipulation of the bladder neck would suggest that while extrinsic obstruction models do reproduce some of the structural and functional consequences seen in clinical PUV bladders, they may also unwittingly distract from the true nature of the problem at the molecular level.

The 'valve' bladder has long been viewed as the bladder's response to a mechanical problem. Bladder SMCs must simply work harder to expel urine. They must mount an increased contraction effort. In doing so, the bladder phenotype (structure and function) changes. Finely tuned neurosensory perception of pressure/stretch, which accompanies higher than expected voiding pressure, is relayed through reflex arcs and may increase efferent motor demands on the detrusor. Furthermore, abnormalities in the outlet region of the bladder neck and sphincter areas, which harbor the valves themselves, may give rise to neurodevelopmental changes that directly influence bSMC function. Nevertheless, the apparent normalization of PUV bladder morphology and function that can occur when valves are ablated suggests that bSMCs can retain the capacity for normal function despite the creation of an outlet defect during gestation. This is in contrast to bSMCs from neurogenic bladders, which appear to harbor more permanent phenotypic changes, as demonstrated by in-vitro culture experiments.[55] It would seem then, that bSMCs themselves are sensing the presence of impedance to flow, whatever the etiology of the obstruction itself.

During development and during the brief periods of normal unobstructed emptying, bSMCs are being programmed to accept and work against a range of elevated intravesical pressures. However, the resistance afforded by the PUV increases this pressure. Whether indirectly through a stretch/tension neural receptor mechanism and/or directly via SMC stretch/mechanoreceptors, alterations in muscle membrane ion channels, or changes in SMC shape, bladder SMCs contract more forcefully. As inefficient emptying progresses, the excessive bladder storage may actually overstretch the detrusor muscle to excess degree and duration; indeed, this may become a dominant insult that erodes bladder function.

Clearly, the role of physical stretch and tension in bSMC biology is more complex and difficult to sort out from a mechanistic point of view than it first appears. We now appreciate that stretch operates under different conditions in different pathologies, and may contribute to bladder alterations at different points in natural history of any given obstructive

uropathy. The paradox is that although mechanical stretching of bSMCs in vitro may generate clinically familiar responses generated by hypercontracting or excessively stretched bSMCs in vivo, it may do so through physiologically irrelevant or unrelated molecular mechanisms. Nonetheless, to determine whether the physical stimulus of stretch per se can predict and elucidate relevant changes in bSMC phenotype, cultured bSMCs have been subjected to controlled mechanical stretching in vitro. Studies of this nature have provided compelling information and suggest that bSMCs alone may be a primary cellular recipient of relevant stretch (mechanical) stimuli in vivo.

Limitations of research tools: in-vivo, ex-vivo, and in-vitro models

The study of any biologic problem is often dependent on the availability of appropriate models. More importantly, investigation may be guided by a series of appropriately framed segments or aspects of the problem. As previously mentioned, these emerging segments include proteins and molecules which affect SMC growth and phenotype, the influence of mechanical and neural stimuli, and the role and regulation of the bladder ECM components. Clearly, these areas of investigation will intersect, and new segments of the problem are to be anticipated. Although none of the molecules currently reported to influence bSMC growth and behavior in the context of bladder obstruction have affected clinical practice as yet, they may hold keys to appreciating how bSMCs truly work. There are, however, conceptual shortcomings to the use of in-vitro, ex-vivo, and in-vivo animal models as a means of deciphering the intricacies behind normal and pathologic bladder function and development. Experimental conditions differ in timing, reversibility, stretching parameters, and cyclicity, as well as the nature (extrinsic vs intrinsic) of the obstructive stimuli. Therefore, the results observed are potentially not the same as the ones elicited by the detrusor in congenital anomalies.

The promise of tissue engineering

As the full potentials of molecular mechanisms and therapeutics, prenatal diagnosis, and sheer curiosity about bladder disease are awakened and converge in the coming decade, we can expect new and frankly unexpected approaches to emerge for the treatment and even prevention of obstructive bladder pathologies. Increasingly, intense research has focused on the fields of regenerative medicine and tissue engineering, as the principles of bioengineering, biomaterials, and cell transplantation are applied to construct biologic substitutes that would restore function in diseased urologic tissues.[56] This process has uncovered that, perhaps not unexpectedly, the biology of the bladder is every bit as complex and enigmatic as the other vital body systems. It has proven difficult to regenerate all the functional layers of the bladder as the engineered tissue needs to have optimal mechanical and structural characteristics while being biocompatible and capable of eliciting enough neovascularization to survive once implanted.[57] Most of the available data are based on in-vitro and promising animal models.[58]

Conclusion

The past decades have witnessed a changing view of the bladder, from a simple organ that contracts in order to volitionally eliminate urine, to a complex unit responsive to fine neuromodulation and smooth muscle–ECM interaction.[1,41,59,60] As such, the approach to bladder dysfunction is shifting from a symptomatic basis (based solely on treating urinary tract symptoms and incontinence) to measures aimed at preventing overdistention and high intravesical pressures. In this manner, the tendency is to prevent end-stage damage to affected organs (requiring aggressive and morbid interventions such as augmentation cystoplasty or renal transplantation) by modulating the fibroproliferative response and its consequent loss of compliance, contraction inefficiency, and hyperdistention.[61] Even though great advances have been made in the past few decades, understanding the molecular mechanisms behind bladder development and response to abnormal stretch and dysfunction remains a fertile area for research and development.

Basic science of prostatic development

48

Ellen Shapiro and Hongying Huang

The fetal prostate is the most proliferative state of the prostate gland and represents an excellent model for the study of morphogenesis, hormonal imprinting, and epithelial–mesenchymal interactions in the genitourinary (GU) tract. Events associated with fetal prostate development and in-utero influences which may alter growth in adulthood will probably provide insights into the mechanisms giving rise to benign and malignant aberrant growth of the prostate.

Embryology of the prostate

The prostate develops from the endodermal urogenital sinus (UGS), which is derived from the terminal end of the hindgut or 'cloaca' (Latin for sewer). Septation of the cloaca by the urorectal septum begins at about 28 days of gestation.[1] The rectum and primitive UGS form by the 44th day. The primitive UGS proximal to the mesonephric duct develops into the vesicourethral canal, whereas the region distal of the mesonephric duct becomes the definitive UGS. The UGS adjacent to the bladder (pelvic urethra) differentiates into the lower portion of the prostatic and membranous urethra.[2]

Prostate growth and development are dependent on androgen production by the fetal testes, which begins at about the 8th week of gestation.[3] Unlike development of the wolffian duct (WD) derivatives, which are dependent solely on testosterone, the differentiation of the UGS is dependent on the 5α reduced form of testosterone, dihydrotestosterone (DHT). DHT is essential for the growth and development of the prostate.[3–6] By 10 weeks, the prostatic ductal network develops from solid epithelial outgrowths, or prostatic buds, which evaginate from the endodermal UGS immediately below the bladder and penetrate into the surrounding urogenital mesenchyme (UGM).[7] The prostatic ducts rapidly lengthen, arborize, and canalize. By 13 weeks, at the peak of testosterone production, 70 primary ducts are present and exhibit secretory cytodifferentiation.[7]

Within the fetal prostate lies the utricle. Although the embryologic origin of the utricle is thought to be a remnant of the fused caudal ends of the müllerian ducts (MDs), compelling evidence from Shapiro et al indicates that the utricle forms as an ingrowth of specialized urothelium lining the dorsal wall of the UGS.[8] This is occurring during complete caudal MD regression (Figure 48.1). Since utricular development from the UGS is similar to that of the vagina in the female fetus, it has been appropriately referred to as the 'sinus vagina'. Testosterone inhibits the formation of the lower vagina in the female, and therefore formation of an enlarged utricle in some males with severe hypospadias may be caused by inadequate virilization of this region of the UGS at a critical time during early gestation.[9]

Prostate morphology

In 1912, Lowsley studied the human fetal prostate and noted that the branching ductal system consisted of five distinct groups.[7] These lobes were termed the posterior, lateral (two), anterior, and middle lobes. The ducts of the posterior lobes originate from the floor of the prostatic urethra distal to the openings of the ejaculatory ducts (EDS) and grow posteriorly. The epithelial buds of the two lateral lobes branch lateral to the verumontanum. The ducts of the middle lobe originate on the posterior urethra proximal to the openings to the EDs. The anterior lobe buds branch anterior to the verumontanum.

Xia et al qualitatively examined prostate growth, histogenesis, and secretory activity in normal fetuses ranging in age from 20 weeks gestation to 1 month

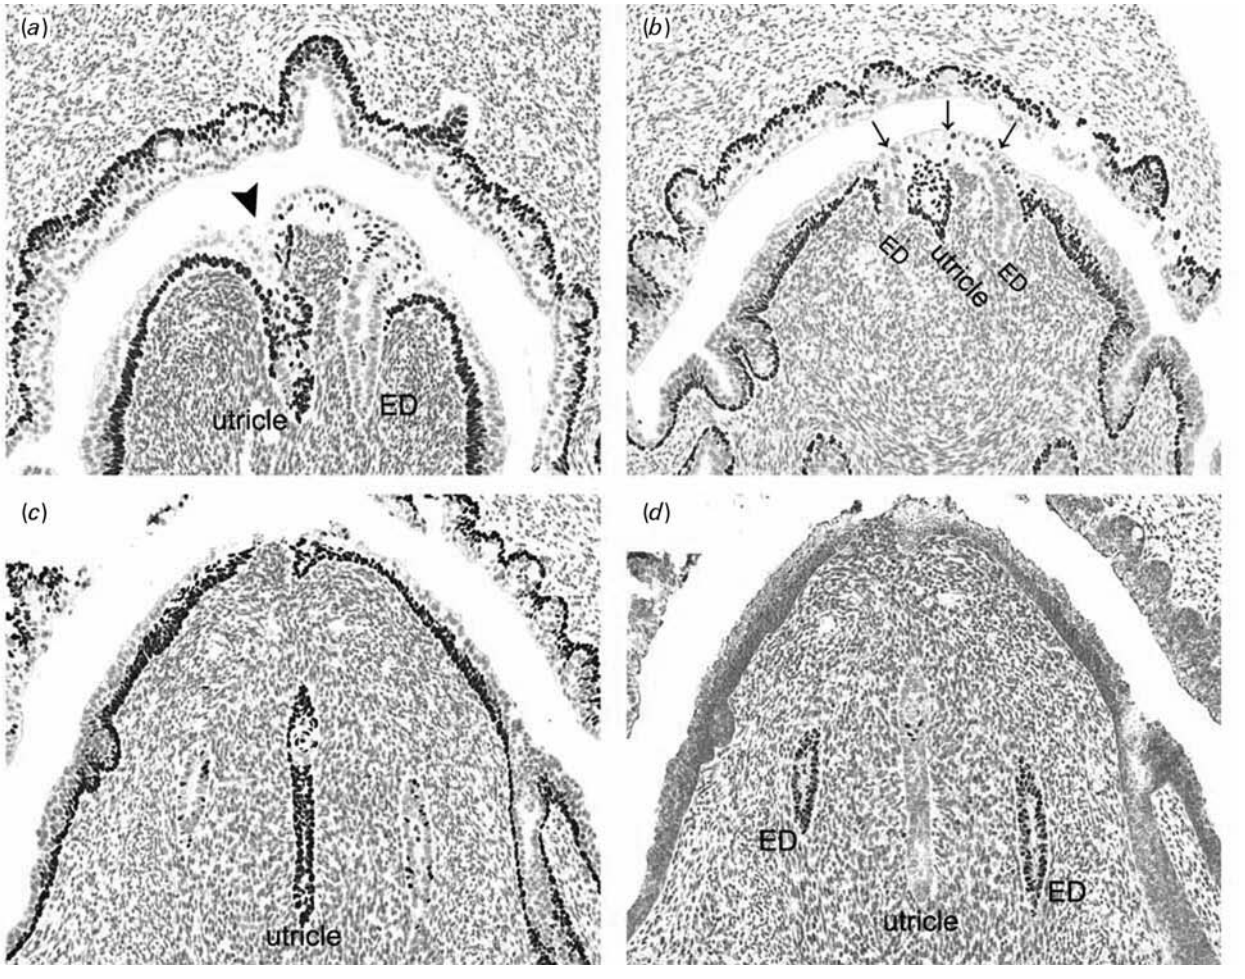

Figure 48.1 Cross section of a human fetal prostate, aged 15 weeks. (*a* and *b*) Two different specimens showing the evaginated p63 (basal cell marker) positive cells that form the utricle (arrowhead) and only weakly staining basal cells in the urogenital sinus (UGS) between the ejaculatory ducts (EDs; arrows). (*c*) The p63 positive cells of the utricle continue to grow into the midline of the mesenchyme and surround the small solid remnants of the müllerian ducts (MDs) in its path, which (*d*) also express Pax-2 (marker for MD and wolffian ducts). The EDs are also Pax-2 positive (×200).

(postnatal).[10] No sharply delineated 'lobules' were recognized. Two zones were identified: the inner submucosal zone (IZ) and the peripheral zone (PZ). The IZ was characterized by a concentric mass of fibromuscular connective tissue containing ducts at various stages of development. The PZ contained less concentrically organized fibromuscular connective tissue, with secondary ducts, gland buds, and groups of acinar glands. Lowsley's work, together with Xia et al's observations, lends support to the current concept of the morphology of the adult prostate gland, which exhibits three zones – central, transition, and peripheral zones – corresponding to three distinct sets of ducts. This is important as prostatic diseases are region-specific, with prostate adenocarcinoma developing primarily in the peripheral zone and benign prostatic hyperplasia (BPH) developing primarily in the transition zone. The development of BPH is important to understand, because growth of new acini in this condition deviates from the normal development of most organs.[11] The prostate is the only organ to demonstrate new growth as part of the aging process. However, the new acinar architecture is unlike that of the fetus, since the ducts of the fetal prostate branch parallel and away from each other rather than toward each other, as seen in BPH nodules.

Endocrinology of prostatic development

Development of the prostate is androgen dependent and DHT is the active intracellular androgen.[3,12] The

5α-reductase deficiency syndrome is a form of autosomal recessive male pseudohermaphroditism characterized by severe penoscrotal hypospadias, a blind vaginal pouch, and normal testes with normal epididymes, vasa deferentia, and seminal vesicles.[13] The EDs terminate in the blind-ending vagina, and the prostate is small or undetectable. The selective effects of testosterone and DHT are defined since the defect in virilization during embryogenesis is limited to the UGS and the anlagen of the external genitalia.

Although there is no compelling molecular evidence for homology between specific rodent prostatic lobes and human prostatic zones, the rodent has been extensively studied to further our understanding of prostatic development. Imperato-McGinley and coworkers demonstrated prostatic bud formation in the rat model of 5α-reductase deficiency,[5] a finding that was unexpected since finasteride, a 5α-reductase inhibitor, did not completely abolish prostatic differentiation, which suggested that budding may have different thresholds of response for DHT. Further studies showed that flutamide, a non-steroidal antiandrogen, in high enough doses to feminize the external genitalia of the male rat, failed to inhibit prostatic development whereas cyproterone acetate (CA), a steroidal antiandrogen, inhibited prostatic bud development and external genitalia development. Low-dose DHT could induce prostatic buds in female fetuses. The WDs could not be abolished in males with CA, and high-dose antitestosterone treatment failed to inhibit prostatic buds. Although DHT is important for prostatic growth, the developing prostate may be responsive to exceedingly low levels of DHT or other androgens.[5]

Also, some aspects of postnatal prostatic growth may be independent of androgens, as castration in the rat during this period does not completely inhibit prostate development,[14,15] which suggests that other non-androgen growth factors such as peptide growth factors are capable of mediating arborization and growth of prostatic ducts.[6] These findings suggest that varying phenotypes occur and are species dependent.

This concept is supported by the observations of Mahendroo and colleagues, where unexpected virilization in male mice lacking steroid 5α-reductase enzymes was observed.[16] These mice had normal external and internal genitalia and were fertile but had smaller prostates and seminal vesicles than controls. As expected, high testosterone levels were found in target tissues. DHT administration led to an increase in seminal vesicles and coagulating gland wet weights in the 5α-reductase type 2 deficient mouse and an increase in the prostate size, seminal vesicle, and coagulating gland in both the 5α-reductase type 1 and 2 deficient mouse. When DHT was administered to the mouse deficient in only 5α-reductase type 2, no increase in prostatic size occurred, whereas DHT administered to the 5α-reductase type 1 and 2 deficient mouse resulted in an increase in prostatic size. Androgen-dependent gene expression was decreased in the seminal vesicles lacking one or more of the 5α-reductase enzymes, but was restored with testosterone or DHT. These studies show that only testosterone is needed for differentiation of the male UGS in the mouse, and synthesis of DHT serves largely as a signal amplification mechanism.

Using immunohistochemistry, we studied human fetal prostates, with gestational ages of 7–22 weeks. Representative tissue sections were stained with antibodies for the androgen receptor (AR) and 5α-reductase. At 7 weeks, we demonstrated AR and 5α-reductase expression in the peripheral stroma, above the ejaculatory ducts (EDs) while only AR is seen in the UGS luminal epithelium. By 9 weeks, AR expression was ubiquitous in the stroma and suprabasal cells of the UGS but was observed in the basal cells of only the central dorsal UGS below the EDs. Stromal 5α-reductase expression was significantly increased and was observed throughout the UGS. By 11–13 weeks, AR expression increased in the stroma especially in the periphery. Epithelial AR increased from the base to the apex with AR observed in all cell layers of the UGS, ducts and acini except for the basal cells of the UGS and ducts above the EDs which remained negative. 5α-reductase expression was observed throughout the stroma except in the ventral SM, ventral periurethral stroma, and the posterior periphery where expression is diminished. Epithelial 5α-reductase expression increased from the base to the apex, with no expression in the ductal epithelium of the posterior lobe (Figure 48.2). The lateral lobes showed only distal duct and acini expression whereas the ducts emanating from above the EDs expressed 5α-reductase throughout their epithelium. By 22 weeks, AR expression is ubiquitous with greatest staining in the epithelium and the posterior and posterolateral peripheral stroma, while 5α-reductase is almost undetectable.

We concluded that epithelial AR expression is significantly greater below the EDs than above the EDs at each gestational age up to 22 weeks, when no difference in the AR expression pattern is observed in the gland and 5α-reductase is almost absent. In contrast, UGS and ductal epithelial 5α-reductase was

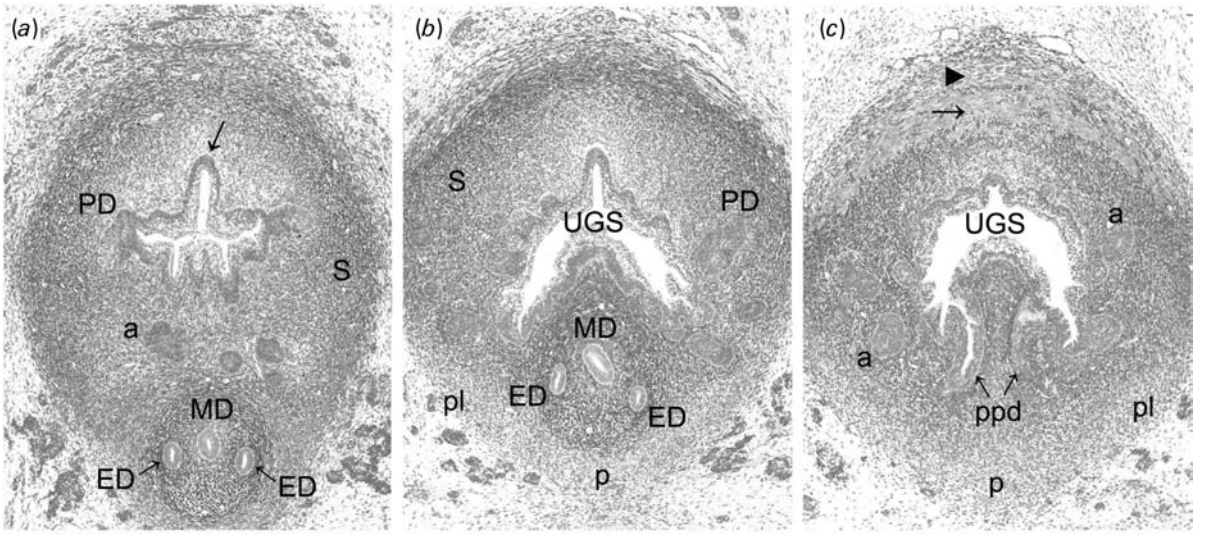

Figure 48.2 Cross section of a human fetal prostate, aged 11 weeks. (*a*) Bladder neck region with significant 5α-reductase expression throughout the prostatic stroma (S) and the stroma surrounding the ejaculatory ducts (EDs) and müllerian duct (MD). Expression is noted in the basal epithelium of the urogenital sinus (UGS) (arrow) and in the prostatic ducts (PD) and acini (a). (*b*) Region between the bladder neck and the entrance of the EDs into the UGS, with similar stromal 5α-reductase expression, except posteriorly (p) and posterolaterally (pl) and much less UGS, prostatic ductal (PD), and acinar expression. (*c*) Region below the entrance of the EDs into the UGS, with no 5α-reductase expression in the UGS epithelium, posterior prostatic ducts (ppd), or lateral acini (a). There is no 5α-reductase in the posterior (p) and posterolateral stroma (pl) or in the smooth (arrow) or skeletal muscle (arrowhead) in the anterior stroma (×100).

expressed in a gradient fashion from the apex to the base/bladder neck. This suggests a regional, reciprocal relationship between select areas of stromal and epithelial AR and 5α-reductase expression. This detailed localization study supports other investigations which have suggested that DHT serves largely as a hormonal signal amplification during prostate development.[16,17]

Stromal–epithelial interactions

Stromal and epithelial interactions that occur in the developing prostate are androgen dependent.[14] Lasnitzki et al performed tissue recombinant experiments by combining mesenchyme isolated from fetal rat or mouse UGS with fragments of prostate or bladder epithelium. These tissue recombinants are grafted under the renal capsule of recipient animals and form prostatic ductal tissue. Lasnitzki has utilized testicular feminization (Tfm) syndrome in mice to elucidate the roles of epithelial vs mesenchymal androgen receptor (ARs) in prostatic development.[18] The Tfm syndrome results in complete failure of the prostate to develop[19] due to defective or absent ARs. The WDs undergo degeneration and the external genitalia are feminized despite normal testosterone levels. Therefore, Tfm mice have deficient AR and fail to develop prostates. When tissue recombinants constructed of wild-type (WT) mesenchyme (UGM) and Tfm epithelium are exposed to androgen as a result of grafting of the recombinants into intact male hosts, normal prostatic morphogenesis ensues.[18,20–23] When the Tfm mesenchyme is combined with either the Tfm or the wild-type epithelium, the prostate does not form. From these studies, it is concluded that there is a critical role for mesenchymal AR in prostate development and that many androgen effects on prostatic epithelium do not require epithelial AR but are elicited by the paracrine action of AR + mesenchyme. It is interesting to note though that mouse prostatic epithelial ARs are not expressed until postnatal day 1, whereas human prostatic epithelial ARs are present in the urogenital epithelium as early as 7 weeks' gestational age.[17,24,25] Prostatic epithelial ARs are required for the expression of AR-dependent secretory proteins during postnatal development.

Tissue recombinant experiments have also been used to examine epithelial–mesenchymal interactions in the differentiation and organization of prostatic smooth muscle (SM).[26] Experiments combined adult prostatic epithelium (PRE) with UGM or seminal

vesicle mesenchyme (SVM) or bladder epithelium (BLE) with UGM or SVM. Prostatic ducts developed in all tissue recombinants when UGM was used with either epithelium. SM cells also organized into sheets that resembled prostate. When SVM was combined with either epithelium, the prostatic ducts were surrounded by thick SM cells, resembling seminal vesicle. The SM was unorganized in grafts of SVM or UGM. These experiments suggest that male UGM dictates spatial organization, but SM differentiation is induced by epithelium. Urothelium may also direct the organization of SM tissue, since urothelium is thought to be a potent inducer of SM differentiation. Cunha has shown that the proximal segments of prostatic ducts near the urethra express urothelial membrane antigen and have associated thick layers of SM cells surrounding them.[12] All of these tissue recombinant experiments show that interactions between the mesenchyme and epithelium are reciprocal.

Hormonal imprinting

For more than 50 years, the role of natural and synthetic estrogens in prostate development and the effects of hormonal imprinting have been studied.[27–29] Estrogens alter the hypothalamic–pituitary–gonadal axis, resulting in decreased androgen levels and subsequent regression of the prostatic epithelium.[30,31] Investigations have focused on the correlation between estradiol and prostatic development in fetal mice depending on their intrauterine position, the effects of experimental increases in estradiol in mouse fetuses, the inhibition of prostate development following administration of high-dose estrogens, and the opposing effects of high- and low-dose estrogen on prostatic development.[32]

It has been postulated in humans that the early testosterone surge at 30–60 days of life may be a critically important 'imprinting' event that may have an impact on the gland's propensity for future abnormal prostatic growth and disease. Hormonal imprinting has been studied in the rat.[33] Naslund and Coffey showed that early hormonal surges are requisite for normal adult prostate growth in the rat, and that an alteration in the normal endocrine events that occurs shortly after birth can have significant and permanent effects on the androgen sensitivity and growth of the adult prostate.[34] These hormonal surges are thought to affect prostatic growth by altering the properties of the prostatic stem cells. Recently, Tsujimura et al have shown that the proximal region of the mouse prostatic ducts is enriched in a subpopulation of epithelial cells that have a number of properties of stem cells: they are slow-cycling, possess high in-vitro proliferative potential, and single cells are able to reconstitute complex highly branched glandular structures in vitro that contain basal and luminal cells.[35] The absolute number of these stem cells is important because it ultimately determines the size of the gland. Therefore, hormonal events occurring before puberty can imprint or program the prostatic size, androgen sensitivity, and function and maintenance of the stem cells.

Prins and others have shown that brief exposure of rodents to estrogens during the neonatal period leads to permanent irreversible and dose-dependent effects of the prostate gland's morphology, cellular organization, and function.[2,3,36,37] If estrogenic exposure is high, the permanent imprints include reduced prostatic growth, epithelial differentiation defects, altered secretory function, and aging-associated dysplasia similar to prostatic intraepithelial neoplasia or (PIN). This process, referred to as estrogenic imprinting or developmental estrogenization, is used as a model to evaluate the role of exogenous and endogenous estrogens as a potential predisposing factor for prostate diseases later in life.[36,37]

Prins' study also examined the effects of neonatal estrogen exposure on the development of the AR.[37,38] Estrogen receptors (ERs) have been shown to be strongly expressed in the mouse prostate mesenchyme.[22] While the stroma is strongly ER positive (ER+ve), the prostate SM is weakly to negatively staining after differentiating from mesenchyme. Fibroblasts remain strongly ER+ve. There are no ERs in the epithelium of the prostate. Brief exposure to neonatal estrogen down-regulates AR and permanently alters its expression, as well as retarding ductal development.[37,38] SM development is generally unaffected, as is the development of basal cells. Estrogenization does not inhibit epithelial cell differentiation (determined by the appearance of luminal cell cytokeratins) completely, indicating that initiation of cytodifferentiation precedes elevated AR expression rather than increasing AR-triggering cytodifferentiation. These experiments suggest that functional differentiation is dependent on AR expression in epithelial cells.

Although this response is mediated through alterations in steroid receptor expression, other downstream mechanisms in the signaling cascade that mediate prostate ductal morphogenesis may be involved. The Sonic hedgehog gene (*Shh*) encodes a

secreted glycoprotein that is expressed at many sites in the vertebrate embryo and participates in the molecular signaling for the development of the notochord, limb, hindgut, and GU tract.[39,40] Loss of *Shh* function results in severe defects in neural and skeletal development, growth inhibition, and embryonic lethality. Using a murine model, *Shh* is expressed in the prostatic anlage of the UGS, and that expression is stimulated by testosterone. Pu et al showed that highly localized *Shh*-patched *gli* expression along with regulation of downstream morphogens participate in dichotomous branching during prostate morphogenesis.[40] Neonatal exposure to high-dose estradiol suppressed *Shh*-patched *gli* and blocked ductal branching in the dorsal and lateral prostate lobes.

Barnett et al studied *Shh* expression in the human fetal prostate at 9.5–20 weeks' gestation.[41] *Shh* expression was present in the prostatic urothelium, prostatic ducts, and glandular epithelium at 9.5, 11.5, 13, and 16 weeks and in the prostatic buds by 11.5 weeks. Staining was observed in the EDs, MDs, and anterior SM and SKM. Staining intensity diminished after 16 weeks as testosterone levels declined to baseline and was almost absent by 18 and 20 weeks, suggesting a direct relationship between testosterone levels and *Shh* expression.

Other studies of the effects of estrogen on the prostate have used the induction of squamous metaplasia (SQM) as a reliable marker for estrogen action on the gland.[31,42] Risbridger et al studied this transformation of the epithelium and showed proliferation of basal cells and the expression of K10.[31] They also showed that mice lacking the stroma and/or epithelial estrogen receptor α (ERα) did not develop SQM.[43] These studies suggest that stroma and epithelial ERα are required for the induction of SQM in the prostate gland.

Shapiro et al examined the immunolocalization of ERα and estrogen receptor β (ERβ) in the human fetal prostate (Figure 48.3). ERα expression was not detected until 15 weeks, with sparse staining in the utricle.[23] By 19 weeks, increased ERα expression is seen within luminal cells of the ventral urogenital epithelium (UGE), basal cells of the dorsal UGE, the utricle, distal periurethral ducts, peripheral stroma, and posterior prostatic duct. K14 is detected in basal cells of the UGE and in several posterior acini. At 22 weeks, ERα expression is more intense in all of these areas. ERβ is expressed throughout the UGE, EDs, MDs, and entire stroma at 7 weeks. Intense ERβ staining is observed in these areas and the prostatic buds by 8 weeks, with persistent intense staining through 22 weeks. The work of Shapiro and associates shows the earliest expression of ERα (15 weeks) and ERβ (7 weeks) and that the induction of SQM in the UGE, distal periurethral ducts, and utricle is associated with ERα expression in these areas, whereas the induction of SQM in peripheral prostatic acini is associated with peripheral stromal ERα expression. This suggests important estrogen signaling pathways in the human fetal prostate via ERα that involve epithelial–epithelial and epithelial–stromal interaction. Also, the timing of the appearance of SQM is thought to be associated with the decline in testosterone levels after 18 weeks when the Leydig cells are known to regress.[44] This results in an imbalance of the hormone milieu, with a predominance of estrogens, which may then induce metaplastic changes

The role of ERα and ERβ in prostatic development has been further elucidated in studies of the estrogen receptor α knockout (ERKOα) and estrogen receptor β knockout (ERKOβ) mouse, respectively.[45,46] Couse and Korach studied neonatal diethylstilbestrol (DES) exposure in males using both ERKOα and ERKOβ knockout cell lines.[46] The ERKOα males were completely resistant to the effects of neonatal DES exposure and the ERKOβ response was similar to the wild type, with significant decreases in the AR levels and seminal vesicle size, increased stromal mass, marked epithelial hyperplasia and dysplasia, and lymphocytic infiltration. It was concluded that the initial effect of DES, resulting in the down-regulation of AR levels, is mediated by ERα. Therefore, the ERKOα males did not show any of the effects of neonatal DES, but, unlike the wild-type, the AR levels recover in the adult ERKOβ males.

Other investigators have suggested an involvement of ERβ in the pathogenesis of prostate cancer, since ERβ expression is down-regulated in prostate cancer, supporting its role in prostatic cellular homeostasis.[47] We have shown that ERβ expression is intense during the early period of prostatic ductal morphogenesis and may be critical in maintaining normal glandular growth and proliferation.

Prostate morphometry

Shapiro et al developed a technique for quantifying the cellular elements of the prostate that involves double immunoenzymatic staining and computer-assisted color image analysis.[48,49] The only comprehensive study of prostatic morphometry in the prepubertal male has been reported by Shapiro et al.[50]

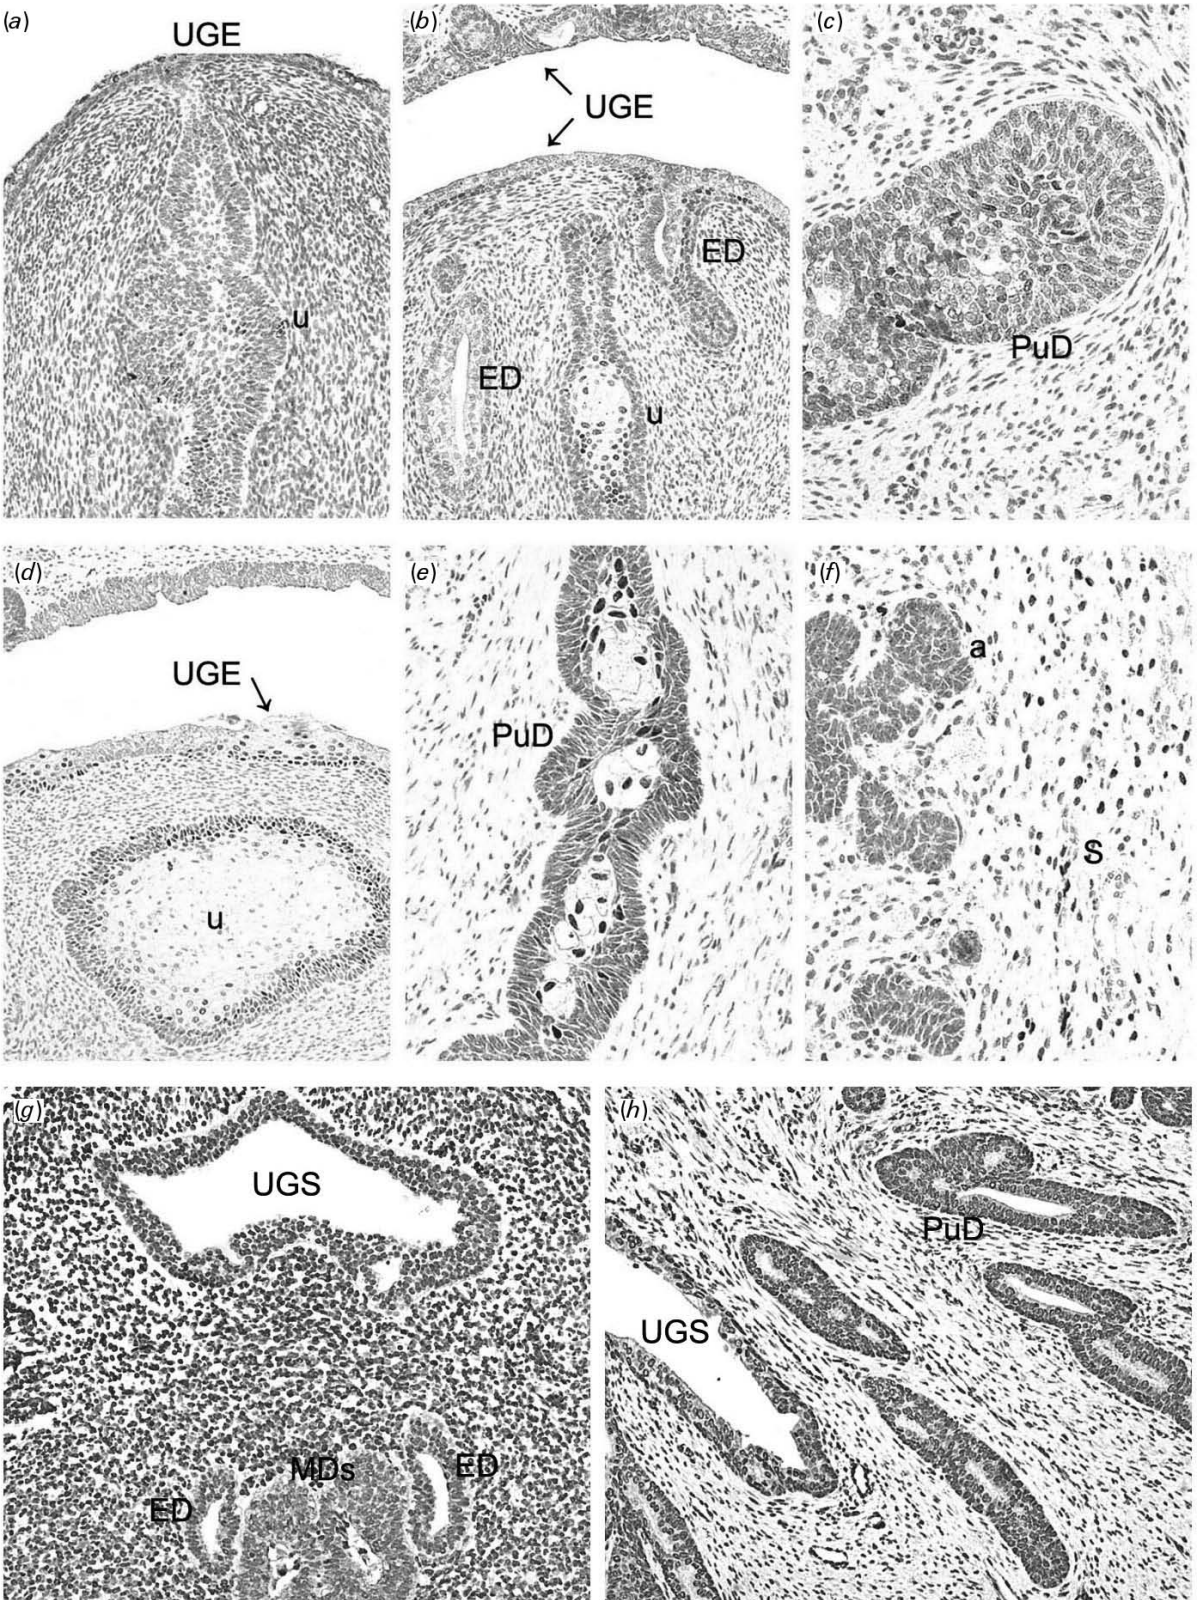

Figure 48.3 Cross section of a human fetal prostate. (*a*) Estrogen receptor α (ERα) expression at 15 weeks in the ventral urogenital epithelium (UGE) and utricle (u) (×200). (*b*) At 21 weeks, ERα expression in the UGE (arrows), utricle, and ejaculatory ducts (EDs) (×200), and (*c*) periurethral ducts (PuD) (×400). (*d*) ERα expression at 22 weeks in the UGE (arrows) and utricle (×200), (*e*) periurethral ducts (×400), and (*f*) peripheral stroma (S), with no staining of the peripheral acini (a) (×400). (*g*) ERβ expression throughout the epithelium and stroma at 7 weeks (MDs, müllerian ducts; UGS, urogenital sinus) and (*h*) at 24 weeks (×200).

Quantitative morphometric studies were performed on pediatric and other non-hyperplastic prostate specimens obtained from 45 males ranging in age from 2 days to 40 years. The entire group was stratified, based upon age, into categories reflecting the neonatal, childhood, peripubertal, adolescent, and young adult period. Double immunoenzymatic staining using antiactin and anti-PSAP was used to label the tissue components.[49] Color image analysis demonstrated age-related changes in the density of SM that appear to parallel serum testosterone levels, which vary as a result of the postnatal testosterone surge and the increased level of testosterone at the onset of puberty.[3,51]

A progressive decrease in SM area density throughout childhood, prepuberty, and puberty was observed. The density of SM significantly increased following puberty and throughout adolescence and early adulthood. There was a concomitant increase in connective tissue (CT) from the neonatal period throughout childhood, prepuberty and puberty, and a decrease after puberty and throughout adolescence and early adulthood. Since the changes in SM and CT were inversely related, the percent contribution of the stromal compartment to the total gland remained constant. No significant changes were seen in the epithelium or glandular lumen during these periods. The stromal to epithelial ratio remains constant from birth to age 40 in non-hyperplastic glands and is similar to those in asymptomatic and symptomatic BPH tissues. These morphometric observations suggest that BPH is not a unique stromal process.[50] These studies demonstrate that the stromal compartment is a dynamic structure, and the relationship between changes in cellular content and hormone milieu may be important to our understanding of growth of the prostate from birth to age 40 and the subsequent development of BPH.

Shapiro et al compared prostate development in normal human male fetuses and those with myelomeningocele (MMC) at 20 weeks' gestational age.[51] Immunohistochemical staining was performed using Masson's trichrome and antibodies to smooth muscle (SM) and skeletal muscle (SKM) actin. S-100 protein for Schwann cell localization and neurofilament protein was also performed. These studies demonstrated a marked decrease in the peripheral innervation to the prostate in MMC. Trichrome and SM actin staining also showed that SM in MMC specimens was less well differentiated. Prostatic size, ductal morphogenesis, and SM were decreased when compared with controls. At the level where the EDs enter into the prostatic urethra, the mean cross-sectional area was 6.79 mm^2 and 11.91 mm^2 in the MMC and normal prostate, respectively. Control prostates showed posterior peripheral SM surrounding acini, which subsequently become cannulated, as well as SM surrounding the EDs and along the periphery. In MMC prostates, SM was absent in the periphery, where ductal branching and formation of acini normally occur. The other areas of SM were also poorly formed. It was concluded that there is a global defect in the development of SM in MMC prostate at 20 weeks' gestation. Since the peripheral nerve density was diminished in the MMC prostate, an intact nervous system may be important in the SM and ductal morphogenesis of the developing prostate.

Summary

The foundation for our understanding of the development of the human prostate was derived from human fetal studies reported by Lowsley and by unraveling the biochemical basis for the 5α-reductase deficiency syndrome. Tissue recombinant studies, genetic knockout studies in nude mice, and meticulous step sectioning of fetal prostates with immunohistochemical staining gestation has greatly enhanced our understanding of prostatic development. Additional studies in animal models have provided insights into the impact of hormonal perturbations on prostatic development. It is likely that future studies extending our understanding of prostatic development in man will provide important insights into the mechanism of benign and malignant prostatic growth in aging.

Embryology of the anterior abdominal wall, bladder, and proximal urethra

49

Steven E Lerman, Irene M McAleer, and George W Kaplan

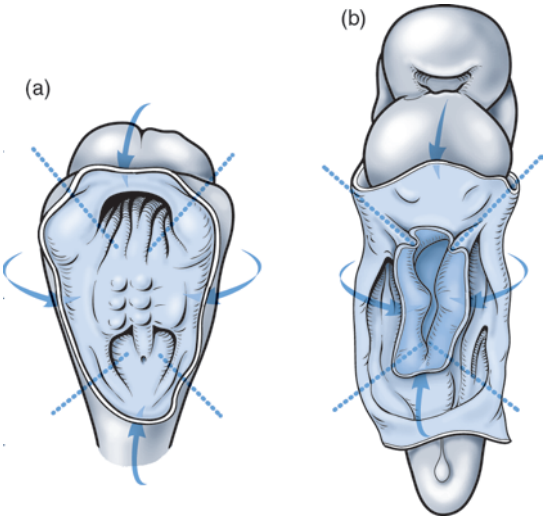

Figure 49.1 Ventral views of human embryos of 2 and 3 mm. The body stalk has been cut distal to the site of the future umbilical ring. Arrows show the direction of infolding; dotted lines indicate the arbitrary boundaries of the four infoldings. (Reproduced from Gray and Skandalakis,[1] with permission.)

Anterior abdominal wall

During the first 3 weeks of development, the embryo is a plate of cells, the embryonic disk, whose ventral surface is a membrane called the somatopleure. The anterior abdominal wall is at first represented by the somatopleure of the overhanging head and tail folds. The somatopleure closes concentrically from the cranial, caudal, and lateral margins, centering on the future umbilical ring (Figure 49.1).

In the 6th week of development, the midgut closes and the body stalk reduces in relative size. The somatopleure is invaded by mesoderm from myotomes on either side of the vertebral column. This mesoderm migrates laterally and ventrally as a sheet (Figure 49.2).

The primordia of the two rectus abdominis muscles form laterally and begin to move toward the midline during the 7th week. At that time, the mesoderm laterally splits into three sheets, eventually producing the external oblique muscle, the internal oblique muscle,

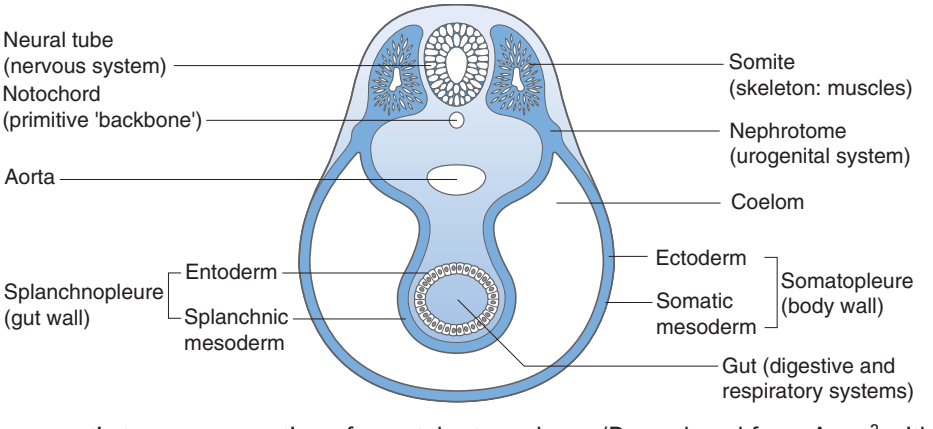

Figure 49.2 Diagrammatic transverse section of a vertebrate embryo. (Reproduced from Arey,[2] with permission.)

and the transversus abdominis muscle. These layers are all recognizable during the 7th week (Figure 49.3). In the infraumbilical area, the formation of three muscle layers is preceded by invasion of secondary mesoderm that arises from the primitive streak just behind the cloaca. This secondary mesoderm then surrounds the cloaca and invades the body wall caudal to the body stalk, providing primary closure to the body wall between the phallus and the body stalk and forming part of the anterior bladder musculature as well (Figure 49.4).[3]

Between the 7th and 12th weeks of development, the rectus abdominis muscles meet in the midline except around the umbilicus. During this same time the secondary mesoderm forming the lower abdominal wall is reinforced externally by invading somatic mesoderm that forms the muscular layers of the lower abdominal wall.

The important urologic anomalies resulting from faulty embryogenesis of the abdominal wall are the Eagle–Barrett (prune belly) syndrome, exstrophy of the bladder or cloacal exstrophy. None of these is an arrested stage of normal embryogenesis. The Eagle–Barrett syndrome seems most likely to be due to faulty mesodermal development during the 6th to the 12th week, as several mesodermal elements (abdominal wall, ureter, bladder, and testes) are usually involved.[4] Another theory states that the Eagle–Barrett syndrome is a deformation of the abdominal wall produced by distended viscera or increased intra-abdominal pressure.[5] A third theory

attributes the urinary abnormalities to a primary abdominal wall defect resulting in decreased intra-abdominal pressure.[6]

Exstrophy may result from a failure of the secondary mesoderm to cover the infraumbilical abdominal wall. Rupture of the cloacal membrane prematurely could also produce such a failure. Should this occur in the 5th week, cloacal exstrophy could result.[7] If this does not occur until the 7th week, so that some of the secondary mesoderm is in place, classical bladder exstrophy might result. Still later (the 10th or 11th week), failure of invasion by somatic mesoderm might result in superior vesical fissure or epispadias.

Lower urinary tract

The development of the lower urinary tract is closely interrelated with that of the genital tract and the hindgut, but for clarity the genital tract is not discussed here but covered in Chapter 58.

During the first 3 weeks the cloaca develops from endoderm as a blind caudal expansion of the hindgut (Figure 49.5). The hindgut meets the ectoderm of the body wall at the cloacal membrane. This membrane extends caudally from the primitive streak and is turned under by the tailfold. It extends from the tailbud to the body stalk. As the mesoderm grows, the area of the cloacal membrane is decreased. The cloaca gives off a ventrally directed allantoic stalk and receives the mesonephric duct laterally and extends caudally as the tailgut.

The cloaca, during the 5th week, is divided by opposing walls of the hindgut in the allantois, meeting in a saddle-shaped notch with its apex pointing caudally. This notch fills in with mesenchyme to form the urorectal septum. This septum pushes caudally as a fold and advances, dividing the cloaca into the primitive rectum posteriorly and a urogenital sinus anteriorly (Figure 49.6).

Various regions of the urogenital sinus are recognizable in the 6th week: the allantois, bladder, pelvic, and phallic portions of the urogenital sinus. The pelvic portion of the urogenital sinus lies cephalad to the entrance of the mesonephric duct but below the bladder, whereas the phallic portion of the urogenital sinus lies caudad to the entrance of the mesonephric duct and extends distally toward the genital tubercle.

By the 7th week the ureters empty into the bladder by a process in which nephric ducts, after the ureteral buds have appeared, are absorbed into the urogenital sinus and acquire four separate openings into the sinus (Figure 49.7). The mesonephric ducts are shifted further caudad in the sinus and come to lie close to each other at Müller's tubercle, while the ureters shift cephalad and laterally into the bladder. It is then that the trigone is formed. The trigone is temporarily mesodermal but fills in with urogenital sinus epithelium, so that it, too, is eventually endodermal.

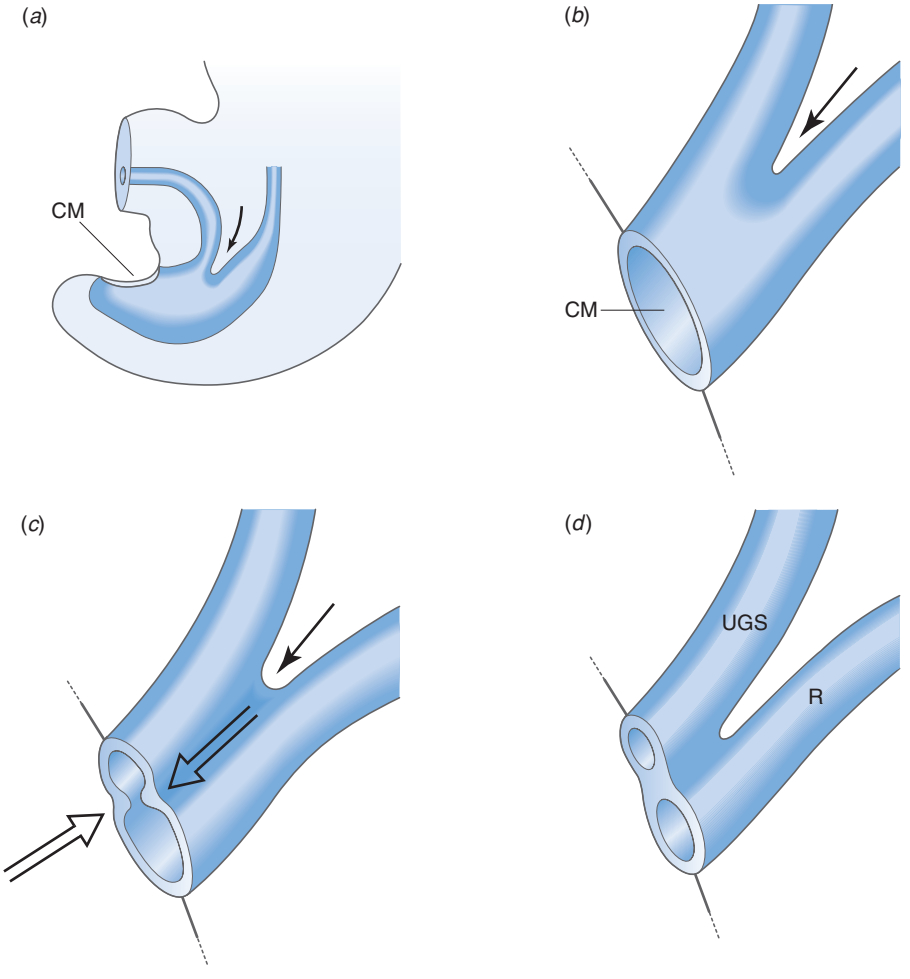

Figure 49.6 Septation of the cloaca. (*a*) Lateral view of caudal embryo (CM, cloacal membrane). Septation of the cloaca occurs in a coronal plane as Tourneux's fold (*b*) extends to the cloacal membrane from above, and (*c*) as Rathke's plicae extend towards each other from the sides. (*d*) Septation establishes the primitive urogenital sinus (UGS) and rectum (R). (Reproduced from Stephens and Smith,[8] with permission.)

The bladder epithelium at this time consists of a single layer.

The urorectal septum reaches the cloacal membrane and divides the cloaca into the urogenital sinus and the rectum; the cloacal membrane then ruptures (see Figure 49.6). The caudal edge of the urorectal septum, which is covered with endoderm, is exposed as the perineal body. It merges with lateral folds flanking this fissure and becomes covered with ectoderm. It is eventually marked by a median raphe and becomes the perineum. Hillocks behind the anus encircle this area and form the anal canal, which eventually becomes lined with ectoderm.

In the 8th week the bladder muscle begins to appear as a longitudinal layer on the dorsal surface of the bladder. By the 9th week the bladder cavity begins to expand into a sac, the apex of which (the urachus) is elongated. The urachus is continuous with the allantoic stalk at the umbilicus. The bladder and urachus elongate as the infraumbilical body wall forms from the somatic mesoderm.

In the 12th week the bladder epithelium becomes transitional, and its muscular wall is formed from mesenchyme. The smooth muscle of the urinary tract is acquired in an ascending fashion from bladder to intrarenal collecting system.[10] The bladder epithelium over the ureteral orifice forms Chwalla's membrane, which temporarily covers and occludes the ureteral orifice. Chwalla's membrane perforates and the ureter becomes continuous with the bladder. By the 16th week the bladder is completely muscularized and the urachus is closed.

Agenesis of the bladder is a rare anomaly that may arise because the allantoic stalk fails to develop.[11]

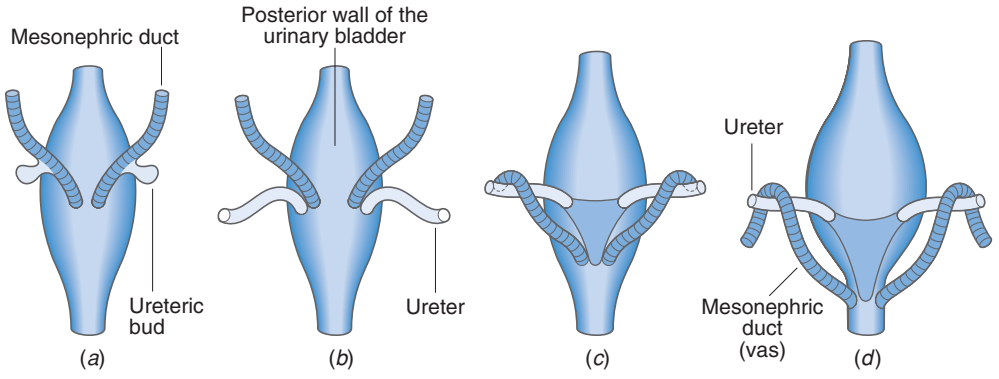

Figure 49.7 (*a–d*) Dorsal views of the bladder to show the relationship of the ureters and mesonephric ducts during development. Initially, the ureters are formed by an outgrowth of the mesonephric duct, but with time they assume a separate entrance into the urinary bladder. Note the trigone of the bladder formed by incorporation of the mesonephric ducts. (Reproduced from Sadler,[9] with permission.)

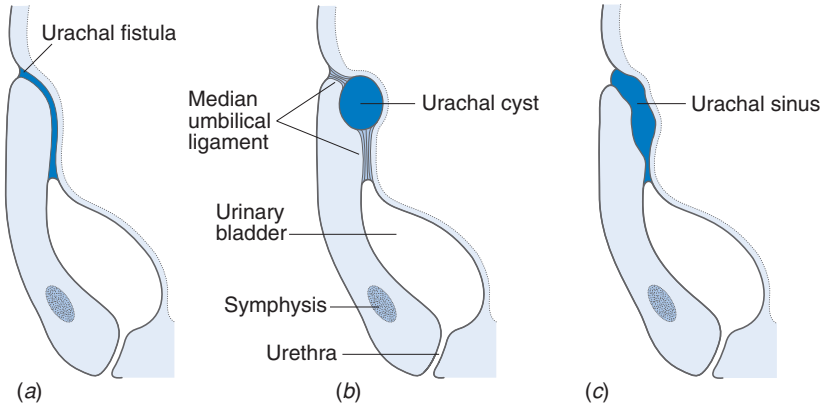

Figure 49.8 Diagrams of (*a*) urachal fistula, (*b*) urachal cyst, and (*c*) urachal sinus. The sinus may or may not be in open communication with the urinary bladder. (Reproduced from Sadler,[9] with permission.)

However, if migration of the ureters and formation of the trigone are the events that induce enlargement of the allantoic stalk, then bilateral failure of ureteral migration with resultant ureteral ectopia would result in the same anomaly.

Urachal anomalies (patent urachus, urachal cyst, urachal sinus, and urachal diverticula) may be encountered clinically (Figure 47.8). Some anomalies result from a general mesodermal failure (the urachal diverticulum of the Eagle–Barrett syndrome);[14] however, most seem to result from delayed closure of the urachus. Lower urinary tract obstruction <12 weeks of age (by virtue of bladder distention) could prevent closure.[12] There is, in addition, a definite association of patent urachus with upper tract problems, and therefore the entire urinary tract should be investigated.[13] Urachal cysts and sinuses presumably result from incomplete closure of the urachus.

Duplications of the bladder and urethra are usually associated with other hindgut and lower spinal cord duplications. Hence, it would appear that these result from a splitting of the hind end of the embryo at a very early stage of development, distinct from the lower abdominal wall defect resulting in exstrophy.

Ureteral ectopia, vesicoureteral reflux (VUR), and paraureteral diverticula appear to arise because the ureteral bud appears at a locus on the mesonephric duct more craniad or caudad than normal. As the ureter is incorporated into the urogenital sinus, its final site would be more craniad and lateral or caudad, respectively. The former results in VUR and diverticula, whereas the latter results in ureteral ectopia.[14]

Ectopic ureteroceles probably result from abnormalities of the ureteral bud in addition to ectopia and are often associated with renal dysplasia.[14] Intravesical (simple) ureteroceles are thought to be due to

persistence of Chwalla's membrane beyond the time when urine flow begins.[15]

Posterior urethral valves (type 1) may result from persistence of the path of migration of the mesonephric ducts distal to Müller's tubercle so that they cross the urogenital sinus and enter anteriorly. Persistence of this portion coupled with anterior fusion might then produce the diaphragm known as valves.[16] Another type of valves (type 3) seems to result from persistence of the cloacal membrance at the junction of the end of the phallic portion of the urogenital sinus and the bulbomembranous urethra.[17]

Radiologic assessment of bladder disorders

50

Douglas E Coplen

Introduction

Congenital anomalies and abnormalities of the urinary bladder can be a significant cause of morbidity in infants and children. The function of the bladder may adversely affect the upper urinary tract and may have an effect on urinary continence. Radiologic evaluation of the bladder and adjacent structures gives useful diagnostic information to direct therapeutic intervention. In children, ultrasonography (ultrasound) is usually the initial diagnostic study. Fluoroscopic imaging (voiding cystourethrogram or VCUG) is frequently obtained as indicated by the clinical history and ultrasound findings. Cross-sectional imaging – computed tomography (CT) and magnetic resonance imaging (MRI) – is often used in complex cases where other imaging does not clearly define the anatomy.

Ultrasound is ideally suited for the evaluation of children with symptoms suggestive of a bladder or lower urinary tract abnormality because it is painless, associated with no radiation exposure, and provides excellent anatomic definition of the bladder. For this study a partially distended bladder is preferable. The clear differentiation between the anechoic urine and the bladder wall and surrounding structures enhances the diagnostic utility of ultrasound (Figure 50.1).

If upper urinary tract dilatation is identified during an examination, the ultrasound should also include imaging after bladder emptying, since the degree of bladder distention may affect the upper tract findings. Doppler ultrasound can be used to identify ureteral jets (urine flow into the bladder) that are evidence of antegrade flow into the bladder.[1] Postvoid views can be obtained to assess bladder emptying and bladder wall thickening. Bladder volume can be estimated by ultrasound using the empirical equation:[2]

$$\text{bladder volume} = 0.7 \times \text{width} \times \text{length} \times \text{depth}$$

The VCUG is the best method of fluoroscopic bladder imaging. The study consists of direct opacification of the bladder with iodinated contrast medium that is usually instilled through a urethral catheter. Preferably both filling and voiding views are obtained during the study. Dynamic visualization of the bladder may give

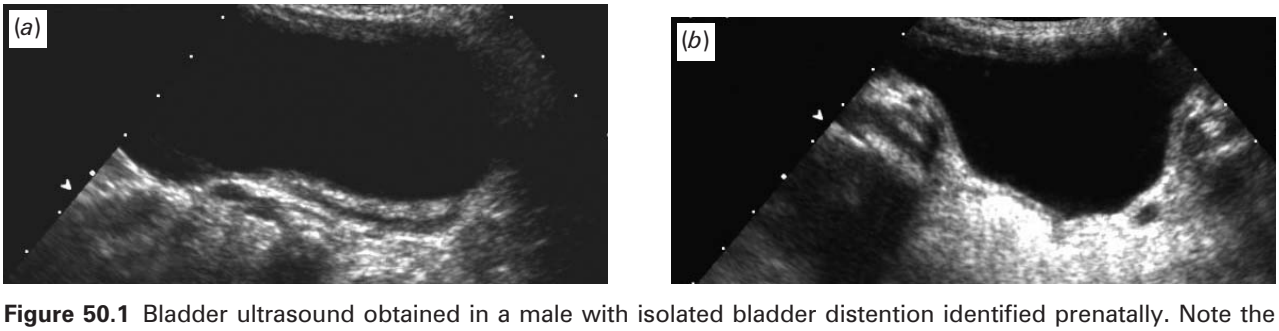

Figure 50.1 Bladder ultrasound obtained in a male with isolated bladder distention identified prenatally. Note the clear definition of the lumen and bladder wall on ultrasound. Longitudinal (*a*) and transverse (*b*) views show a dilated left ureter is seen posterior to the bladder. The child had bilateral grade V reflux but no infravesical obstruction.

very useful information regarding bladder function and disordered elimination. Voiding views are especially important in the male, since abnormalities of the bladder outlet and urethra greatly impact the bladder.

Intravenous pyelography (IVP) is rarely used as a primary bladder imaging modality. The excreted contrast gives passively filled bladder images. This modality may be preferable in older males who are reluctant to undergo urethral catheterization, but the contrast is dilute and opacification of the bladder and urethra is not as good, perhaps resulting in a non-diagnostic study.

CT and MRI give improved spatial resolution when compared with more commonly utilized imaging modalities. Images are obtained in an axial mode, but can be reformatted in both the sagittal and coronal planes. With current software, both planar reconstructions and three-dimensional reconstructions give excellent resolution.[3]

Superior soft-tissue resolution is an advantage of MRI over CT. On T1-weighted images the bladder wall may be indistinguishable from the urine, but on T2-weighted studies fluid-filled structures like the bladder are very well defined (Figure 50.2).[4] Because of prolonged acquisition times, sedation is required in younger children. MRI is very expensive when compared with ultrasound and fluoroscopy and should probably be reserved for complex cases where anatomy is not well-defined using other modalities.

Figure 50.2 MRI obtained on a 6-year-old adopted male with an apparent history of bladder exstrophy based on physical examination. He is incontinent of both urine and stool per 'rectum' but these do not appear to be mixed. The study clearly defines the lower tract anatomy. On coronal section (*a*) the rectum is visualized anterior to the sigmoid 'bladder', which has been pulled through posterior to the rectum. The ureters are reimplanted into a sigmoid segment as seen in sagittal section (*b*) (filling defect in sigmoid 'bladder').

Bladder enlargement

An enlarged bladder may be identified on physical examination. Whereas bladder distention may be a normal finding prior to voiding, it may be indicative of significant bladder or urethral pathology. Congenital anomalies such as spinal dysraphism and prune belly syndrome should be evident on examination and help with the differential diagnosis. A thickened bladder wall on ultrasound is suggestive of bladder outlet obstruction, although, when the bladder is markedly distended, wall thickening may not be readily apparent (Figure 50.3).[5] Concomitant ureteral dilatation in the presence of bladder distention and a thin bladder wall is suspicious for high-grade vesicoureteral reflux (see Figure 50.1).

A VCUG gives both the anatomic detail and functional information that defines the etiology of bladder distention. Views of the urethra are essential in the evaluation of these children. Bladder trabeculation and cellules are commonly identified in children with posterior urethral valves or neurogenic bladder. Children with prune belly syndrome or megacystis/microcolon usually have large smooth-walled bladders (Figure 50.4).

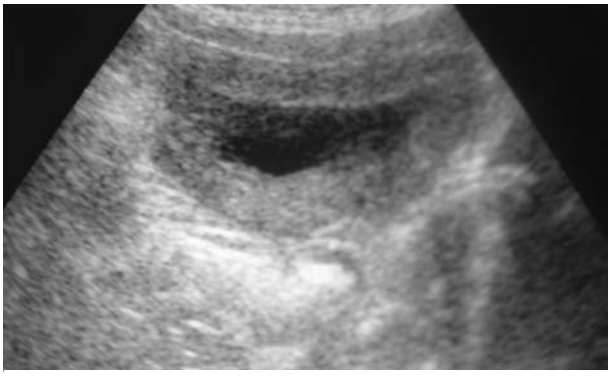

Figure 50.3 Postvoid ultrasound in a boy with posterior urethral valves. He empties completely, and marked bladder wall thickening is clearly apparent.

Urachal abnormalities

The urachus, sometimes called the median umbilical ligament, has usually obliterated by the 12th week of gestation. In theory, a patent urachus may occur in the presence of bladder outlet obstruction, but no evidence of obstruction is identified in the majority of cases.[6] Occasionally, a patent urachus is identified at birth when there is free discharge of urine through the umbilicus. More commonly, only a tiny fistula is present and the umbilicus is enlarged or edematous. In these situations, the differential diagnosis includes omphalitis, 'normal' hypertrophic granulation tissue, and a patent omphalomesenteric duct. Ultrasound may identify an inflamed tract, but a fistulogram with radiopaque contrast is often diagnostic (Figure 50.5). Voiding cystourethrography is helpful in fully evaluating the lesion and any associated bladder outlet obstruction.

Partial obliteration of the urachus results in a urachal cyst. These cysts are usually asymptomatic but occasionally become infected and are identified during the evaluation of lower abdominal pain, fever, and voiding symptoms. The diagnosis can be made by ultrasound. CT may be useful in defining the extent of the cyst and evaluating adjacent structures (Figure 50.6).

A urachal diverticulum is often an incidental finding on VCUG that does not require treatment. A large diverticulum is commonly identified in prune

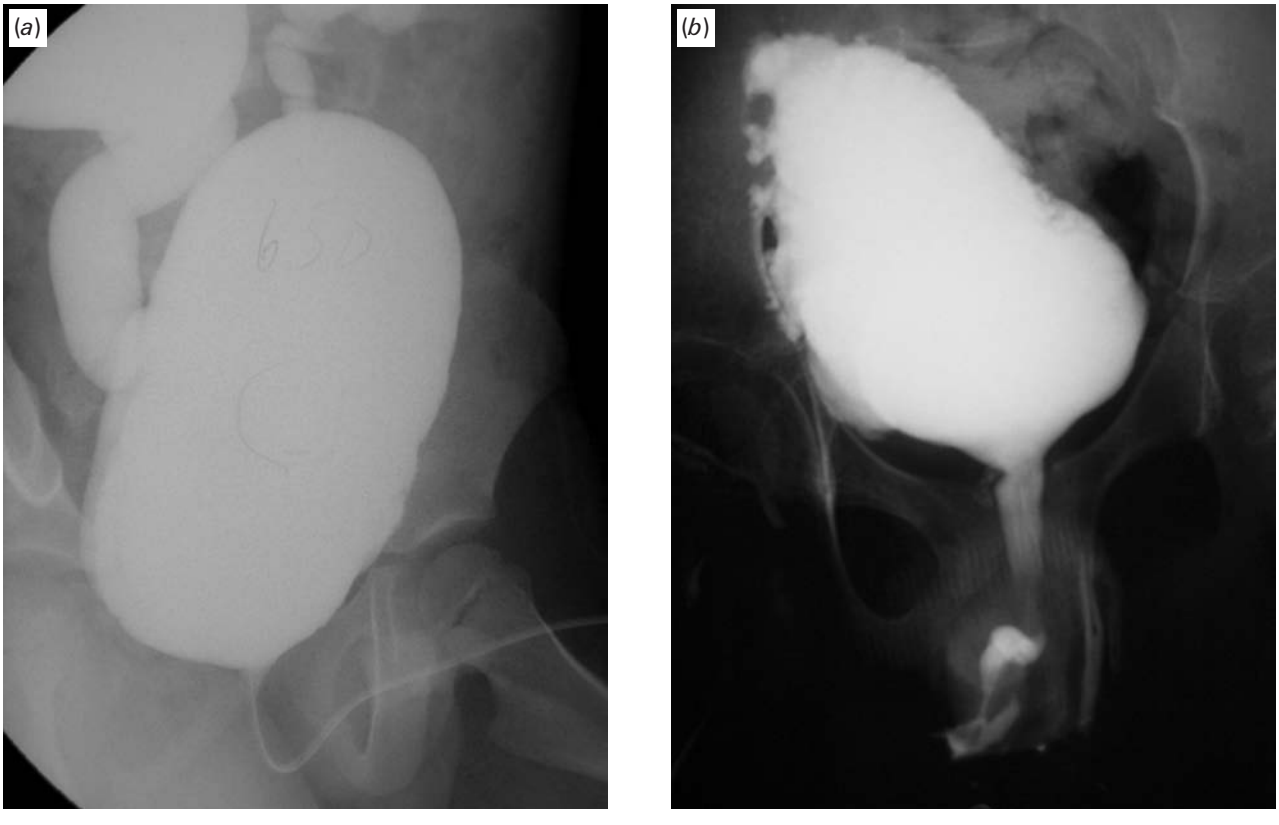

Figure 50.4 VCUG in two boys with bladder enlargement: (*a*) bilateral high-grade reflux with a smooth bladder wall and no outlet obstruction; (*b*) marked bladder trabeculation and 'Christmas tree' deformity in a boy with spinal dysraphism.

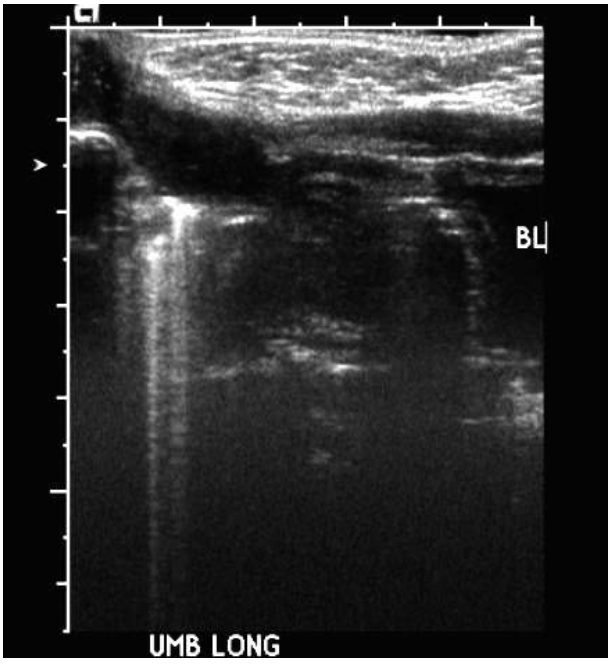

Figure 50.5 A 1-month-old male with a moist umbilicus. The ultrasound shows a well-defined tract from the umbilicus down to the dome of the bladder (BL). The tract expanded during a bladder contraction (real-time imaging), documenting a communication with the bladder.

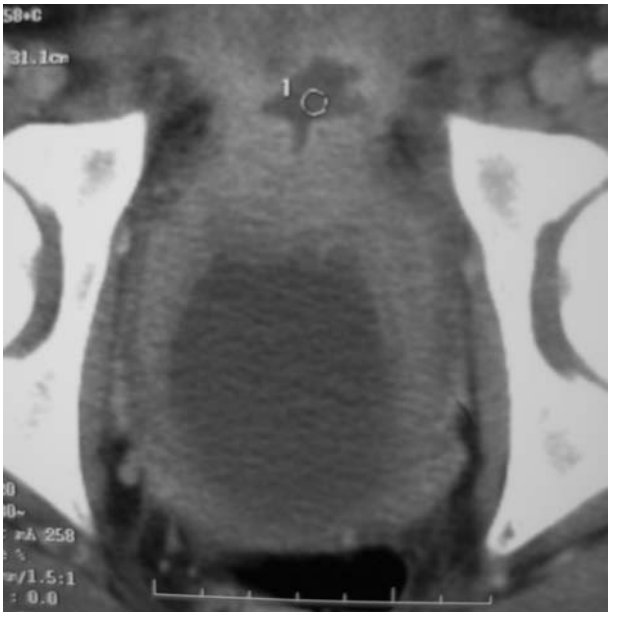

Figure 50.6 A 14-year-old male with lower abdominal pain, pyuria, and an infected urachus. CT shows an inhomogeneous mass cephalad to the bladder. Anterior bladder wall inflammation and thickening can be seen.

belly syndrome and rarely may require excision if it is a source of significant urinary stasis (Figure 50.7).

Bladder diverticulum

A bladder diverticulum is the result of a weakening in the muscular layer of the bladder wall. This may be congenital, but it can be acquired in the presence of bladder outlet obstruction or dysfunctional voiding. In children, the diverticulum is most commonly periureteral. Diverticuli are most commonly identified during the evaluation of urinary tract infections and they may, theoretically, be a significant source of urinary stasis. The fluid-filled extravesical structure identified on ultrasound is definitively differentiated from a dilated ureter on VCUG (Figure 50.8). The oblique bladder views localize the location of the diverticulum and whether or not it is broad based.

Bladder masses

Bladder masses are distinctly unusual in children. Presenting symptoms are usually related to outflow obstruction (strangury). Occasionally, gross hematuria is identified by the parents, but most children with gross hematuria have no identifiable anatomic abnormality and have a nephrologic source of bleeding. Ultrasound is the initial test of choice in children, because it is non-invasive and will usually identify an intravesical or infravesical abnormality. If an abnormality is identified, cross-sectional imaging is usually

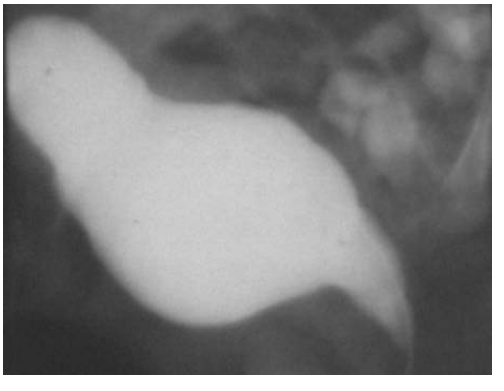

Figure 50.7 A VCUG in a boy with an abnormal abdominal wall shows a wide-mouthed urachal diverticulum. Typical bladder neck and urethral findings confirm the diagnosis of prune belly syndrome.

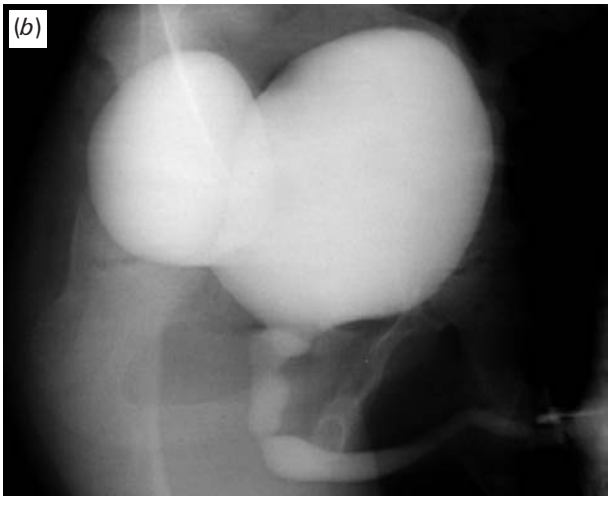

Figure 50.8 Bladder diverticulum in a 7-year-old male with recurrent staphylococcal cystitis. (a) On ultrasound, it is evident that the tubular structure does not extend cephalad and is not a ureter. (*b*) On VCUG, the lateral view confirms an origin low on the bladder base, which is consistent with a congenital periureteral diverticulum.

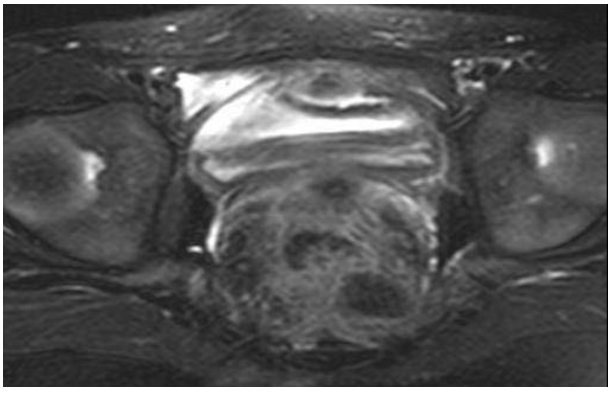

Figure 50.9 Rhabdomyosarcoma detected during evaluation of a febrile urinary tract infection. T2-weighted imaging reveals thickening of the bladder base and lateral walls. There is bladder wall bulging, with no evidence of perivesical involvement.

obtained, although in some clinical situations an endoscopic evaluation is the next best step.

Rhabdomyosarcoma is the most common bladder malignancy in children: most present with obstruction and a palpably distended bladder and/or lower abdominal mass. An ultrasound usually reveals a mass at the base of the bladder. MRI offers the best detail in relation to other pelvic organs and is the preferred study for radiologic staging (local and metastatic) (Figure 50.9).

Transitional cell carcinomas of the bladder and fibroepithelial polyps are very rare in children. They are usually well visualized on ultrasound because they usually have a narrow stalk and project into the lumen of the bladder (Figure 50.10).

Bladder calculi

Historically, bladder calculi were related to dietary intake. However, stones are now identified in up to 50% of children after bladder augmentation.[7] They are often identified during routine follow-up imaging. On ultrasound, stones are echogenic foci, with associated shadowing (Figure 50.11). They are usually mobile on the dependent portion of the bladder. Images are better if the bladder is partly distended, since stones may be in some mucosal folds and confused with echogenic stool that is often present in the true pelvis of these children. A KUB (kidney, ureter, and bladder abdominal X-ray) helps define the number of calculi.

Although ultrasound is not the best imaging study for upper tract stones, it can be useful in the evaluation of distal ureteral calculi that are not readily apparent on plain films. A dilated distal ureter is easily visualized behind the bladder and a shadowing and echogenic focus at the ureterovesical junction confirms the presence of a stone. If the ureter is not dilated or the stone is proximal to the bladder, ultrasound is usually not useful.

Bladder rupture

Bladder perforation may occur with blunt abdominal trauma and/or pelvic fractures. Children with a history of bladder augmentation may have spontaneous perforation in the absence of any identifiable trauma. A high index of suspicion is required in the evaluation of children with a history of bladder augmentation and abdominal pain. A VCUG is diagnostic in most cases, but thorough technique, including

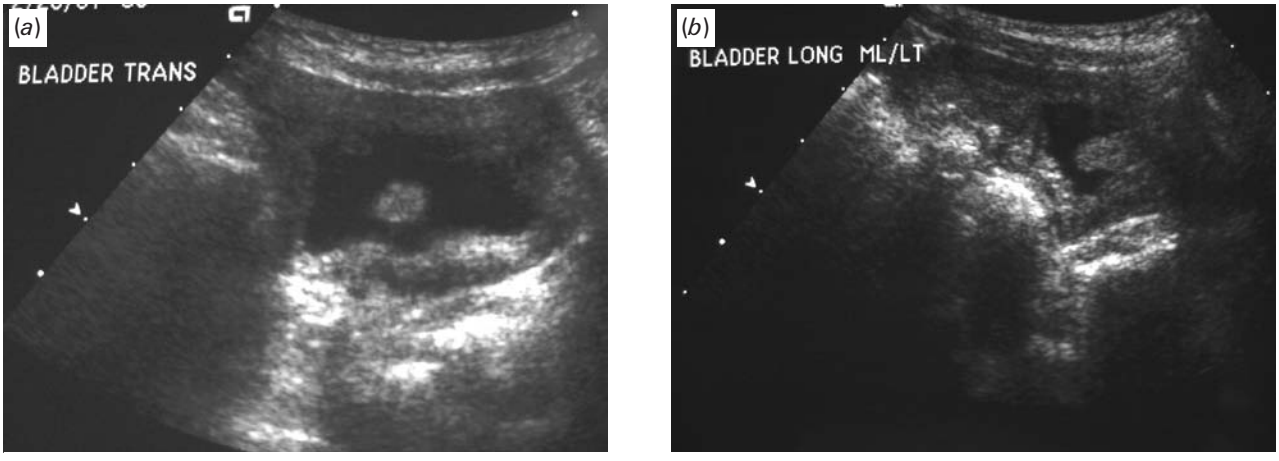

Figure 50.10 A fibroepithelial polyp identified in a 2-year-old male with intermittent urinary retention. Transverse views (*a*) show a 'free-floating' mass that extends across the bladder neck on longitudinal views (*b*) of the bladder. The bladder wall is thickened, which is consistent with intermittent obstruction.

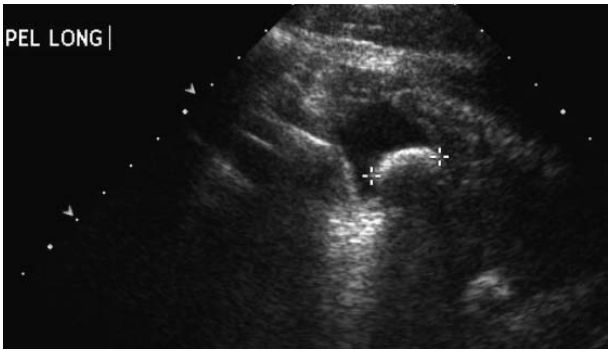

Figure 50.11 Bladder calculus in an augmented bladder. A curvilinear shadowing defect is evident on the bladder base.

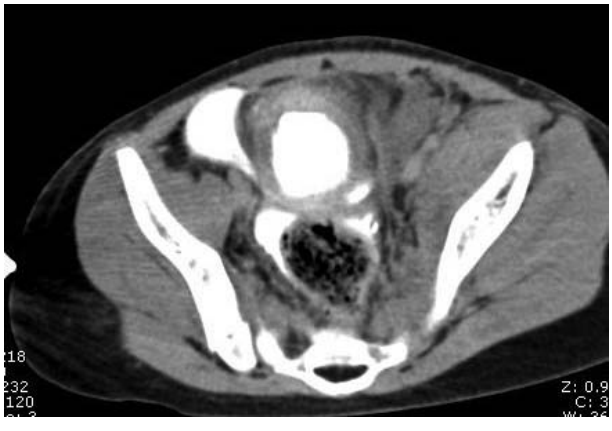

Figure 50.12 Intraperitoneal bladder perforation after blunt abdominal trauma. The CT scan reveals contrast in the bladder but it is also evident in the peritoneal cavity and perirectally in the pouch of Douglas.

postdrainage films, is required to identify smaller perforations. The irregularities normally present in the augmented bladder increase the chance of a false-negative study and a CT scan improves the diagnostic accuracy. Passive bladder distention is inadequate. Retrograde distention with diluted (4–5%) contrast is necessary to appropriately evaluate for perforation using CT cystography (Figure 50.12).[8] A CT cystogram should be obtained when a perforation is suspected and a VCUG is normal.

Ureteral abnormalities

Anomalies of the distal ureter are frequently identified during bladder imaging. The normal ureter should not be visualized on ultrasound imaging. When a dilated ureter is identified, it may be indicative of urethral, bladder, or ureterovesical junction pathology.

Megaureter is a generic term applied to an enlarged ureter. Ultrasound easily identifies the presence of these dilated ureters (Figure 50.13). The megaureter can be obstructed or non-obstructed, and refluxing or non-refluxing. While ultrasound identifies the dilation, a VCUG and renal scintigraphy are required to classify the megaureter.

Ectopic insertion of the ureter occurs most commonly in the setting of renal duplication. The duplication is usually easily identified on ultrasound evaluation of the upper tract because the lower pole of the kidney is not associated with a dilated ureter. Longitudinal ultrasonic bladder views frequently demon-

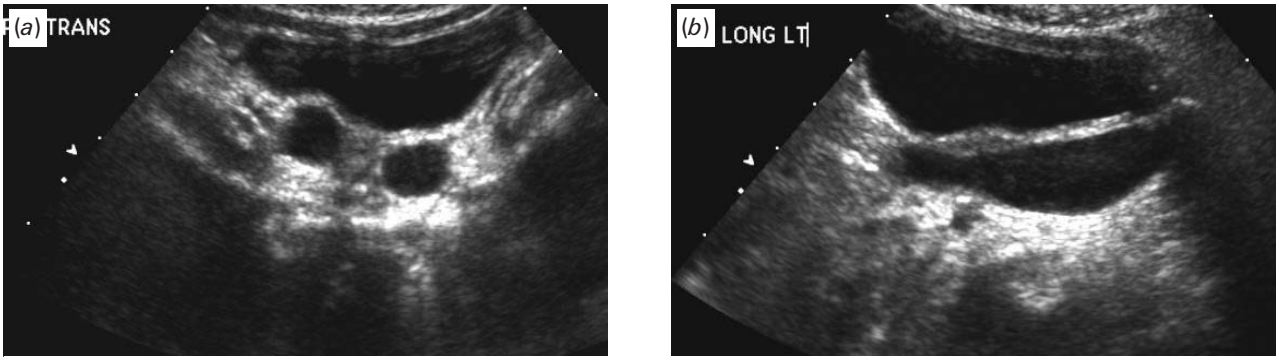

Figure 50.13 Bladder ultrasound in a female with recurrent febrile urinary tract infections. (*a*) A Transverse view reveals dilation of the distal ureters bilaterally. (*b*) A longitudinal view shows the dilated ureter coursing distal to the bladder neck. The child had bilateral duplications, with upper pole ectopia.

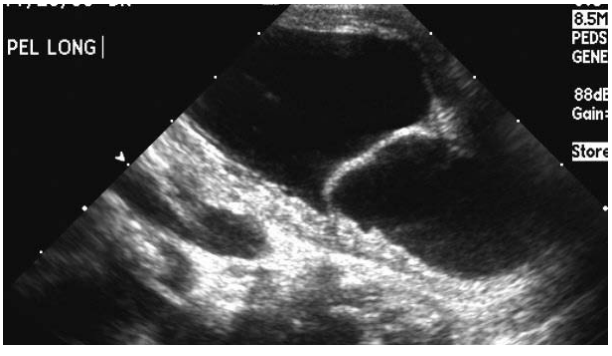

Figure 50.14 Bladder ultrasound images in a male with an ectopic ureterocele that obstructs the bladder outlet. The ureterocele extends down into a dilated prostatic urethra. Note the bladder wall thickening and trabeculation secondary to the outlet obstruction.

Figure 50.15 Cystogram in a female with a ureterocele. The filling defect in the urethra confirms its ectopic position. The ureterocele also everts during voiding because of the muscular deficiency in the right hemitrigone.

strate a ureteral insertion distal to the bladder neck. Occasionally, the dilated ureter deforms the posterior bladder wall and can be confused with a ureterocele. This pseudoureterocele can be differentiated by noting that the anterior wall is the same thickness as the rest of the bladder wall.[9]

Ureteroceles are cystic dilations of the intravesical segment of the ureter. Ureteroceles have a unique appearance on ultrasound: they are thin-walled cystic masses at the bladder base (Figure 50.14). Ureteroceles are usually simple, but are occasionally bilobed or lobulated. In the presence of infection, they may contain echogenic debris. Occasionally, a large ureterocele is not identified if the child has just voided because the apparent bladder urine is actually within the ureterocele, with no urine outside the ureterocele in the bladder. Ureteroceles are usually associated with a dilated ureter posterior to the bladder wall. Intravenous urography and cystography usually reveal a non-opacified filling defect in the bladder. There may be a significant detrusor defect and the ureterocele often everts during bladder filling on VCUG, resembling a diverticulum (Figure 50.15).[10]

Urodynamics of the lower and upper urinary tract

51

William E Kaplan

Introduction

Many of the patients evaluated by a pediatric urologist have urinary tract dysfunction requiring urodynamic studies. Although the majority of urodynamics performed involve the assessment of lower tract function, there are select patients who need upper tract urodynamic studies.

Most children referred for urodynamic studies already have a specific pathologic diagnosis (spinal dysraphism, spinal cord injury, cerebral pathology, etc.) but require a more definitive neurologic classification for appropriate therapy. Many patients with voiding dysfunction require urodynamics to determine whether their urinary problems are neurologic or functional in origin. In addition, patients are referred for urodynamics when other diagnostic studies, e.g. radiographic or isotopic, are equivocal.

The expansion of pediatric urodynamics in the late 1970s and early 1980s came about because of the need to understand the volume–pressure relationships of the urinary tract. The introduction of clean intermittent catheterization in the 1970s[1] opened the creative gates for the management of children with dysfunctional storing and emptying of their urinary tracts. However, correct characterization of the pathology by urodynamics was critical.

Adult diagnostic techniques needed modification for children, and what began with work on flow rates by Gierup et al,[2] progressed to sophisticated flow and electromyographic (EMG) studies by Blaivis et al,[3] and to the introduction of surface monitoring of the pelvic floor by Maizels and Firlit.[4] An additional valuable contribution of correct filling rates by Joseph in 1992,[5] and sedation techniques, emphasized the importance of a more focused approach to children.

There is still controversy regarding the diagnostic methodology best suited for upper tract pathology. The child with idiopathic hydronephrosis with preservation of renal function and no symptoms creates the greatest diagnostic dilemma. Standard imaging techniques are usually adequate for patients with normal renal function. However, when renal function becomes impaired, renal perfusion studies may offer a more useful diagnostic role. It is clear that the physiology of the upper tract does not exist in isolation. Therefore, although pure upper tract obstruction – e.g. well-defined ureteropelvic junction (UPJ) obstruction – is associated with pressure elevation with less dependence on lower tract function, the surgeon must always be aware of the equilibrium between lower and upper tract pressures. The fact that bladder pressure must be 'in the loop' in any diagnostic study emphasizes how important bladder dynamics has become in modern pediatric urology. The ability to assess and manage bladder function and pressure has contributed to the increase in surgical, pharmacologic, and neuromodulating techniques used to manage the child with neurourologic dysfunction.

This chapter focuses on pediatric urodynamic studies that best categorize neuropathology and help to define the best treatment modalities.

Historical features

The basics of pediatric urodynamics are founded on the principles of good medicine. A thorough history and physical examination must precede any diagnostic study (Table 51.1). In patients in whom the diagnosis is clear, e.g. spinal cord trauma or myelomeningocele, eliciting a diagnostic history will not usually be challenging. However, patients with urinary tract dysfunction with no obvious neurologic abnormality will challenge the diagnostic skill of even the experienced pediatric urologist.

Table 51.1 Evaluation of children who wet

History	Prenatal, congenital history Voiding characteristics Bladder and bowel function
Physical examination	Abdomen and perineum Spine Lower extremities: Reflexes Gait Physical structure
Laboratory	Urinalysis/culture Chemistry: urine/serum
Radiography	Ultrasonography: renal/bladder Voiding cystography Flat plate abdomen/spine (AP and lateral)
Urodynamics	Flow/bladder capacity Cystometry Pelvic muscle evaluation: pads/needle Compliance: LPP/VLPP and PSBV

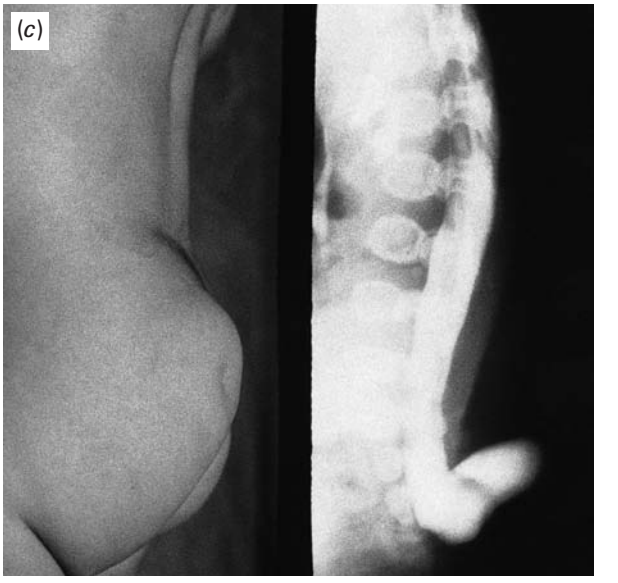
AP = anteroposterior; LPP = leak point pressure; VLPP = Valsalva leak point pressure; PSBV = pressure-specific bladder volume.

An accurate voiding history is most important. The patient's age and expectations of urinary control may dictate the concerns about voiding habits. However, even in infants, the pattern of wet and dry diapers may be important to discovering the diagnosis. Newborns with constant dribbling or signs of overflow incontinence may have undergone a traumatic delivery, e.g. hyperextension injury to the cervical spinal cord. Infants of diabetic mothers have an increased risk of neural tube defects. Infants of mothers with substance abuse are at increased risk for hydronephrosis. These are only a few examples that illustrate the importance of a thorough prenatal and obstetric history before scheduling and tailoring the type of urodynamics study.[6–8] Historic information, such as prematurity or global delay in physical or mental capabilities, is important. Although this information may not aid in therapy, it may help to explain to parents how delays in gaining urinary control occur. Infants with irregular bowel habits (diarrhea or constipation) in association with urinary symptomatology should prompt careful evaluation.

As the child matures, urinary tract infections (UTIs) or incontinence may become the primary symptoms. Van Gool et al[9] proposed the use of a standardized questionnaire that addressses common themes in the child with dysfunctional voiding. Frequency of wetting, voiding characteristics, and the presence of urgency are the focus of the questionnaire. The concept of a standardized approach is valid, although in a large practice, the similarity of the patients in any given day may ensure a routine history.

The use of a voiding diary or 12-hour home pad test may also be helpful.[10,11] In practice, the clinician may easily misinterpret the results if less than fastidious notes are kept, or if the pads are not changed promptly. The quality of the flow rate and whether a child is always wet despite effective voiding are important historic features. The boy with a poor flow rate would be suspicious for having posterior urethral valves, whereas the girl with paradoxical incontinence (continuously damp while voiding normally) might have an ectopic ureter. In the older child, the history must include details on bowel habits, because it is clear that constipation has a direct relationship to urinary control, as well as urinary infections.[12,13]

Physical examination



Before planning a urodynamic study, a thorough physical examination is essential. Children may exhibit evidence of delayed gross motor development or abnormal fine motor skills consistent with global abnormalities from in utero or birthing issues. In these children, a complete neurologic examination by a pediatric neurologist, including muscle tests and nerve conduction velocity, may be indicated.

A routine systematic approach, including having the child completely undressed from head to toe (although covered with a warm blanket and with a nurse and parent in attendance), will help to reveal general congenital defects that might contribute to syndromes that involve the urinary tract. Following the general assessment, most of the pertinent pathology is found below the umbilicus. The abdomen should be palpated for stool, although significant fecal retention can exist with a soft abdomen and an empty rectal vault.

The back, perineum, and lower extremities should be examined critically. During examination of the back, all midline abnormalities should be cause for concern. However, there is less importance if a simple dimple can be grasped with the tip of the coccyx. Obvious or subtle midline skin tags, tufts of hair, or

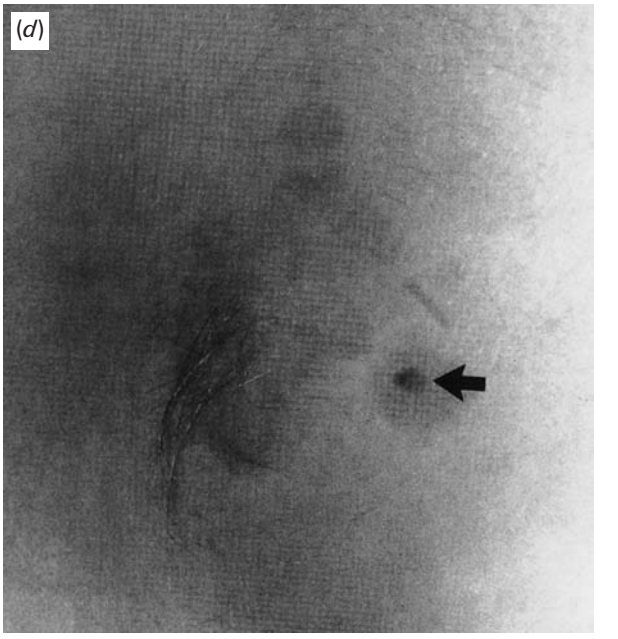


Figure 51.1 Cutaneous lesions discovered on midline spinal examination: (*a*) dermal sinus tract (open arrow) in infant who developed meningitis shortly after birth; (*b*) a subtle fullness of one buttock and mild scoliosis in a child with incontinence and subsequently discovered to have a lipoma; (*c*) an obvious sinus tract and lipoma in infant with lipomeningocele; (*d*) a sinus (arrow) and associated hairy patch characteristically associated with a flat capillary hemangioma; (*e*) an unusual appendage and dermal sinus tract.

vascular malformations may indicate underlying spinal malformations, e.g. lipomas, and spinal magnetic resonance imaging (MRI) is then indicated. A short or abnormal gluteal cleft may indicate an underlying sacral dysgenesis or agenesis. A flattened buttock suggests deficient gluteal muscle tone, consistent with an anorectal malformation or caudal regression syndrome (Figure 51.1).

Rectal tone, perianal sensation, and the presence or absence of a bulbocavernosus reflex should be noted. A digital rectal examination confirms the presence of stool and rules out rare prostatic lesions. The vaginal introitus should be inspected to rule out significant labial adherence or urethrovaginal abnormalities. In the boy, the meatus should be observed, and if uncircumcised, the foreskin either retracted gently or pulled forward, so that the meatus can be inspected through the tunnel of foreskin.

The lower musculoskeletal system should be examined and any discrepancy in muscle tone or muscle mass should be noted. It is essential to remove the shoes and socks to discover a high arched foot or hammer claw digits, consistent with a true neurologic abnormality (Figure 51.2). A gait disturbance is noted easily in barefoot children as they walk up and down the corridor. The author recently saw an incontinent child who was a star rollerblader, but on barefoot gait analysis was noted to have severe ankle weakness and intoeing. This was masked by the above-the-ankle rollerblades. Subsequent MRI revealed a tethered spinal cord. Finally, the deep tendon reflexes should be evaluated. Exaggerated reflexes are consistent with cerebral palsy.

At the first office visit, a urinalysis (glucose and specific gravity), flow rate, and postvoid residual measured by ultrasound should be accomplished. In children with a normal renal/bladder sonogram, and no history of significant UTIs, the majority of patients will be started on a timed voiding program, with attention to bowel habits, and a brief course of anticholinergic medication. In the remaining patients, a more thorough work-up, including radiographic evaluation and urodynamic studies, is indicated.

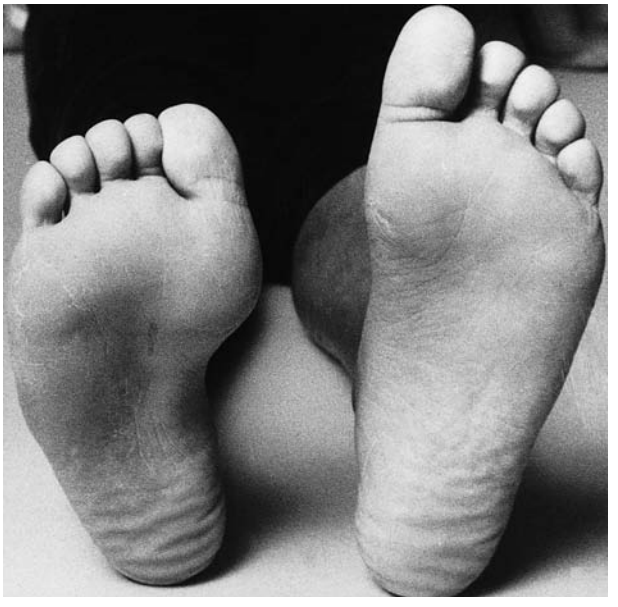

Figure 51.2 Leg length and foot asymmetry in a 10-year-old child with spina bifida.

Figure 51.3 Lumbosacral MRI. T1-weighted image indicates a long tethered spinal cord. The elongated (bowstring) cord ends in the lipoma rather than at L3.

Radiographic evaluation

Radiographic examination is used selectively. All children undergo a renal and bladder sonogram with postvoid imaging to evaluate bladder emptying and the effects of bladder fullness on upper tract dilatation. If UTIs are an issue, a conventional X-ray voiding cystourethrogram (VCUG) is performed to evaluate the bladder, outlet, and urethra. This study can document whether there is significant stool in the colon. Children with both fecal and urinary incontinence should have lumbosacral images. In patients with clearly abnormal studies, spinal MRI is performed (Figure 51.3).

Lower urinary tract urodynamics

A complete voiding history should precede urodynamic evaluation. A parental questionnaire includes the details of the foregoing discussion. This can be accomplished at the time of the examination, but the study can be best modified to the needs of the child if the staff is made aware of significant problems by telephone or mail consultation before the office appointment. All outside studies should accompany the family to the laboratory.

In the majority of cases, the child with a non-neurogenic voiding abnormality will be old enough to cooperate, tolerating a precystometrogram flow study followed by a cystometrogram with patch electrodes and a postvoid study. Typically, the child with neurogenic disease comes to the laboratory on a clean intermittent catheterization program and is being evaluated because of increasing dysfunction (tethered cord, shunt malfunction). Voiding studies become less important and needle electrode myography may be more important. In all instances, a relatively clean rectum will result in a more accurate study.

It is most important that the child is comfortable, and that the laboratory is child friendly (posters, movies, books, stickers, etc.) and temperature controlled. All voidings should be as private as possible. For the older child, a separate room with a flowmeter and a one-way mirror to observe voidings can be helpful. Given enough time and patience, most studies can be completed successfully with reproducible results. Meperidine, 1 mg/kg, can be given to an extremely anxious child, although this is not common practice (Table 51.2).[14]

Table 51.2 Urodynamic studies

Urodynamic study	Purpose: to evaluate:
Uroflow/residual urine	Voiding function sensation, storage, emptying of the bladder
Cystometry	Coordination/function of muscular outlet
Pelvic floor/external sphincter EMG	Bladder/outlet function
Leak point pressure:	
Bladder	Storage pressure
Stress (VLPP)	Competence of bladder neck/proximal urethra
Videourodynamics	Anatomy and function of bladder and outlet (simultaneously)

EMG = electromyogram; VLPP = Valsalva leak point pressure.

Urinary flow rate and bladder capacity

The urinary flow rate measurement is a simple noninvasive study that is defined as the voided volume per unit time (ml/s) (Figures 51.4 and 51.5). This study can evaluate incontinence secondary to problems in storage or emptying. Reliability comes from repeated studies (at least two) and is related to voided volume. Bladder capacity (BC) should be based on age rather than body surface. Although the linear formula of Berger et al[16] and Koff:[17]

$$BC\ (\text{ounces}) = \text{age} + 2$$

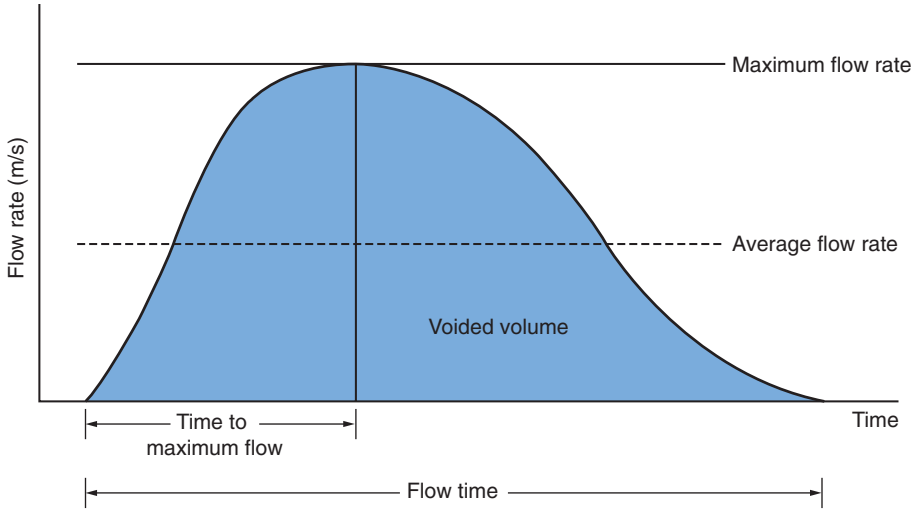

Figure 51.4 Idealized diagram of urine flow. (Modified with permission from Blaivas and Chancellor.[15])

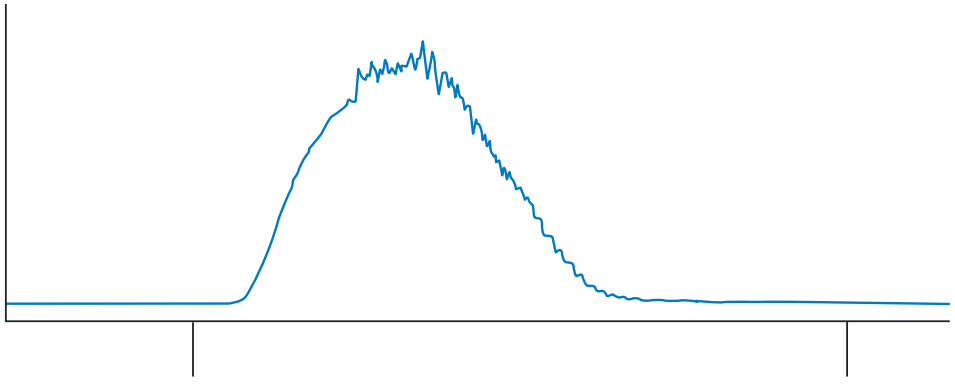

Figure 51.5 Normal uroflow in a 12-year-old male: maximum = 38 ml/s, average = 17 ml/s, volume = 222 ml.

has been the most frequently used to estimate bladder capacity, it is clear that bladder growth from a newborn (especially in the first years) to 13 years is not linear. Kaefer et al[18] responded to the challenge of modifying this equation with their non-linear equation:

$$2 \times \text{age (years)} + 2 = \text{capacity (ounces)}$$

for children <2 years old and

$$\frac{\text{age (years)}}{2} + 6 = \text{capacity (ounces)}$$

for children ≥2 years old. In all of these studies, data were based on findings in normal children. Children <14 years of age with spina bifida and neuropathic bladders do not exhibit similar growth rates to normal children. In fact, on comparing bladder growth in a small group of patients with spina bifida to the linear formula of Berger, bladders of patients with spina bifida grew half as well as those without neurologic abnormalities.[19] Thus, in order to calculate normal flow patterns and rates, one must first know the expected bladder capacity in order to determine whether the voiding volume is within the expected range. Accurate determination of the flow rate/voided volume is a common problem, particularly in the anxious child or in the child who voids frequently in small volumes. In general, voided volumes of <50% expected capacity should be suspect.[20,21] I recommend filling the bladder by forcing oral fluids on the way into the laboratory or by intravenous hydration. Multiple voids can be spontaneous, but furosemide administration can be helpful to ensure repeated measurements.

Critical features of the flow rate include the shape of the curve, maximum flow rate, and average flow rate. In a study of 180 schoolchildren aged 7–16 years, 98% had a bell-shaped flow pattern[20] (see Figure 51.4). The shape of the curve had no relationship to voided volume, but the other parameters were volume dependent. Although the maximum flow, average flow, and time to maximum flow can be of diagnostic interest, the shape of the flow appears to be the best screening parameter. Repeated deviations from the bell-shaped curve should prompt further studies (Figure 51.6). Estimation of residual urine can be an important clue to overall bladder function. Except in infants, the child's bladder should empty to completion with each void. There are multiple pitfalls when evaluating for retained urine. An anxious child in a foreign setting will not void efficiently. Furthermore, children with significant reflux may often harbor residual urine just after voiding. Thus, whereas complete evacuation can be helpful to know, an elevated postvoid residual may not signify important pathology. A bladder scan with ultrasound or placement of a catheter just prior to the cystometrogram will determine the residual urine.

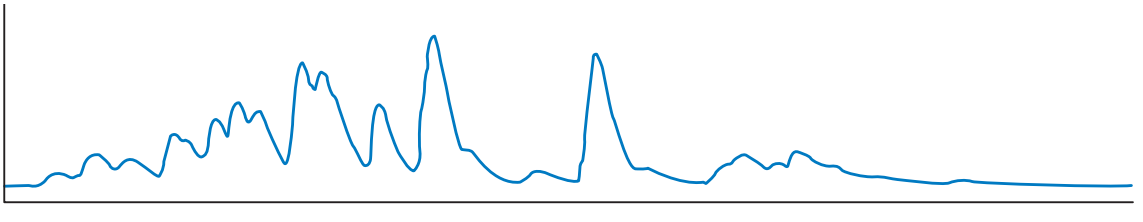

Figure 51.6 Abnormal uroflow in an 8-year-old male with abdominal straining and no detrusor activity.

Cystometry

Cystometry is the pressure–volume study of the bladder that examines both the storage and the voiding phase of micturition (Figures 51.7 and 51.8). Both parameters are instrumental in the assessment of bladder health in relationship to upper tract drainage. An accurate assessment of bladder storage must begin in a calm laboratory setting with the necessary techniques and props to decrease patient anxiety. The technician then passes an age-appropriate catheter. Male newborns usually require a 5 Fr feeding tube connected to a three-way stopcock that allows for both measuring pressure and fluid instillation. We try to take care to avoid an overly large catheter in newborns, which can obstruct the urethra and produce an abnormally high leak point pressure, as the fluid tries to leak around the catheter.[24] In older children, we use a 7–10 Fr catheter. Latex-free materials are essential for individuals with spina bifida, as they are prone to severe latex allergy and reactions.

We record both intravesical and abdominal pressures. The abdominal pressure is obtained by inserting a pressure catheter into the rectum. These readings are easily made by tying a latex-free finger cot to a small plastic tube connected to a pressure monitor. The software from the urodynamics system then

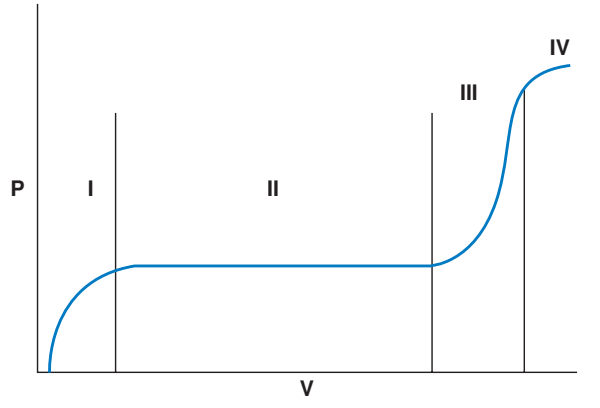

Figure 51.7 Cystometrogram indicating four phases and filling and detrusor activity: I, initial vesical pressure with early filling; II, stable tonus limb; III, increase in tonus at full vesicoelastic expansion; IV, voiding. (Modified with permission from Dmochowski.[22])

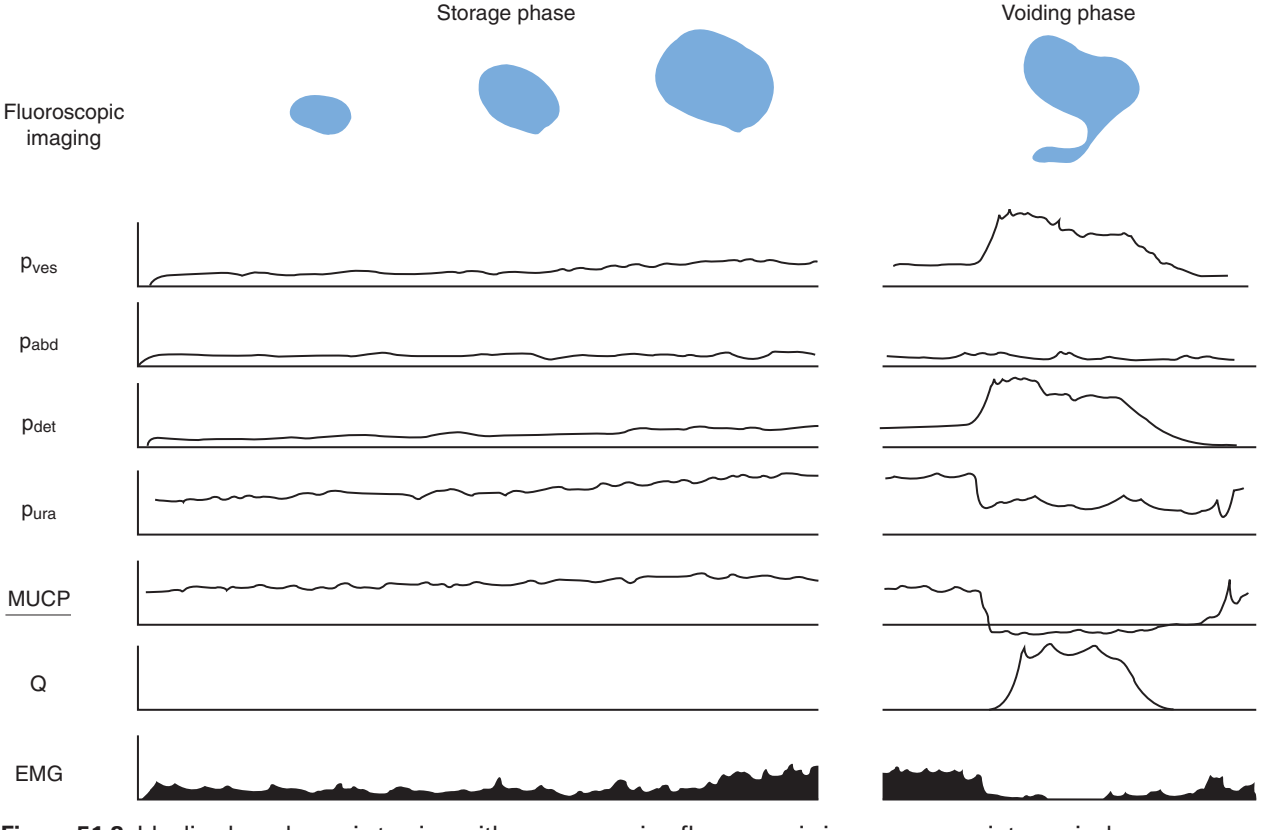

Figure 51.8 Idealized urodynamic tracing with accompanying fluoroscopic images. p_{ves} = intravesical pressure; p_{abd} = abdominal pressure; p_{det} = detrusor pressure; i.e. the $p_{ves} - p_{abd}$; p_{ura} = urethral pressure; MUCP = maximal urethral closure pressure; Q = urinary flow; EMG = surface electromyography. (Modified with permission from Abrams et al.[23])

subtracts the rectal (abdominal) pressure from the intravesical pressure to obtain a true detrusor pressure. These are basic measurements taken with a two-channel recorder. Membrane or microtip transducer catheters and multichannel recorders are readily available if so desired. The equipment varies; however, direct, hands-on, expert observation is probably more important than the size and complexity of the equipment. Straining, crying, and gross movements need to be noted and subtracted to obtain accurate detrusor pressures. The pressure transducer should be level with the symphysis pubis.

We use warm saline from a range of body to room temperature. We don't recommend carbon dioxide. Joseph[5] noted that a change in detrusor pressure, as well as maximum detrusor pressure, was adversely affected by increasing the rate of filling from slow (approximately 2% of estimated bladder capacity, 0–10 ml/min) to medium fill (approximately 20% of estimated bladder capacity, 10–100 ml/min). In general, we recommend filling at less than 10 ml/min in children.

An EMG should be performed at the same time as detrusor pressure evaluation. The electrodes can be surface pads, wires, or concentric needles. In children with neurogenic disease and lack of perineal sensation, we record from the external sphincter/perineal floor. In the male, we place a concentric needle directly into the bulbocavernosus muscle by aiming towards the bulb of the urethra. For the external sphincter, the needle is placed through the perineal skin just below the bulb of the urethra. A finger in the rectum will help to guide the needle. In females the external sphincter is identified by a needle placed just lateral to the urethral meatus and advanced <1 cm. To capture individual motor action potentials correctly, both an audio channel and oscilloscope are needed. A trained neurophysiologist best performs this study. This technique is the most accurate method of diagnosing the degree of denervation of the urethral sphincter and establishing the diagnosis of detrusor–sphincter dyssynergia (Figure 51.9). It should be noted, however, that in the majority of children, surface pad electrodes give excellent information about a composite view of muscle activity.

In select circumstances, a urethral pressure profile is helpful. Saline is infused at a rate of 2 ml/min while the catheter is slowly withdrawn at 2 mm/s. The urethral pressure profile measures the passive resistance of a particular point in the urethra. To obtain dynamic information of the outlet during voiding, we use micturition urethral pressure profilometry. This study is done in mid-voiding cycle to help eliminate the transient responses of the bladder neck and external sphincter during micturition. In some sophisticated laboratories, microtipped transducer catheters are used rather than saline infusion.

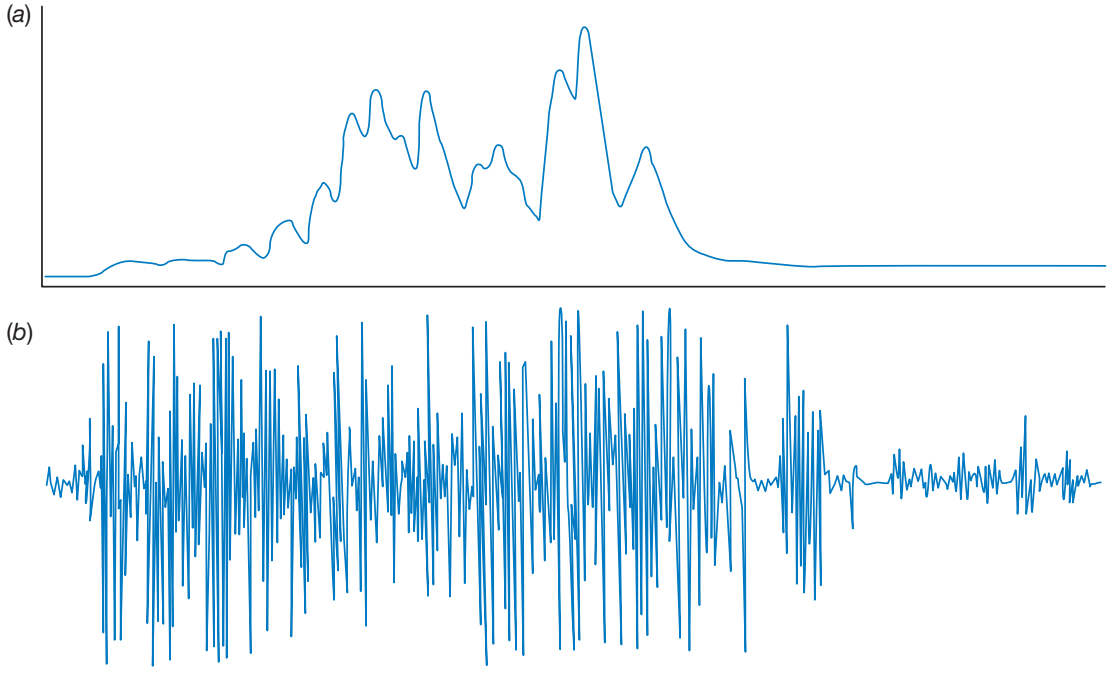

Figure 51.9 Urodynamics tracing in incontinent child with vesicosphincter dyssynergia: (*a*) uroflow; (*b*) electromyogram.

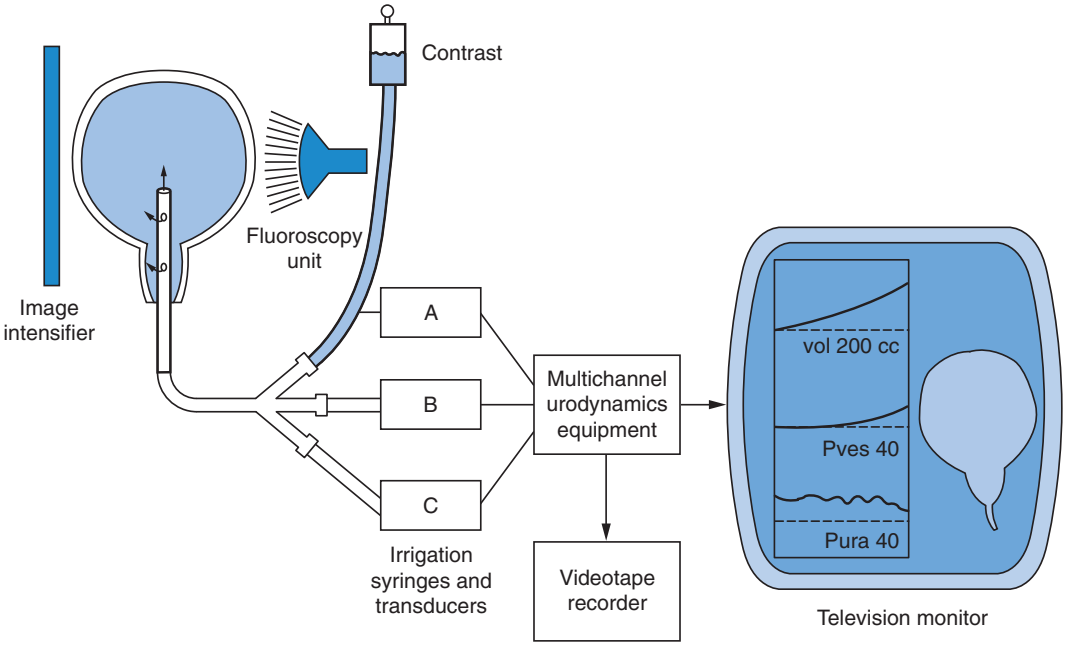

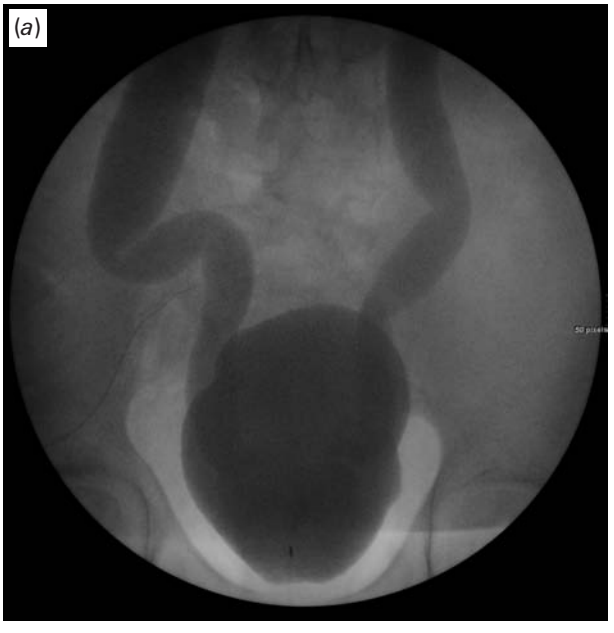

Figure 51.10 Videourodynamic equipment. (Modified with permission from McGuire et al.[25])

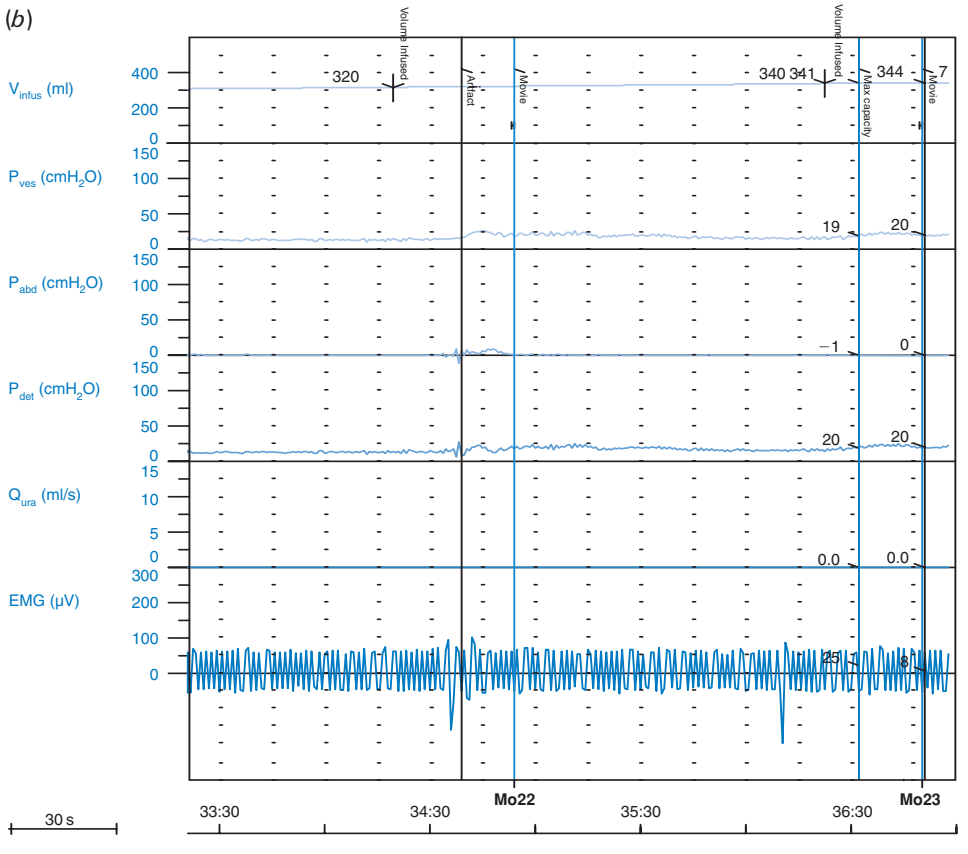
Videourodynamics is a technique that simultaneously combines the evaluation of the anatomy of the lower tract with recorded urodynamic studies (Figure 51.10). In the last 10 years, compact video recording equipment and computer technology have advanced this once research tool into an accessible clinical modality. As cost containment becomes more essential, portable urodynamic equipment can be brought into the fluoroscopy suite, to help share costs with the radiology team. Some investigators have found that real-time ultrasonography can be a suitable alternative to fluoroscopy. The disadvantage of ultrasonography is the less than ideal anatomic resolution.

In our facility, computer-generated digital images are stored and urodynamic parameters are superimposed on the image. Hard copies of the storage and voiding phase are also obtained and results in a radiologic interpretation component. Regardless of the imaging technology, videourodynamics is especially useful in delineating the bladder outlet during storage and voiding and identifying the causes of incontinence. When assessing the incontinent patient without uninhibited contractions noted on the cystometrogram, the urologist may evaluate the position and function of the bladder neck and proximal urethra under fluoroscopy to determine whether the urethra's incompetence or mobility is the etiology of the wetting. Videofluoroscopy may also be used to evaluate bladder compliance in relation to vesicoureteral reflux (VUR): i.e. reflux may act as a 'pop-off' valve for elevation in detrusor pressure, and knowledge of the time of reflux relative to bladder pressure can be important for proper management with clean intermittent catheterization and anticholinergics (Figures 51.11 and 51.12).

The urodynamic portion of videourodynamics is conducted in the routine fashion, by having the child arrive at the urodynamic suite in as a relaxed state as possible. Prestudy rituals include detailed discussions with the family about expectation and methods to alleviate the child's fears during the procedures. A scout film before placement of EMG patches or catheter probes helps to assess bowel status and guides future management of constipation if present. Severe constipation adversely affects vesicosphincter activity. If the child arrives with a full bladder, we perform a non-invasive flow study with patch electrodes. For the cystometry portion of the examination, the technique is the same, except that the infusant is radiographic contrast. A triple-lumen urethral catheter is slowly withdrawn and a urethral pressure profile is obtained. We position a radiopaque marker that identifies the urethral port at the point of highest urethral pressure.

The study can be performed initially with the patient supine on a fluoroscopy table, imaged with a C-arm that eliminates the need for an expensive table, or seated in a multipositional, radiolucent micturition seat. The standing position can help delineate the bladder neck and urethrovaginal component more



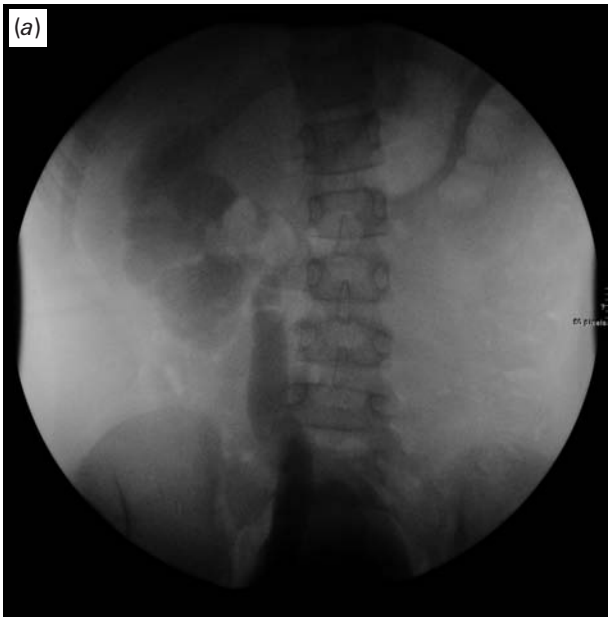


Figure 51.11 A 14-year-old male with imperforate anus, tethered spinal cord, and neurogenic bladder. He presents with recurrent urinary tract infection and incontinence despite clean intermittent catheterization and pharmacotherapy. (*a*) Videourodynamics were performed to evaluate the incidence of reflux and the bladder dynamics prior to further management. (*b*) Videourodynamics revealed a bladder capacity of 760 ml and low-pressure (19 cmH_2O) bilateral VUR. The bladder outlet was competent. Surgical options include augmentation cystoplasty with antireflux surgery. A Mitrofanoff and Malone antegrade colonic enema (MACE) procedure would be an option.

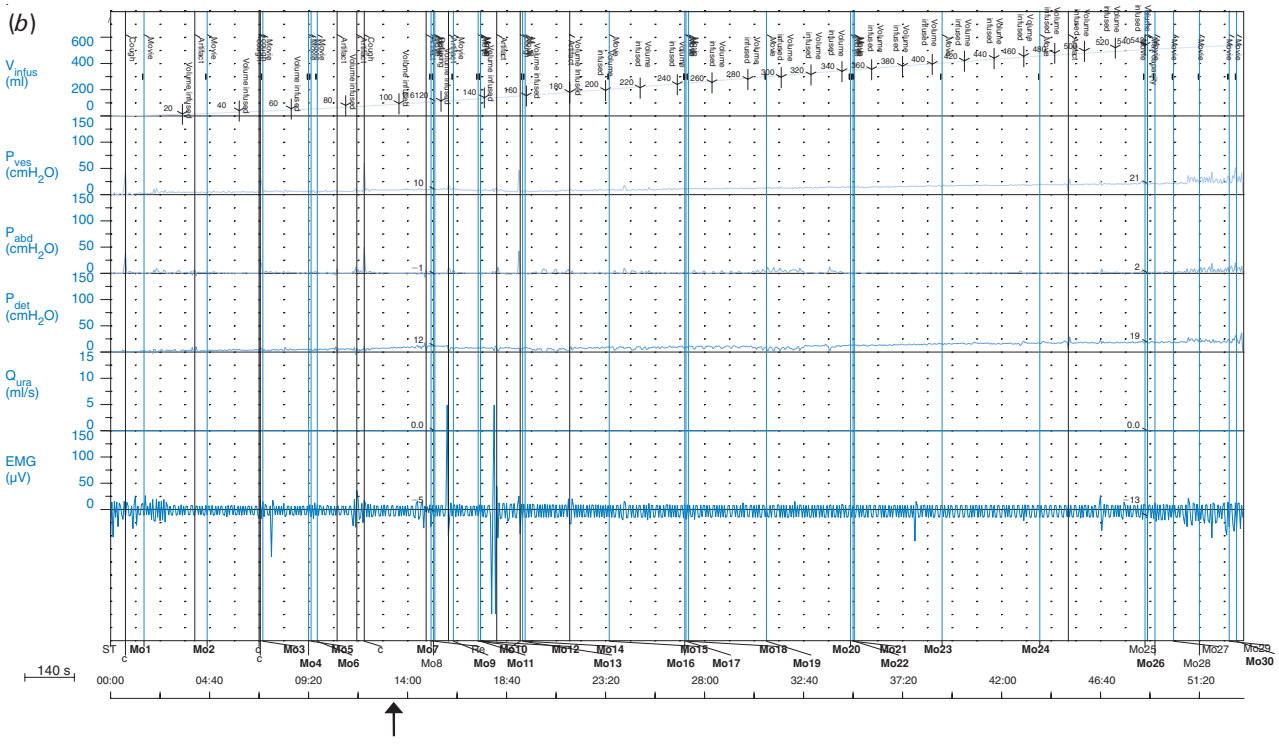
V_{infus} = volume of infusete; P_{ves} = intravesical pressure; P_{abd} = abdominal pressure; P_{det} = detrusor pressure; Qura = urinary flow.

readily; however, many adolescent and young adult females may not easily initiate a void in the unusual standing position. In the standing position, the right posterior oblique projection provides the best image of the bladder neck. Under fluoroscopic control, the bladder, bladder neck, and urethra are visualized while the pressure is recorded.

Bladder filling is accomplished at 10% of expected bladder capacity. Valsalva and requests for repeated coughing are utilized to provoke the patient's incontinence symptoms. We examine the bladder base and urethra fluoroscopically for mobility and leakage, respectively. A postvoid residual is calculated and compared with the prestudy non-invasive residual. The



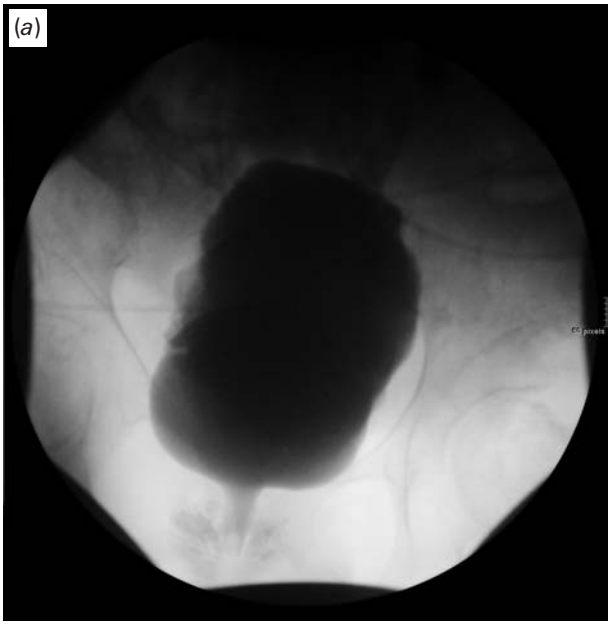


Figure 51.12 A 9-year-old female with dysfunctional elimination syndrome with recurrent febrile urinary tract infections. Videourodynamics revealed a bladder capacity of 875 ml, with no leakage. Her capacity pressure was 20 cmH_2O and she revealed grade 4 reflux at 117 ml (arrow) with a pressure of 10 cmH_2O. Her management included bowel management, biofeedback, and a subsequent successful subureteric injection of Deflux paste. (Key, see Figure 51.11.)

videourodynamic study accurately detects detrusor leak point pressure with straining. The importance of this finding relates to bladder compliance. If the outlet is open fluoroscopically, incontinence occurs with no change in bladder compliance. On the other hand, if the outlet is closed during a detrusor contraction (detrusor–sphincter dyssynergia), incontinence may still occur, but only with elevated detrusor pressures (compliance).

The first leak through the bladder neck is recorded. McGuire used videourodynamics and the abdominal leak point pressure (ALPP), also called the stress leak point pressure, to correctly diagnose the incontinent older patient with detrusor instability/ineffective outlet, as well as the pediatric patient with complex causes of incontinence (Figure 51.13). Videourodynamics easily evaluates the neurologically normal child with pseudosphincter dyssynergia and helps in the diagnostic dilemma of the child with neurogenic disease and decreased compliance, detrusor–sphincter dyssynergia, and areflexic emptying[25] (Figure 51.14).

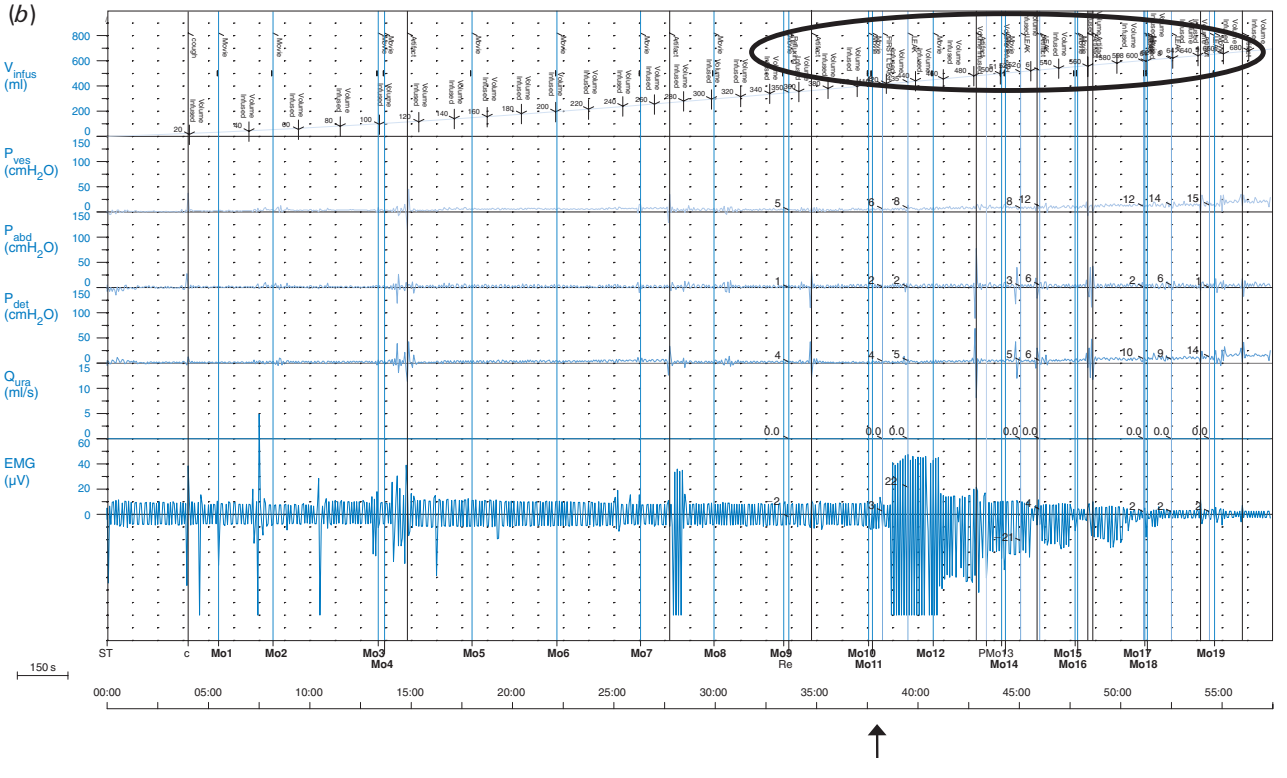

Figure 51.13 A 16-year-old male with L3–4 myelomeningocele had previous augmentation cystoplasty, Mitrofanoff and MACE procedure. He presented with continued incontinence, despite adequate anticholinergic therapy and clean intermittent catheterization (CIC) every 3–4 hours. His videourodynamic study revealed a bladder capacity of 810 ml. Radiographically, reflux occurred at 353 ml, (arrow) and the urethra was visible at his first leak point of 4 cmH_2O at 418 ml. His therapy included a sling procedure and a suburetric injection of Deflux paste. (Key, see Figure 51.11).

Compliance

Since the late 1970s, great advances in pediatric urology have occurred in the field of bladder management. A firm grasp of the importance of bladder health or 'safe' compliance became evident coincident with the introduction of clean intermittent catheterization by Lapides. The interest in neurourology blossomed with non-surgical as well as reconstructive techniques introduced to reconfigure bladder compliance. McGuire[26], Houle et al,[27] and McGuire et al[25] (1996) described two complementary studies to evaluate lower tract function and health.

McGuire popularized the concept of the leak point pressure. The leak point pressure is the detrusor pressure at which leakage occurs through the outlet. It is dependent on the resistance to flow. Without fluoroscopy the point of resistance will not be evident. It

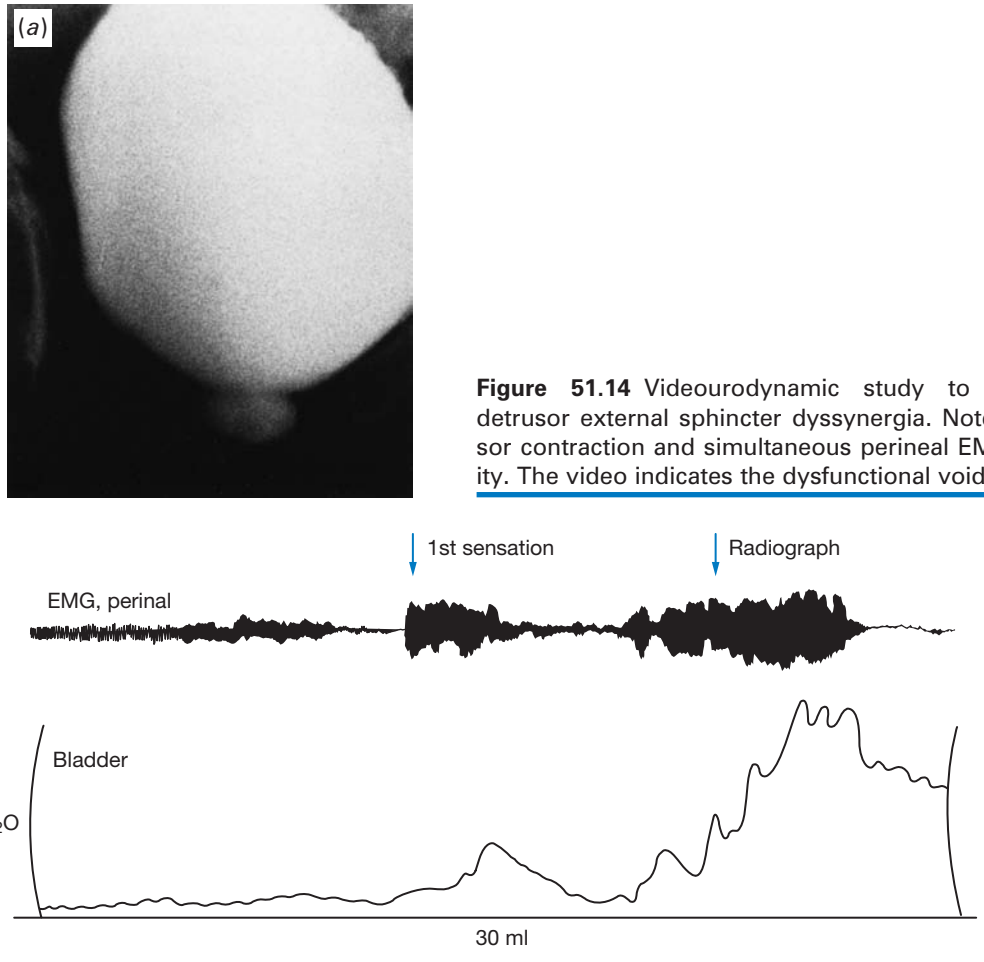

Figure 51.14 Videourodynamic study to indicate detrusor external sphincter dyssynergia. Note: detrusor contraction and simultaneous perineal EMG activity. The video indicates the dysfunctional void.

is measured by performing a slow fill cystometrogram, noting the pressure at which the leak occurs around the catheter per urethra. It has been shown in several centers that in the myelodysplastic population, children with leak point pressures of >40 cmH_2O are at greater risk for upper tract damage (hydronephrosis and reflux) than patients who have leak point pressures <40 cmH_2O.[27,28] Although many groups base their treatment program on this 'magic number' of 40, the limitations of a single leak point pressure are considerable.

Despite its relationship to outlet resistance, measurement of leak point pressure can be misleading when used to evaluate continence capability. Specifically, a high leak point pressure implies a good chance for continence. However, in the myelodysplastic population, the leak point pressure may be high but still not correlate with significant continence in the presence of a fixed but open bladder outlet.

The stress leak point pressure measurement was an innovation to help in the assessment of continence capability. The stress leak point pressure is slightly different from the simple bladder leak point pressure and can be determined without fluoroscopy. This value is obtained by slowly filling the bladder and having the child strain as if to have a bowel movement. The lowest pressure is then noted during which leakage first occurs. We ask the child to cough vigorously while the pressure is measured. This marker helps evaluate the capability of the outlet in both the open and poorly functioning state (e.g. the myelodysplastic child). The stress leak point pressure helps to determine whether outlet reconstructive procedures are needed to achieve urinary continence.[29]

The leak point pressure is an accurate measure of bladder storage pressure. However, Houle proposed that observing the volume at which a child can safely store urine, i.e. pressure-specific bladder volume, might better assess bladder storage characteristics. Houle indicated that in normal children, 99% of bladder capacity can be stored at <30 cmH_2O. Thus, a safe pressure of 20–30 cmH_2O was chosen and the volume noted which kept the pressure in that range.[26,30] This may be a most useful judge of compliance. Therapeutic interventions can be implemented based on this safe storage pressure. Voiding

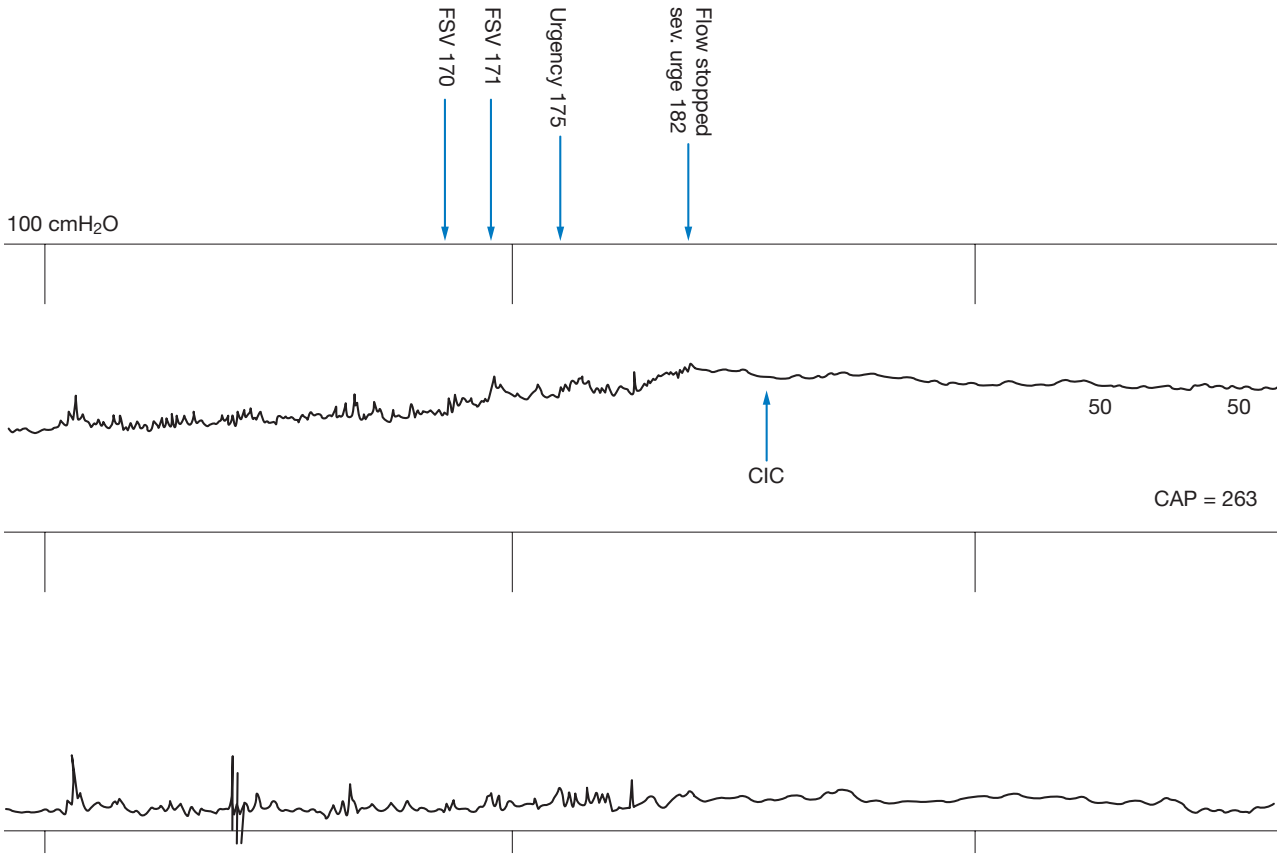

Figure 51.15 Urodynamic study to show poorly compliant neuropathic bladder pressure at capacity is 62 cmH_2O and patient-recorded typical catheterization volumes (CIC) that were at elevated pressures (70 cmH_2O). Failure at conservative management resulted in augmentation.

and catheterization diaries for patients may be obtained, and evacuation schedules or additions of medications (anticholinergics) adjusted accordingly. If conservative measures do not consistently allow the bladder to store in a safe zone, augmentation or neuromodulation procedures are used (Figure 51.15). It seems prudent and it is easy to obtain the leak point pressures, both simple and stress, as well as the pressure-specific bladder volume. However, it is unclear whether these data alone should be used as a basis to intervene prophylactically or must be interpreted in conjunction with imaging (e.g. renal and bladder sonography). Both programs have their staunch advocates. Accurate studies performed in a consistent and timely manner can only benefit the current population of children and give guidance for future cost-effective management.

Upper tract urodynamics

The issue of flow and pressure extends to the upper urinary tract. There is a variety of modalities to evaluate the functional patency of the upper tract. As in most aspects of medicine, the more tests that are available to evaluate a single subject, the more likely it is that no one test is the gold standard. At both ends of the spectrum, one would hope that clear-cut obstruction versus non-obstruction would be evident by studies including serial ultrasonography, diuretic excretory urography, retrograde pyelography, or diuretic renography. Urodynamics of the upper tract may be helpful when any or all of these studies become equivocable. Although the invasive Whitaker study (as originally described) would have promise as being the gold standard, it is also fraught with interpretive error. However, as in the case of the static leak point pressure, stress leak point pressure, and pressure-specific bladder volume, a variety of methods exist to evaluate the response of the upper urinary tract to flow and pressure.

The classic antegrade perfusion test as applied by Whitaker,[31] based on the work of Kiil[32] and Backlund and Reuterskold,[33] is well known. Simply, the test requires the infusion of saline into the renal pelvis at a constant flow rate, and pressure transducers placed

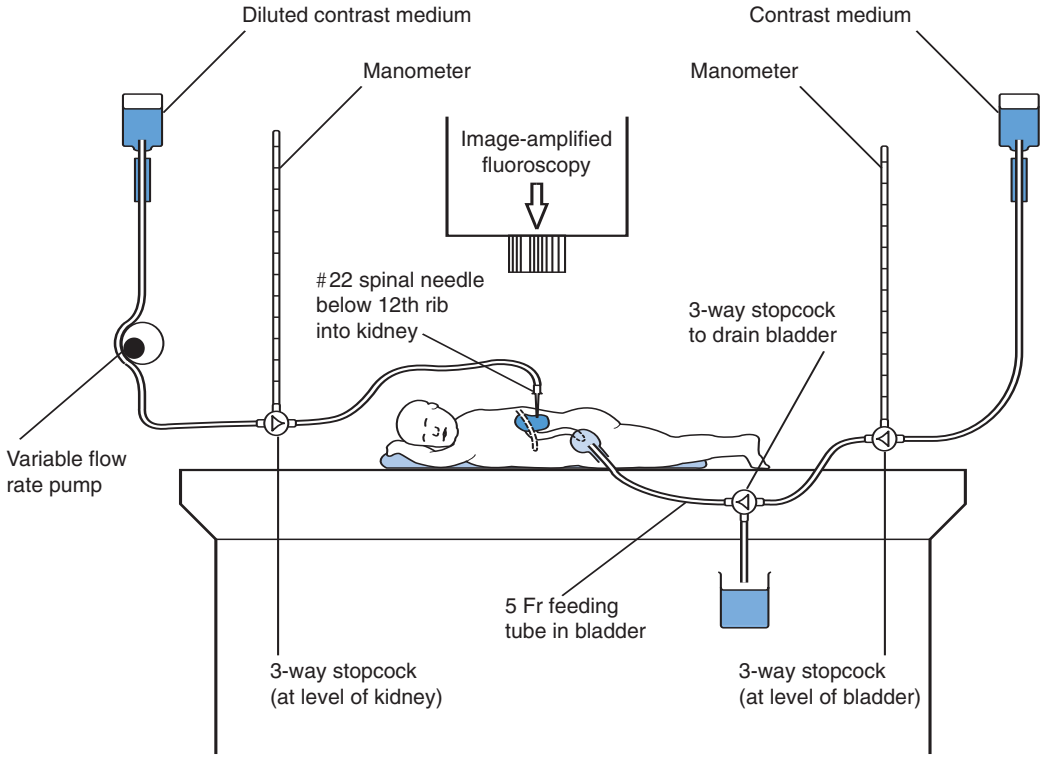

Figure 51.16 Whitaker test. Percutaneous puncture of renal pelvis and measurement of renal and bladder pressure. (Modified with permission from King and Levitt.[34])

in the renal pelvis and the bladder simultaneously to record the relative pressures. The access to the pelvis is typically percutaneously (in the preoperative evaluation); however, open access is certainly possible (Figure 51.16).

Why would one feel compelled to go to the bother and expense of this invasive test? There is a select group of patients and circumstances where diuretic renography will not be diagnostic: i.e. in the child in whom renal function is so compromised that the renal parenchyma cannot adequately handle the introduced isotope, technetium 99 m diethylenetriamine pentaacetic acid (^{99m}Tc DTPA).[35] The technique of the renogram, as well as the timing of the diuretic administration and the upper tract compliance can also influence the results. The diuretic renogram, even under ideal conditions, cannot evaluate renal pelvic pressure. Thus, in the proper setting, the effort involved in a urodynamic evaluation of the upper tract is indicated.

The patient is sedated and often anesthetized, and a catheter is inserted into the bladder and attached to a three-way stopcock. We place the patient prone, but before renal pelvic access, the 22-gauge access catheter is infused at 10 ml/min to determine the resistance of the catheter itself. Both the infusion and bladder catheters are connected to pressure transducers and leveled to the renal pelvis and superior border of the symphysis pubis, respectively. For the classic Whitaker pressure–flow study; a motor-driven syringe pump infuses fluid at a constant rate of 10 ml/min. The study can be repeated at 5 and 2 ml/min. If there is a sudden and rapid rise in renal pressure, the catheter may be abutting against the wall of the pelvis, and needs adjustment. If the bladder pressure rises significantly, the stopcock is opened and the bladder drained. The issue of bladder fullness is critical, because as the bladder fills and its pressure elevates, it can result in greater emptying pressure of the ureter and pelvis. The bladder pressure, as well as the infusion pressure through the infusant catheter and tubing, needs to be subtracted from the pelvic pressure.[36] The pelvic or absolute pressure, minus the bladder and tubing pressure, equals the relative pressure.

During the analysis of the pressure data, two groups of patients emerge: those with relative pressures <15 cmH_2O and those with relative pressures >22 cmH_2O. In the ideal, the test can indicate obstruction (>22 cmH_2O), no obstruction (<15 cmH_2O), and the general site of obstruction. That is, if the renal pelvic pressure and bladder pressure drop by emptying the bladder, elevated bladder

Table 51.3 Summary of the Whitaker test

Kidney pressure	Normal	Raised	Raised	Raised
Relative pressure (cmH_2O) (Pelvic–tubing–bladder)	<15	>22	<15	>22
Bladder pressure	Normal	Normal	Raised	Raised
Result	Unobstructed	Obstructed	Non-compliant bladder	Non-compliant bladder and obstruction

pressure is causing the poor emptying of the renal pelvis and bladder management is needed, i.e. to improve bladder compliance by surgical or non-surgical means. If the relative pressure differential is subtracted from the absolute renal pelvic pressure and the result is >12–15 cmH_2O, there is some degree of ureteral obstruction[37] (Table 51.3). There are several concerns regarding the accuracy and predictability of Whitaker's relative pressure. In the original description, Whitaker noted that the fullness of pelvis and ureter could be noted if radiopaque contrast is used for the infusant. This equilibrium/fullness factor, however, may be somewhat arbitrary. To assess the pressure correctly, the system needs to be full. The infusion rate has also come under question. Fung et al[38] adjusted the nomogram, by suggesting that the original Whitaker test may be made more accurate by infusing a volume more individualized for patient size and glomerular function rather than the standard rate of 10 ml/min. Mortensen et al[39] found, in the pig, large enough overlaps in the relative pressure to call into question the concern over a 12–15 cmH_2O pressure. Forthcoming were debates over constant flow versus constant pressure studies. The constant pressure technique is compared with the pressure-specific bladder volume work: i.e. it may be important to know the pressure required to produce flow across the system, as the pressure should be the final determinate of upper tract health. In the human one-kidney model, keeping pressure constant by elevating the infusant solution to known levels and measuring flow can be assessed. However, in the child with two kidneys, measuring output from the studied kidney only is still a challenge.[40,41] Finally, a variety of influences on the urinary tract can significantly alter the renal pelvis emptying pressure, e.g. pharmacotherapy (principally anticholinergics), infections, and reflux.[42–44]

The expanded subject of the pressure–flow study, renogram, prediction of pathology, and prediction of renal salvage is beyond the scope of this technical chapter. Complex diagnostic dilemmas may not be solved by the use of urodynamics of the upper tract (however one chooses to execute the study). In the select patient with poor renal function and a dilated system, however, a carefully planned diagnostic attack should also include the capability to perform a reproducible evaluation of the pressure–flow characteristics of the system.

Neurologic control of storage and voiding

52

Julian Wan and John M Park

Introduction

The body controls storage and emptying of urine by a series of neurologic pathways. These pathways are similar to electrical circuits that help control and coordinate the activities of a complex machine. They grant the ability to rapidly shift the lower urinary tract between two different modes of function: storage and emptying. In infants, the switching process between these two functions acts in a reflex manner to produce involuntary voiding. In older children, urine storage and emptying are under voluntary control. This degree of control is unique in the body. Autonomic or involuntary reflex mechanisms almost exclusively control other visceral structures, such as the heart, bowels, and lungs. They react to volitional activity but are not under volitional control. Yogis have been able to consciously slow their heart rate and rhythm and elite athletes such as Olympic target shooters can delay the onset of their QRS complex as seen on an electrocardiogram (ECG) to allow them to fire between ventricular contractions. Yet, neither of these groups exhibits the degree of volitional control exerted over an autonomic system as experienced routinely by children over their bladder and urethra.[1–3]

In over a century of study, the physiology and neurology of the bladder and urethra have been fruitful areas of research. Clinical observation of patients, laboratory studies of human tissue, and animal models have helped to contribute to this knowledge. For pediatric urologists, an understanding of the normal process of urine storage and drainage provides the foundation for the evaluation and treatment of congenital and acquired abnormalities of storage and emptying. This chapter reviews what is currently understood about these neurologic pathways, their interaction with the target organs, and their clinical relevance to pediatric urology. We use specific disease entities as examples to further our discussion, but these conditions (e.g. neurogenic bladder dysfunction) are discussed elsewhere in detail. We begin by reviewing the various components of bladder physiology and follow in each case with a description of the reflex pathways that contribute to coordination of bladder filling and emptying. We also discuss the role of higher centers and the plasticity of neurologic control.

Overview summary

The lower urinary tract, which comprises the bladder, urethra, and urinary sphincter, has two principal functions: storage of urine and emptying of urine. A complex neural control system involving the brain, spinal cord, and autonomic and somatic nerves governs these actions. This system performs as a series of circuits that overlay each other. At the most basic level, it works as a simple switch to maintain a reciprocal relationship between the reservoir (bladder) and the outlet (urethra, urinary sphincter). The circuits also interconnect and create a complex sequence of coordinated selective excitation and inhibition of the bladder, urethra, and sphincter (Figure 52.1). A variety of neurotransmitters play significant roles in these pathways, and may provide opportunities for pharmacologic intervention.

During bladder filling, the viscoelastic properties of the bladder wall and an absence of an excitatory input from the parasympathetic ganglia to the bladder smooth wall musculature allow the bladder to accommodate more urine while keeping pressures low. As the bladder continues to fill, an increase in outlet resistance occurs by means of a rhabdosphincter somatic reflex called the guarding reflex. In humans

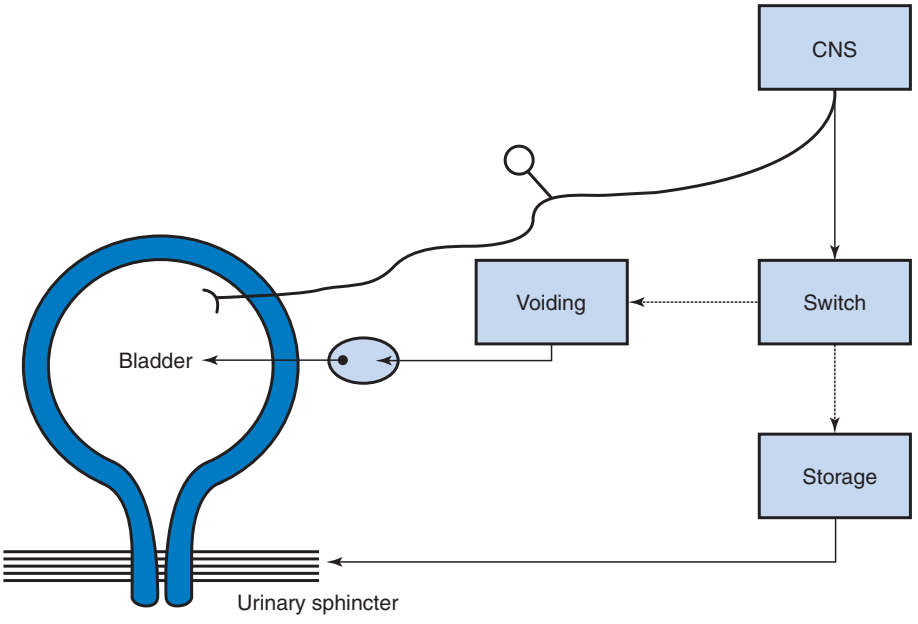

Figure 52.1 The relationship between the anatomy of the lower urinary tract and the switch function of the micturition pathways. During urine storage, a low level of afferent activity activates efferent input to the urethral sphincter. A high level of afferent activity caused by bladder filling activates the switch in the central nervous system (CNS). This causes firing of the efferent pathways, inhibition of the efferent pathway to the urinary sphincter, leading to relaxation, and excitation to the bladder, causing contraction and emptying.

and many mammalian species, a sympathetic reflex also aids this process by increasing outlet resistance. This is achieved by increasing tension on the smooth muscle component of the sphincter and by inhibiting bladder contractility through an inhibitory effect on the parasympathetic ganglia. Finally, the sympathetic output also decreases the tension of bladder smooth muscle. The intrinsic competence of the bladder outlet, with some reflex help from the rhabdosphincter, maintains continence during increases in intra-abdominal pressure.

Bladder emptying can be volitional or involuntary and involves an inhibition of the spinal somatic and sympathetic reflexes and activation of the parasympathetic pathways leading to the bladder. The coordinating center lies in the pons region of the brainstem. Initially there is relaxation of the bladder neck and sphincter muscle, which is controlled by the cessation of somatic and sympathetic spinal reflexes as well as local factors such as nitric oxide (NO) released by parasympathetic stimulation. Subsequently, a coordinated synchronized contraction of the bladder smooth muscle occurs. The bladder neck or outlet develops a funnel shape that is due in part to the continuity of the bladder base and proximal urethra. There is modulation of this process from other peripheral reflexes and from supraspinal sources. The bladder then empties and drains normally to completion.

The ability to control and modulate between these two states develops with maturation. In neonates, the switch between the two modes of storage and emptying occurs on a reflex level once the bladder reaches a threshold volume. With maturation, the ability to modulate this action develops volitionally. This change occurs because a layer of modulating and inhibitory controls that originate above the sacral spine and are mediated by the cerebral cortex and other higher centers is overlaid to modify the primitive set of pathways that function initially. These pathways remain malleable throughout life. Injury and disease can cause these suprasacral inhibitory and modulating pathways to become lost or diminished. Earlier reflex pathways are then unmasked and can re-emerge. Plasticity and re-emergence of earlier more primitive pathways may help to explain the nature of many conditions caused by neurogenic dysfunction.

Target organs: bladder, urethra, and urinary sphincter

A multilayer weave of smooth muscle surrounds the bladder and urethra. The bladder and urethra form

one anatomic unit with two distinct functional regions: the body or fundus, and the base and proximal urethra. The demarcation between these two areas roughly coincides with the division between the bladder body and the trigone.[4–6] The bladder and urethra receive different types of autonomic innervation. Muscarinic cholinergic receptors are found throughout the smooth muscle but are most numerous in the fundus. Preganglionic cholinergic receptors in the sympathetic and parasympathetic ganglia are nicotinic, as are the cholinergic receptors of the striated muscle component of the urinary sphincter, the rhabdosphincter. α-Adrenergic receptors are more numerous in the smooth muscle of the posterior urethra and bladder base.[4,7,8] This cluster of α-adrenergic receptors is more concentrated in boys than in girls and many contribute to the tight bladder neck closure seen during ejaculation.[9] Beta-adrenergic receptors are found in the fundus and act to help relax the bladder during filling.[10] Human fetal studies have shown that β-adrenergic and cholinergic receptors are present as early as 3 months' gestation.[11] α-Adrenergic receptors appear in the trigone and urethra after 6 months' gestation.[6] These observations suggest that even very early in infancy a complex system is already at work. Pharmacologists have exploited the differences in receptor distribution to create drugs that target specific receptors. This distribution may change as a result of injury or disease.

The organization of the bladder smooth muscle affects its normal function. Smooth muscles are organized into fascicles of 4–12 cells. Extracellular matrix (ECM), consisting of collagen, elastin, and rare fibroblasts, surrounds each fascicle.[12] These bundles collectively form circumferential and longitudinal patterns around the bladder and proximal urethra; they are interwoven, with no distinct layers. In males, the smooth muscle forms part of the prostatic capsule. The rhabdosphincter consists of circumferential fibers of striated muscle that surround the smooth muscle from the bladder base to the urogenital diaphragm.[13] It appears that the rhabdosphincter is distinct and separate from the urogenital diaphragm and pelvic-supporting striated muscles in both males and females.[14,15] The striated muscles are both fast and slow twitch. The fast-twitch, more easily fatigued fibers fire during voluntary attempts to stop micturition or during acts of active suppression of voiding. The slow-twitch fatigue-resistant fibers contract during bladder filling as part of the guarding reflex. The rhabdosphincter initially contracts as a reflex. With maturation, it comes under volitional control from the higher cortical centers. In addition to somatic and sensory connections, the urinary sphincter also receives parasympathetic and sympathetic fibers from the pelvic plexus, making it 'triple innervated.'[16] Clinically, this concept is important, as α blockers are useful in treating urinary obstruction and dysfunctional voiding. This combination of sympathetic, parasympathetic, and somatic innervation is present in the cat; the sympathetic component is present in humans. The full functional significance of the autonomic innervation of the striated sphincter in humans is not yet known. Urinary physiologists have identified autonomic innervation of the striated sphincter in patients with lower motor neuron lesions but not in patients with detrusor–sphincter dyssynergia (DSD) – suggesting that the degree of autonomic innervation changes as a response to injury or disease.[4,17]

Nerve endings do not innervate each individual smooth muscle cell of the human bladder. Electron microscopy shows that normal muscle cells are about 0.2 nm apart without intercellular links.[4] Direct cell-to-cell excitation has not been shown. Electromechanical coupling rather than direct neuronal excitation propagates efficient coordinated detrusor contractions. A few muscle cells are directly triggered, which in turn contract and pull on their neighboring cells, thereby triggering further excitation. Some researchers believe that changes at a myogenic level may be responsible for urge and urge incontinence seen with overactive bladder.[18,19]

The normal bladder exhibits excellent compliance and viscoelasticity. The parameters are influenced by the properties of the ECM, which (as stated previously) is a mixture of collagen, elastin, and occasional fibroblasts. In many pathologic states, there are changes in the ECM that affect the mechanical function of the bladder. The type of collagen that is present appears to play an important role.[20] Type I and type III collagen predominate in the ECM: type I is thicker and stiffer, whereas type III is thinner and more pliable. As the human fetus matures, the ratio between types I and type III decreases, with an associated rise in bladder compliance and increase in elastin. A normal fetal bladder becomes more compliant as gestation progresses. Fibroblasts in the interstitium are the source of most of the connective tissue. Normally there is little fibroblast activity in the bladder. Denervation experiments show that increases in ECM may be in part due to a slowing of collagen degradation and decrease of activity of local proteases. Increases in ECM come not only from the fibroblasts

but also from the smooth muscles themselves.[21] Dedifferentiation of smooth muscle cells under repetitive stress leads to more elaboration of collagen and elastin in the interstitium. This resembles the process seen in stressed walls of vasculature, wherein an injury or disease can initiate a spiraling cascade of pathology. A neurogenic bladder, for example, may lose the neurologic modulation that maintains compliance, which in turn leads to higher storage pressure, which causes higher stress, which promotes dedifferentiation of smooth muscles and greater deposits of elastin and collagen, which further decreases elasticity and compliance, and so on. Removal or alteration of normal innervation may result, therefore, in lasting changes to the histology of the bladder.

Neurotransmitters

The basic autonomic neurotransmitters are well known. The sympathetic nerves are adrenergic and use norepinephrine as a neurotransmitter in postganglionic synapses. Preganglionic sympathetic and all parasympathetic nerves are cholinergic and use acetylcholine. Less well known is a third system, the purinergic or peptidergic system. Found in animals and humans, it comprises a wide variety of molecules, including vasoactive intestinal peptide (VIP), neuropeptide Y, adenosine triphosphate (ATP), substance P, somatostatin, and calcitonin gene-related peptide (CGRP).[4,22,23] This third pathway acts as a modulator of overall autonomic activity. Neuropeptides are present throughout the smooth and striated muscle of the lower urinary tract. In addition, observations in some pathologic states of autonomic denervation suggest that the effects are clinically more significant. The existence of this third pathway of the autonomic system was inferred when muscarinic blockade with atropine did not completely ablate in-vitro bladder muscle contraction.[7] Atropine is also less effective in blocking bladder muscle contractions from specimens taken from neurogenic bladders, suggesting that there is an enhanced purinergic factor in these pathologic bladders.

Several purinergic transmitters are inhibitory: opioid peptides (enkephalins), inhibitory amino acids [glycine, γ-aminobutyric acid (GABA)], serotonin, dopamine, and non-opioid peptides such as neuropeptide Y and corticotropin-releasing factor. All of these can inhibit the micturition reflex when applied to the central nervous system (CNS). Excitatory purinergic transmitters include glutamic acid, neuropeptides such as substance P and VIP, NO, and norepinephrine.[24,25] These neurotransmitters affect the vascular smooth muscle, may alter local blood flow, and can appear in increased concentration in obstructed or neurogenic bladders. VIP is lower in concentration in biopsy specimens of hypercontractile bladders.[26] Because of elevated levels of VIP and neuropeptide Y in the urethras of patients with spinal cord injury, a compensatory role for them has been suspected.[27] ATP levels are higher than normal in the bladder muscle of spina bifida patients and interact with two families of receptors: P2X receptors and the G protein-coupled P2Y receptors.[6] Therefore, it has been speculated that hyperactivity observed in neurogenic and obstructed bladders might be the result of abnormal purinergic influences mediated by these neurotransmitters.[28]

Cholinergic receptors found throughout the smooth muscle of the lower urinary tract are numerous in the body of the bladder but are distributed with subtle variations depending on the anatomic location.[8] At least five subtypes of muscarinic receptors exist (M1–M5). Types M1, M2, and M3 are found in the human bladder.[29] Types M2 and M3 may act synergistically, with M2 enhancing the effect of M3-mediated contractions. Types M2 and M4 together may play a role in the prejunctional inhibition of acetylcholine release.[30] The identification of subtypes make possible the development of specific agents that act not only to crudely block the postjunctional receptor but also may be able to modulate prejunctional release. The preganglionic cholinergic receptors in the sympathetic and parasympathetic ganglia in contrast are nicotinic, as are the cholinergic receptors in the rhabdosphincter. Pancuronium, an anesthetic, and botulinum toxin, both nicotinic blocking agents, may be used to paralyze the rhabdosphincter, but total incontinence does not result because the smooth muscle component of the sphincter and bladder neck remains unaffected.[31]

As noted earlier, α-adrenergic receptors are concentrated in the posterior urethra and trigone bladder neck and are more numerous in boys than in girls.[8] Stimulation of β-adrenergic receptors in the detrusor leads to relaxation of the smooth muscle. Adenylylcyclase mediates the effect, which leads to accumulation of cyclic adenosine monophosphate (cAMP). This observation led to speculation that β blockers could be used directly or that phosphodiesterase (PDE) inhibitors, which slow the breakdown of cAMP, could be adapted as drugs for treating bladder instability.[32] Hypogastric nerve stimulation and

α-adrenergic agonists produce a rise in intraurethral pressure that is blocked by α antagonists.[33] This supports the role for α-agonist agents in treating some forms of incontinence and α blockers in relaxing the bladder neck and urethra.

Nitric oxide is a major inhibitory transmitter mediating relaxation of the urethral smooth muscle during micturition.[34] Parasympathetic postganglionic nerves release NO. Inhibitors of nitric oxide synthase block relaxation. NO is also involved with bladder afferent modulation. In situations of bladder irritation, NO inhibitors help decrease or eliminate bladder instability. NO-mediated smooth muscle relaxation results from increased intracellular accumulation of cyclic guanosine monophosphate (cGMP). PDE inactivates cGMP, as it does cAMP, and therefore cGMP may be a target for PDE inhibitors.

Neuropeptides such as substance P, neurokinin A, CGRP, VIP, pituitary adenylate cyclase-activating peptide (PACAP), and enkephalins play a role in modulating afferent sensory nerves. The actions of these purinergic transmitters have led to the recognition that the bladder urothelium may act as a large sensory organ, and the urothelium as an integral part of the afferent pathway in the same way the detrusor or rhabdosphincter act as distinct components.[35,36] Their actions help shape and form the type of afferent signal that enters the micturition reflex. This concept has led to novel approaches to treating conditions such as overactive bladder and interstitial cystitis. Rather than focusing on the efferent pathways, new treatments and therapies aim to dampen or alter the afferent signals from the urothelium.[35–37] For example, neuropeptides are active in capsaicin-sensitive C-fiber bladder afferents. These afferents are of particular interest because they are normally quiescent but become very sensitive when faced with major bladder inflammation or other noxious intravesical events.[38–40] Agents directed against vanilloid receptors can desensitize them. Capsaicin and its analogue resiniferatoxin have attracted recent interest because of their potent ability to affect the vanilloid receptors and desensitize these C fibers.

Peripheral innervation

The peripheral innervation of the lower urinary tract includes components of the sympathetic, parasympathetic, and somatic nervous systems. They connect to the target organs of the bladder, urethra, and urinary sphincter by the pelvic, hypogastric, and pudendal nerves. There are also modulating influences from the sympathetic ganglia chain and intramural ganglia.

The pelvic nerves are parasympathetic and originate from the sacral spinal cord. They excite the bladder and relax the urethra and urinary sphincter. The efferent nerves originate from the upper and middle sacral spinal cord segments S2–S4 and course outward as the pelvic nerves. Parasympathetic preganglionic neurons are located in the lateral part of the sacral intermediate gray matter in the region termed the sacral parasympathetic nucleus (SPN) and the axons exit the ventral roots to reach the peripheral ganglia. In humans, parasympathetic postganglionic neurons are located in the detrusor wall layer as well as in the pelvic plexus. Patients with cauda equina or pelvic plexus injury may be neurologically decentralized but are not completely denervated. Afferent and efferent neuronal interconnection at the level of the intramural ganglia is still possible.[39]

The hypogastric nerves are sympathetic and arise from the lumbar spinal cord. They excite the bladder base, urethra, and urinary sphincter. The efferent sympathetic nerves originate from spinal cord segments T11–L2. These nerves pass from the cord to the lumbar chain ganglia and then to the superior hypogastric plexus. Nerves from the plexus coalesce to form the right and left hypogastric nerve. Sympathetic pathways arise from the rostral lumbar spinal cord and provide noradrenergic excitatory and inhibitory stimuli to the bladder and urethra.[37] Activation of the sympathetic nerves causes relaxation of the bladder body and contraction of the bladder outlet and urethra, which facilitates storage of urine in the bladder.

The pelvic and hypogastric nerves meet to form the inferior hypogastric plexus. Nerves from this plexus then travel to the lower ureter, bladder, urethra, and urinary sphincter. The preganglionic nerves of the hypogastric plexi are closely associated with the ganglia close to or within these target organs. Intramural ganglia are present in the adventitia, muscle, and suburothelium of the bladder and urethra. Postganglionic nerves from the intramural ganglion then travel the final distance to directly innervate the smooth muscle lining these organs. This last group of ganglia and nerves comprise the so-called urogenital short neuron system.[5,31]

The pudendal nerves excite the rhabdosphincter. They are somatic and arise from the sacral cord segments S1–S4. The nucleus of these nerves resides in the lateral border of the ventral horn of the sacral cord and is called Onuf's nucleus (after Wladislaus

Onufrowicz, Swiss anatomist, 1836–1900): found in cats, dogs, and humans, it also innervates the bulbocavernosus and ischiocavernosus muscles. The rhabdosphincter initially behaves reflexively and later comes under voluntary control from the higher cortical centers with maturation. The sphincter motor neurons have dendrites that project laterally to the lateral funiculus, dorsally to the intermediate gray matter, and dorsomedially to the central canal. These connections with interneurons allow for a complex pattern and reflexes to be created.

The ability to sense fullness is important to both the storage and emptying of urine. Afferent activity that occurs during bladder contraction has an important reflex function and appears to reinforce the central drive that maintains detrusor contraction. All of these named nerves also carry afferent sensory information back to the spinal cord.[39] Afferent nerves travel along the hypogastric and pelvic nerves to link the urogenital smooth muscle to the hypogastric plexus and further upward to the lumbar and sacral dorsal root ganglia (DRG). Afferent sensory nerves also travel along the pudendal nerve to the sacral spinal cord. These nerves conduct information from the bladder suburothelium and muscle, the sense of fullness, urgency, and pain. The primary afferent nuclei of the pelvic and pudendal nerves are contained in the sacral DRG, whereas the afferent innervation of the hypogastric nerves come from the rostral lumbar DRG. The central axons of these DRG neurons carry the sensory information to the second-order neurons within the spinal cord.[39,41] Visceral afferent fibers of the pelvic nerve and pudendal nerve enter the cord and move within the portion of the dorsal cord called Lissauer's tract[41,42] (after Heinrich Lissauer, German neurologist, 1861–1891). This is a longitudinal bundle of thin, unmyelinated, and poorly myelinated fibers capping the apex of the posterior horn of the spinal gray matter composed of posterior root fibers and short association fibers that interconnect neighboring segments of the posterior horn. Pelvic nerve afferents monitor bladder volume and degree of contraction and are carried on both myelinated and unmyelinated axons. The myelinated axons are Aδ fibers and the unmyelinated axons are C fibers. Neuropathic conditions and possibly inflammatory conditions can lead to recruitment of C fibers which can form new functional afferent pathways which are believed to cause urge incontinence and possibly increased bladder pain. Aδ fibers carry information from smooth muscle and sense wall tension: when inflamed, there is increased discharge at a lower threshold pressure. The C fibers carry stretch and bladder fullness sensation from urothelium and smooth muscle and act as nociceptors for overdistention. Usually quiet, when irritated C fibers discharge at lower threshold, become more sensitive, and unmask new afferent pathways during inflammation. This has formed the basis for several lines of treatment that act against the sensory end (e.g. capsaicin, resiniferatoxin). Current theory holds that several different types of afferents are present: stretch, volume, tension, and silent (nociceptors). Irritation intravesically can lower the pressure threshold. Most C fibers are insensitive to normal distention but can become mechanosensitive and active when irritated or inflamed.

Reflex pathways

Several reflex pathways help mediate urinary storage and emptying. The central pathways that control the lower urinary tract function are organized as simple on–off switching circuits. Some reflexes promote urine storage and others facilitate voiding. These reflexes can become interlinked to create complex feedback mechanisms. The guarding reflex, which links bladder distention to external sphincter activity during filling, activates sphincter afferents that inhibit the parasympathetic excitatory inputs to the bladder; this explains how bladder to rhabdosphincter activity could lead to decreased bladder activity during storage. The disruption or discoordination of these interactions may be the underlying cause in forms of neurogenic bladder dysfunction (Figures 52.2 and 52.3).

There are four types of pathways in the spinal cord that link together to form the reflex pathways:

1. Spinal efferent nerves, which include autonomic preganglionic neurons and somatic motor neurons.
2. Spinal interneurons, which are located between the dorsal and ventral horns.
3. Primary afferent neurons.
4. Central neurons from the brain and brainstem, which modulate spinal reflexes.[40]

These pathways were elucidated using intracellular labeling, pseudorabies virus tracing, and measurement of gene product expression.[43]

Urine storage, guarding, and sphincter-to-bladder reflex

During the storage of urine, distention of the bladder stimulates afferent nerves. These in turn stimulate

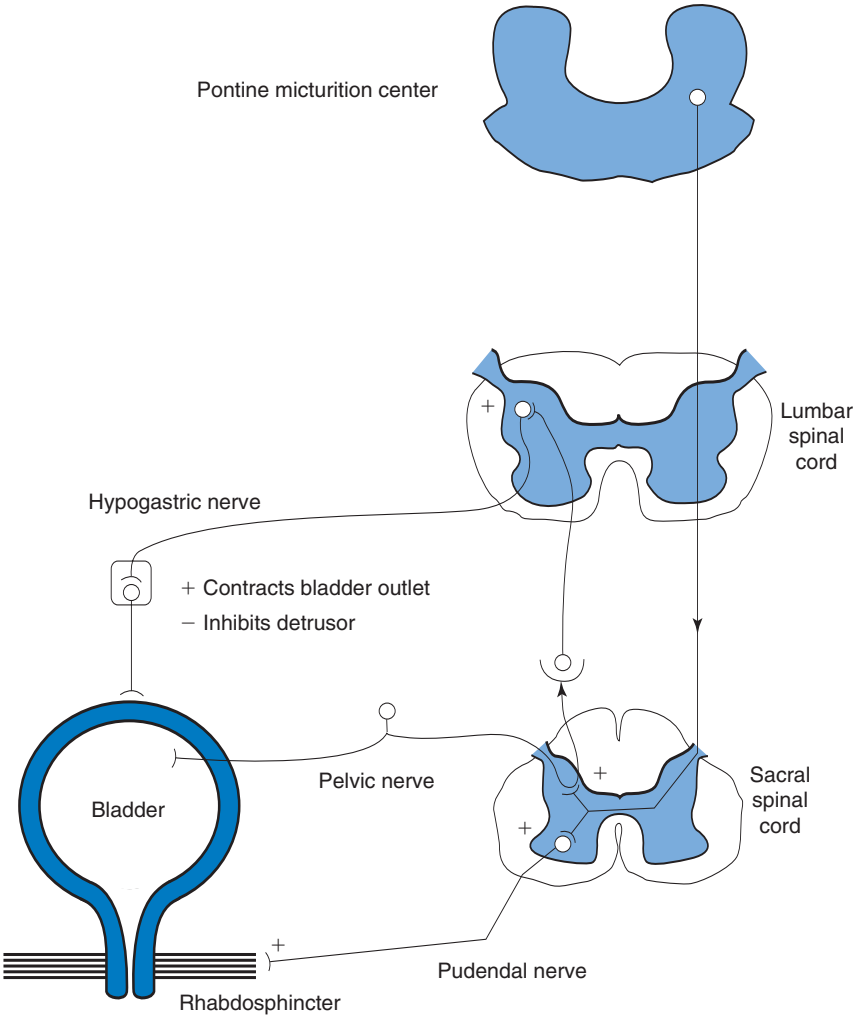

Figure 52.2 During storage, distention of the bladder causes low-level bladder afferent activity, which in turn activates the sympathetic outflow to the bladder and urethra, and increases pudendal nerve activity to the rhabdosphincter. These effects constitute the guarding reflex. Sympathetic activity also inhibits detrusor activity and transmission in the bladder ganglia.

sympathetic excitatory outflow to the bladder trigone and urethra, and pudendal outflow to the rhabdosphincter. These responses together are collectively known as the guarding reflex. Sympathetic stimulation also inhibits detrusor muscle and bladder ganglia transmission. The guarding reflex in turn diminishes during the start of micturition.[39,44] This sequence of reflex activity is demonstrable clinically. During bladder distention with urodynamic measurement, an involuntary increase in the activity of the rhabdosphincter is measurable with either an intraluminal pressure transducer placed at the highest-pressure zone of urethral pressure or by a perineal electromyogram (EMG) (Figure 52.4). The EMG of the urinary sphincter will show increased activity, reflecting the increase in the efferent firing in the pudendal nerve and an increase in outlet resistance that contributes to the maintenance of continence. The external urethral sphincter activity reaches a peak just before the onset of micturition. At low bladder volume, the reflex is involuntary, but as the bladder volume reaches the sensory threshold of fullness, the external urethral sphincter activity increases and becomes a conscious and voluntary phenomenon. Whereas bladder afferent stimulation is the primary activation of pudendal motor neuron activity, urethral and perineal afferents may contribute.[44,45] This part of the guarding reflex links proprioceptive afferents from the pelvic floor to induce closure of the urethral outlet.

How is this clinically important? It was originally theorized that the reflex increase might be a mechanism that protects against stress incontinence.[46] This

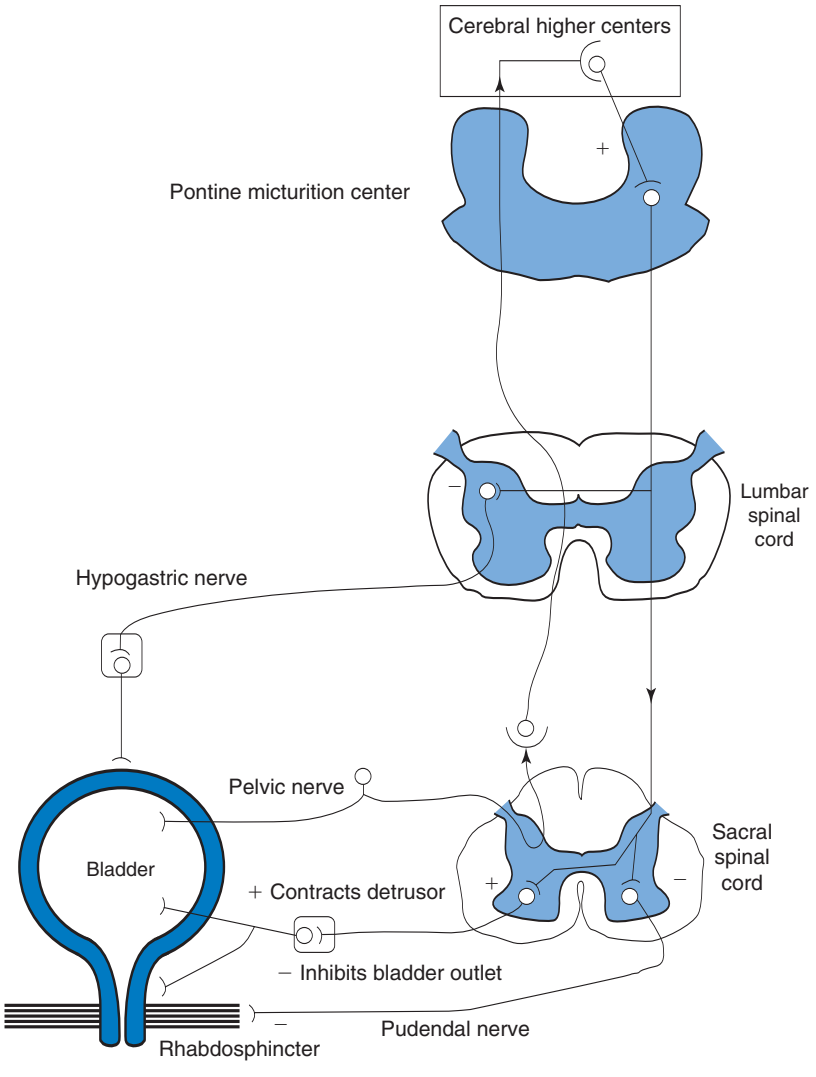

Figure 52.3 At the initiation of voiding, bladder afferent activity increases, which activates the pontine micturition center. This inhibits the spinal guarding reflexes, which are conducted via the pudendal nerve. It also stimulates the parasympathetic outflow to the bladder and bladder neck. Ascending afferents complete the reflex loop by bringing feedback input to the cerebral cortex and higher centers.

mechanism explains how certain avoidance maneuvers, such as vigorously crossing the legs repeatedly and 'squirming' (doing the 'potty dance') or tucking the heel into the perineum (Vincent's curtsy), are used by children who are infrequent voiders to reduce feelings of urgency, thereby allowing them to continue to hold urine for prolonged periods. The fact that stimulation of the somatic afferent pathways of the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding further supports this observation. Afferent input can come from a variety of sites, such as the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter. This pathway has been termed the sphincter-to-bladder reflex pathway. Studies in cats suggest that this is mediated by suppression of the interneuronal pathways in the sacral spinal cord and by direct inhibition of the parasympathetic preganglionic neurons.[47] The sacrolumbar intersegmental spinal reflex pathway, which is triggered by vesical afferent activity in the pelvic nerves, initiates sympathetic firing at least in part. The vesicosympathetic reflex represents a negative feedback mechanism whereby an increase in bladder pressure triggers an increase in inhibitory input to the bladder, thus allowing the bladder to accommodate larger volumes of urine. The reflex pathway is inhibited during voiding, and this inhibition is in turn abolished by transection of the spinal cord at the thoracic level, which suggests that it originates at a supraspinal site, probably at the pontine micturition center.

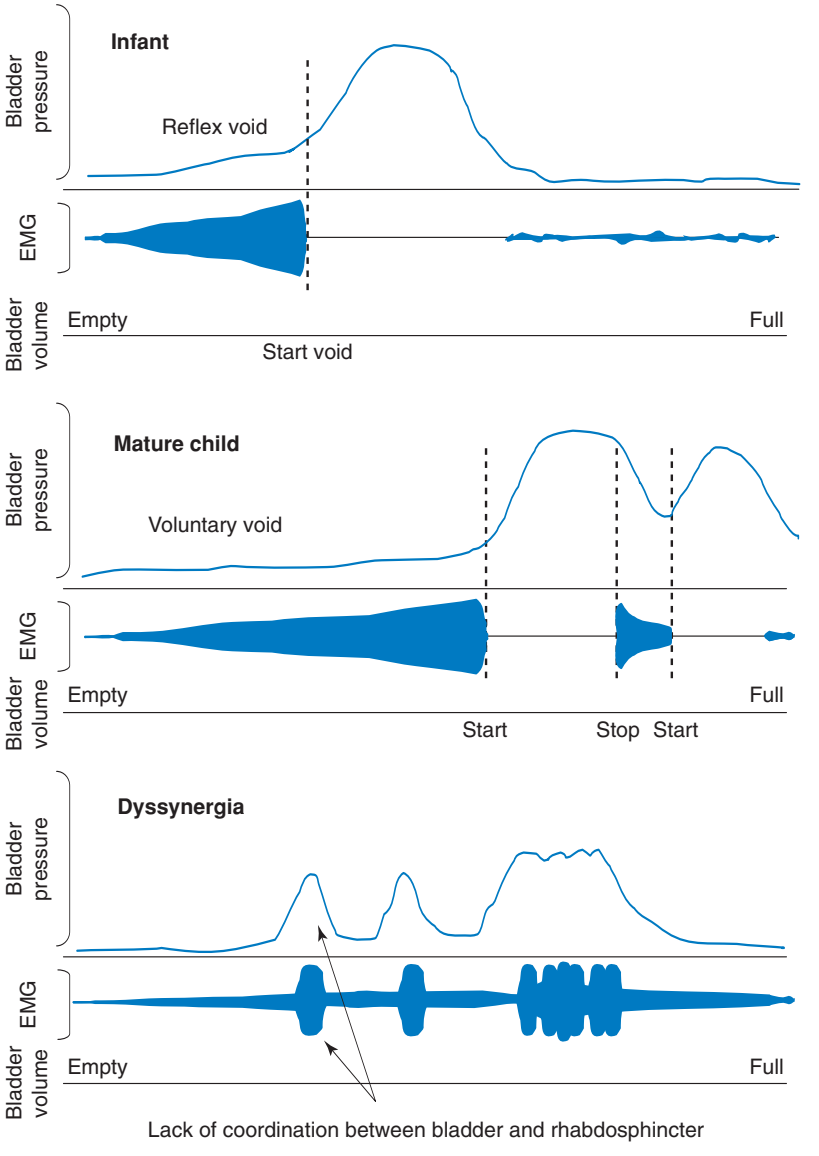

Figure 52.4 The differences between infantile, mature child, and dyssynergic voiding, where there is a loss of coordination between the bladder and sphincter. The latter condition is often seen as a result of injury or disease to the central nervous system. Note that in both the infantile and mature child there is coordination between bladder and the sphincter, so that the sphincter relaxes before the onset of bladder contraction; the EMG becomes quiet. In the mature child and adult there also exists the ability to interrupt voiding volitionally. When this occurs, note that the sphincter activity precedes the cessation of bladder contractions and, when voiding is restarted, relaxation of the sphincter occurs before voiding is resumed. In contrast, in dyssynergia, the detrusor and sphincter contract out of sequence, thereby working against each other.

Voiding or micturition reflex

The switch from storage to voiding phase can occur voluntarily or reflexively. Infants and patients with neuropathic bladder demonstrate the former, when the volume of urine exceeds the threshold volume beyond which micturition occurs (see Figure 52.3 and 52.4). At that point, increased afferent firing from the tension receptors in the bladder leads to a shift in the efferent activity. Sympathetic and somatic pathways are inhibited; sacral parasympathetic activity increases. There is an initial relaxation of the urethral sphincter, followed within a few seconds by the contraction of the bladder, an increase in bladder pressure, and a flow of urine. Relaxation of the urethral smooth muscle during micturition is mediated

by a parasympathetic stimulation to the urethra that triggers the release of NO, which acts as an inhibitory transmitter, and by removal of excitatory inputs to the urethra. The parasympathetic outflow to the detrusor and urethra has a more complicated central organization that involves spinal and spinobulbospinal pathways passing through the pontine micturition center (PMC). When this coordination is disrupted by injury or disease, simultaneous contraction of the bladder and rhabdosphincter can occur, leading clinically to DSD (see Figure 52.4).[48]

Voiding is mediated by activation of the sacral parasympathetic efferent pathway to the bladder and the urethra, along with reciprocal inhibition of the somatic pathway to the urinary sphincter. Cat studies reveal that the neurons in the brainstem have an essential role in the control of the parasympathetic component of voiding. Removal of the areas of the brain above the pons usually facilitates voiding by removing inhibitory inputs from higher centers. Transection at any point below abolishes micturition. The region thereby isolated is located in the pontine region and is termed the pontine micturition center. Physiologic and anatomic experiments show that the PMC is the key switch in the voiding pathway. Chemical and electrical stimulation of the PMC in cats and dogs causes suppression of the urethral sphincter EMG activity, firing of the sacral preganglionic neurons, bladder contractions, and release of urine. These regions have a regulatory role, as shown by injections of inhibitory transmitter, GABA, into the PMC of cats, which can increase the volume threshold for inducing micturition and, in high-enough doses, completely block reflex voiding. In contrast, administration of a GABA inhibitor, such as bicuculline, can lower micturition volume threshold. Injuries above the lumbosacral area but beneath the PMC lead initially to an areflexic bladder and complete retention (similar to the spinal shock seen in human spinal cord injury patients) and later with automatic micturition but with bladder hyperactivity and DSD.[39,49]

The voiding reflex analogy to the guarding reflex is the urethra-to-bladder reflex. Barrington first noted that flow of urine or mechanical stimulation of the urethra with a catheter would excite afferent nerves, which can lead to bladder contractions in anesthetized cats.[50,51] It was thought that the urethral-to-bladder reflex helps to promote emptying. Two pathways have been identified: one pathway is activated by somatic afferents in the pudendal nerve and needs facilitation from the PMC; the other pathway uses afferents in the pelvic nerves to facilitate other spinal reflex mechanisms. Desensitizing the urethral afferents by capsaicin decreases this reflex. This pathway may explain why stress and urge incontinence can occur together. The leakage of urine into the urethra triggers the reflex, leading to urgency. Similarly, correction of stress incontinence seems to paradoxically improve detrusor instability.[43,52]

Spinal and supraspinal pathways

In the spinal cord, afferent pathways terminate and connect with second-order interneurons that relay information to the brain and to other regions of the spinal cord, including the preganglionic and motor nuclei at other levels. These are polysynaptic processes and interlink the various bladder, urethral, and sphincter reflexes. These interneuronal mechanisms play an important role in modulating lower urinary tract function.[53] The lower tract interneurons also receive afferent inputs from the bladder. Glutamic acid is the excitatory transmitter of these pathways.[52] About 15% of interneurons located medial to the sacral parasympathetic nuclei have inhibitory connections to the parasympathetic preganglionic nuclei (PGN). These inhibitory neurons use GABA and glycine.[52] Reflex pathways, which control the external sphincter muscles, also use glutamic excitatory and GABA or glycine inhibitory interneurons. Afferents from the cutaneous and striated muscle sources modulate the micturition reflex at the spinal cord level. Stimulation of afferent fibers inhibits the firing of sacral interneurons evoked by bladder distention that occurs as a result of presynaptic inhibition of primary afferents or due to direct postsynaptic inhibition of second-order neurons. Direct postsynaptic inhibition of bladder PGN occurs by somatic afferent stimulation in the pudendal nerves. Suppression of bladder hyperactivity in patients with sacral root stimulation reflects in part activation of the afferent limb of these inhibitory reflexes. Urologists have used this mechanism to artificially modulate bladder behavior by sacral nerve stimulation.[54]

Control of the bladder function starts in the higher cortical centers through the brainstem pons regions in the PMC. These impulses are mediated through the spinal cord nuclei to the efferent and afferent peripheral pathways. The micturition reflex is normally controlled and mediated by the pathway linking the brain with the reflexes described above. This pathway is termed the spinobulbospinal reflex pathway. Animal brain lesion studies show that the neurons in the

brainstem at the level of the inferior colliculus have an essential role in the control of the parasympathetic component of micturition.[39] Decerebration above the colliculus facilitates micturition by eliminating inhibitory inputs from more cephalad centers. Transections below the colliculi abolish micturition. The essential control center thus isolated was found in the dorsal pontine tegmentum. First described in 1921, this center is commonly referred to as the pontine micturition center or medial location.[55] The medial and lateral region of the pons is responsible for the micturition reflex. The medial region controls detrusor contraction via the reticulospinal tracts, which synapse with the preganglionic parasympathetic neurons in the sacral micturition center. Electrical stimulation of the medial region causes relaxation and opening of the urethral sphincter, followed within milliseconds by a contraction of the detrusor muscles.[56] The lateral regions of the PMC are connected via the corticospinal tracts to Onuf's nucleus. Electrical stimulation of this area leads to contraction of the rhabdosphincter. Voluntary control is via a link with the frontal cortex.[57,58] Neurons from the PMC project to the periaqueductal gray matter, thalamic nuclei, and limbic system. Neurons from the PMC communicate with supraspinal neuronal clusters that coordinate micturition with other functions. The location is of note because of two interesting neural topographic findings. First, the facial nerve nucleus is very near the PMC. Patients with Ochoa's syndrome (urofacial syndrome) exhibit a combination of voiding dysfunction and a characteristic inversion of facial expression. Researchers have failed to show an obvious structural lesion on imaging studies, but speculation suggests that there could be subtle synaptic or interneuron abnormalities.[59] Secondly, the nucleus locus ceruleus within the brainstem is a close neighbor of the PMC. The locus ceruleus in animals is activated by colonic stimulation. The PMC has been shown to affect the afferent signals from the pelvic viscera that reach the locus ceruleus. This has led to speculation that there may be bilateral interaction. Clinically, constipation and bowel dysfunction are associated with bladder dysfunction. A local phenomenon such as rectal distention impinging on the trigone or the pelvic nerves may be responsible. However, this concept fails to explain why women seem to be equally affected yet have the uterus and vagina 'shielding' the bladder from the rectum. Perhaps the problem is at the central level and results from interaction between the PMC and the locus ceruleus.[60,61]

The PMC has important direct synaptic inputs to the sacral PGN and to the GABAnergic neurons. The former carry excitatory outflow to the detrusor, whereas the latter act as an inhibitor on rhabdosphincter motor neurons. These reciprocal connections results in promoting bladder urethral sphincter synergy. Studies in rats indicate that inotropic glutamate receptor antagonists block activation of bladder PGN from the PMC, suggesting that neurons in the PMC utilize glutamate as a neurotransmitter.[48,62–64]

Central cerebral pathways

Voluntary control of voiding is dependent on the connections between the frontal cortex and the septal/preoptic region of the hypothalamus as well as connections between the paracentral lobule and the brainstem.[39] Lesions to those areas of cortex appear to directly increase bladder activity by removing cortical inhibitory control. Brain imaging by positron emission tomography (PET) has implicated the frontal cortex and anterior cingulated gyrus in the control of micturition and that it is predominantly a right-sided function.[65,66] Since sacral parasympathetic pathways to the bladder form a predominantly positive feedback system, further inhibitory modulation is required to store urine and prevent early voiding. Higher centers such as the cerebral cortex, cerebellum, basal ganglia, thalamus, and hypothalamus thus play an inhibitory role, modulating the activity of the PMC.[67]

Studies in humans indicate that voluntary control of micturition is dependent on connections between the frontal cortex and septal preoptic region of the hypothalamus, and the paracentral lobule, brainstem, and spinal cord. Lesions in these areas as a result of trauma, tumors, or cerebrovascular disease appear to indirectly increase bladder activity by removing cortical inhibitory control. In cats, removal of the cortex lowers the functional bladder capacity. If the rest of the neuraxis is intact, removal of the cerebrum lowers the inhibitory input from the cortex. The hypothalamus plays a role in activating the sacral parasympathetic excitatory pathways, thereby inducing bladder contraction and voiding. It is thought to act through direct inputs to the PMC and sacral micturition center or indirectly. This is not a unidirectional process. The hypothalamus receives modulating afferent inputs from the bladder. The gene *c-fos* has been identified as a marker for subsets of second-order neurons. Expression of the *c-fos* gene is increased in these neurons.[68,69]

Plasticity, maturation, and re-emergence

The neonatal bladder is not an effective storage organ. At birth, there is little cerebral input and the bladder reflexively empties. In modern urodynamic parlance, a newborn through infancy and early toddler years has bladder instability. This is also seen in neonatal animals, whose bladders show early spontaneous repetitive contractions. These early pathways become incorporated into more mature pathways by active inhibition from increasing cerebral maturation. Inhibition rather than cessation of these infantile reflexes is the important observation. Much as a layer of inhibition from the cerebrum modulates the spinal reflexes, a layer of inhibitory control is overlaid atop the neonatal reflexes. In newborn kittens and rats, a primitive reflex, the exteroceptive perineal-to-bladder reflex, is the principal voiding reflex until the mature spinobulbar or PMC-based reflex begins functioning at several weeks of life.[70] During the subsequent weeks, the adult-type voiding mediated by the micturition center and spinobulbospinal pathway becomes active and the perineal–bladder reflex becomes progressively weaker and ultimately vanishes. Studies using pseudorabies virus tracing, cellular labeling, and CNS transection preparations in animals demonstrate that there is prominent reorganization of synaptic connections in the bladder reflex pathways.[71] At this time, the bulbospinal pathways that connect to the PMC are fewer and weaker. But as the neonate matures, there is pruning of the interneu-

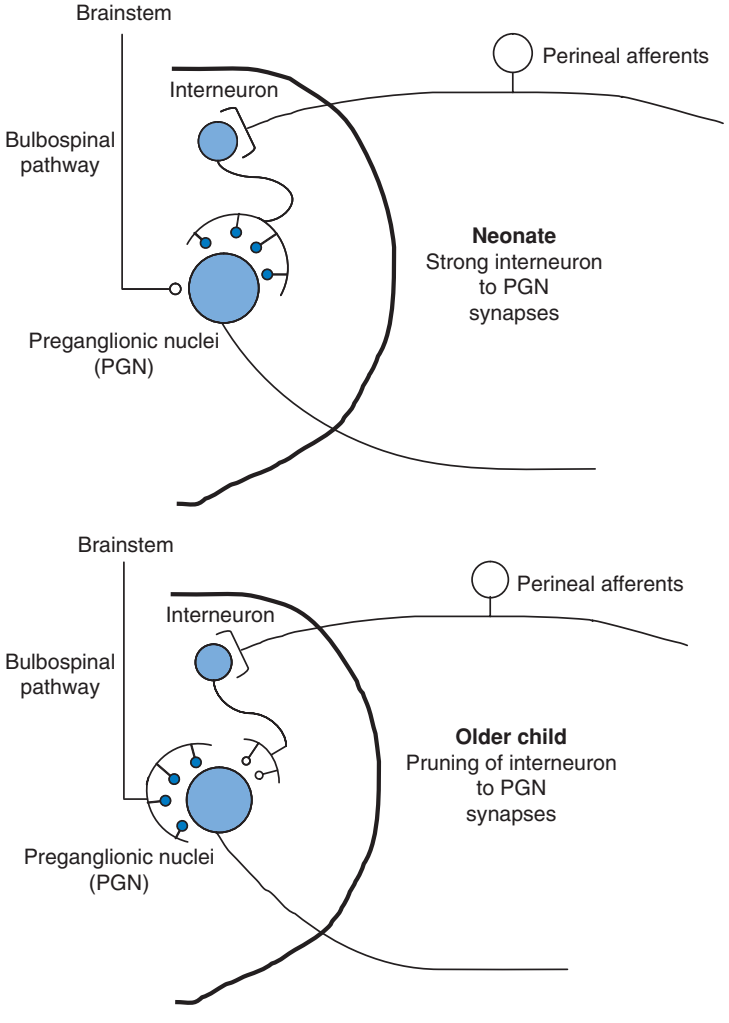

Figure 52.5 Schematic diagram shows possible anatomic changes at the synapses of the preganglionic nuclei in the sacral spinal cord of neonatal mammals (rats and kittens) and presumably humans as well, that explain the changes which occur during the first few weeks of life. Early in life, the interneurons bring greater active input (●) from the perineal afferents; but with maturation, these connections become pruned and become down-regulated (○). Input from the bulbospinal pathways then predominates.

ron to preganglionic synapses from the afferents and increased synapses from the bulbospinal pathways[71,72] (Figure 52.5).

Interestingly, the higher pathways seem to be present and organized but inactive at birth. In animal studies, decerebration unmasks reflex bladder activity that responds to bladder distention, and is mediated by a supraspinal pathway. This indicates that supraspinal bladder-to-bladder reflexes are organized early after birth but are suppressed by inhibitory mechanisms within the brain. Postnatal development is associated with a marked reorganization of the circuitry of the CNS affecting micturition.

The mechanism underlying the developmental suppression of the perineal-to-bladder reflex and the later re-emergence after spinal cord injury appears to be similar to the maturation process. Down-regulation occurs in the interneuronal to preganglionic neuron excitatory synapses, possibly by synapse elimination as a result of competition for synaptic space between the boutons of the interneurons and the descending axons. Injury that causes degeneration of the descending axons, such as transection of the spinal cord, blocks this reorganization and maintains the primitive neonatal reflex. A similar degeneration of the descending axons in mature animals could stimulate axonal sprouting in interneuronal pathways and cause re-emergence of the neonatal perineal-to-bladder reflex. Although the exact details are not known, it is certain that remodeling of the interneuron to preganglionic synapses in the sacral parasympathetic nuclei has a prominent role. This synaptic plasticity and rearrangement leads to the down-regulation of primitive spinal reflexes and the appearance of mature supraspinal control of voiding.[71]

Plasticity is therefore not a one-way process. Where inhibitory controls can be overlaid, they can also be removed. Disease processes can decrease or eliminate inhibitory influences, thereby unmasking the primitive neonatal reflexes. The urologic sequelae of injury and disease, therefore, may not be a 'new' change as much as an old reflex pathway that has re-emerged. The classic example is the chilled water bladder test. Infants will develop involuntary bladder contractions when saline cooled to 4°C is instilled rapidly into the bladder. Mature children and adults can sense the cold but are able to maintain control. Patients with neuropathic bladders are not able to do so. The cold receptors are mediated by C fibers, and the chilled fluid response reflects unmasking of the neuropathology. It is positive until about age 4.[73,74] Further studies have shown that unmasking of reflexes can lead to structural changes that are not limited to the CNS and can occur in the periphery as well. In chronic spinal cord transected cats, the afferent limb of the micturition reflex consists primarily of C-fiber afferents, whereas in intact cats the pathways are myelinated Aδ afferents.[75]

In the human fetus before maturation of the nervous system, urine is presumably eliminated by non-neural mechanisms. Later, primitive reflex pathways organized in the spinal cord regulate voiding. As the CNS matures, this reflex voiding is eventually brought under voluntary control that originates in the higher centers of the brain. Like the animal models, a hierarchical control system overlays the more primitive components that are intrinsic to the target organs and spinal cord as well as more complex components of the cerebral cortex. In adults, injuries and diseases of the CNS can lead to the re-emergence of primitive functions that were suppressed during maturation.[76]

How do these observations correlate with the development of micturition control in humans? It appears that the process in humans does not occur suddenly. The process of maturation is not a simple switch from a primitive voiding reflex to the mature model, but rather a gradual transition. Several observations support this viewpoint. First, small infants wake up to void when asleep.[77] By age 6 months, 90% of infants show signs of waking or arousal with voiding.[78] Another observation is that if an infant is disturbed while voiding, micturition halts or becomes interrupted. Longitudinal studies show increasing percentages of infants who arouse when voiding at night. This correlates with the degree of activation of cortical areas of the voiding reflex and the degree of maturation.[77,78] The infant may also have variable bladder volumes, which puts doubt that threshold volume alone triggers voiding.[77–79] Interrupted voiding has been noted. This is defined as being two voids within 10 minutes: seen in two-thirds of preterm and only one-third of full-term infants, it decreases over the first year and is not seen at all in the fully toilet-trained child. This may be due to a form of DSD. Studies suggest that this dyssynergia may be a normal part of development.[80,81] There seem to be more interrupted voids in patients with posterior urethral valves (PUV) and high-grade vesicoureteral reflux (VUR). Whether there is a more severe form of dyssynergia than the normal physiologic form or an increase in hyperactivity of the neonatal detrusor is unclear. It is also unknown if this observation has any relationship to bladder problems that can be associated with these conditions later in

life (e.g. detrusor instability with VUR, myogenic detrusor failure with PUV).[81,82] Increasing bladder capacity with age has been observed, and leads to speculation that the stimulus for increasing bladder capacity is when the child begins to hold more urine at night, contrary to the conventional notion that daytime continence is a prerequisite for night-time dryness.[79,80] Finally, during the first few months, increased hyperactivity on cystometry may be present, and may be a response to filling that is faster than normal and/or stimulus by the catheter. This fades as the neonate matures.[81] Increased reactivity of the detrusor may be responsible also for high voiding pressures. Voiding pressures of up to 100 cm H_2O have been measured in infants, which decreases by age 3 years, down to 70 cm H_2O, and continue to drop thereafter.[83]

These observations together suggest that the first few years of life mark an important transition period for infants and toddlers as they begin to shift over from a more primitive to a more mature micturition process. This transition seems to progress through a period where neither reflex pathway is clearly pre-eminent; hence, the higher voiding pressure, hyperactive detrusor, and the period of physiologically normal DSD. Therefore, the transition in infants is not as abrupt and rapid as seen in animals, which accomplish this change over weeks rather than months. These findings, and the earlier observation of the plastic nature of the micturition pathways and the re-emergence of primitive pathways, suggest that perhaps voiding dysfunction seen in childhood may have its roots in an incomplete transition to a more mature micturition pathway or the re-emergence of the more primitive pathway.

Neurogenic voiding dysfunction and non-surgical management

53

Stuart B Bauer

Introduction

Neurologic lesions that affect lower urinary tract function cause at least 25% of the more severe clinical problems in pediatric urology. The advent of clean intermittent catheterization (CIC), introduced in the early 1970s by Lapides,[1] and the refinements in the techniques of urodynamic studies in children,[2–4] dramatically changed the way these children were managed.[5] As a result, a greater understanding of the pathophysiology of the many diseases that primarily affect children coupled with improved functional assessment of the lower urinary tract has changed the thinking regarding treatment options.[6,7] Once it was realized that urodynamic studies could define children at risk for urinary tract deterioration, early aggressive and even proactive therapy became the mainstay of management. Urodynamic testing is discussed in Chapter 51.

Assessment

Initially, all children with overt or suspected neuropathic bladder dysfunction should undergo a thorough evaluation:

1 History:
- prenatal health
- birth and development
- perinatal complications
- bowel and bladder habits
- pattern of incontinence
- bowel emptying regimen:
  frequency, soiling.

2 Physical examination:
- spine
- lower extremities
  reflexes
  muscle mass and strength
  sensation
  gait
  perineal sensation/tone/reflexes
- central nervous system
  handedness
  fine/gross motor coordination.

3 Laboratory:
- urine analysis/culture
- urine specific gravity
- serum creatinine level.

4 Radiography:
- renal and bladder sonography
- voiding cystourethrography (VCUG)
- spine radiograph – ultrasound <3 months of age; magnetic resonance imaging (MRI) >3 months.

5 Urodynamics:
- flow rate
- residual urine (via ultrasound or catheterization)
- cystometrogram
- external urethral sphincter electromyography (EMG)
- static/filling/voiding urethral pressure profile.

Of paramount importance in the work-up of children with neuropathic bladder dysfunction are the history and physical examination. The child's voiding habits prior to any injury and the current pattern of bladder emptying should be delineated. It is imperative to note whether the child voids voluntarily, spontaneously, or only with a Credé maneuver. Does the child have periods of dryness between voiding, or is there constant urinary leakage? Is the incontinence characterized by urgency and an inability to reach the toilet on time? Does the urine flow with a steady or intermittent stream or only dribble out during emptying? Does leakage occur with crying or laughing?

Has the child had a urinary infection? How much urine is produced each day? What is the pattern of bowel emptying? Is there small- or large-volume fecal soiling?

A careful assessment is made of perianal and perineal sensation, anal sphincter tone, and the presence of bulbocavernosus and anocutaneous reflexes. Placing one's finger just at or slightly inside the external anal sphincter and briskly squeezing the glans penis or compressing the clitoris elicits the bulbocavernosus reflex. If the reflex is present, the external anal sphincter should contract. The anocutaneous reflex is elicited by scratching the pigmented skin directly adjacent to the anal opening, which results in a contraction of the perianal muscle. In children with suspected neuropathic bladder dysfunction, complete evaluation of the back, including looking for agenesis of the sacrum, abnormalities of the gluteal cleft, or a cutaneous manifestation of an underlying occult spinal dysraphism, is an important diagnostic aid.[8–10] Examination of the lower extremities, comparing muscle mass and strength of each leg, eliciting deep tendon reflexes, pinpointing sensory losses, and observing the gait, may provide clues to the presence of an occult spinal dysraphism affecting not only the sacral but also the lumbar cord. Left-handedness in a family in which all members are right-handed, learning disabilities at school, poor fine and/or gross motor coordination, and attention deficit disorders all suggest the possibility of a central nervous system (CNS) disorder that might adversely affect lower urinary tract function.

Classification of neuropathic bladder

The classification of neuropathic bladder dysfunction used in this chapter is that which has been adopted by the Urology Section of the American Academy of Pediatrics (AAP) in conjunction with the Urodynamic Society's classification, the International Continence Society (ICS),[11,12a] and, most recently, with the International Children's Continence Society (ICCS).[12b]

Under normal conditions, all portions of the lower urinary tract (detrusor, bladder neck, and external sphincter mechanism) function as a coordinated unit for adequate storage and efficient evacuation of urine. When a neurourologic lesion exists, these components usually fail to act in unison. A classification has been adopted based on dysfunction of a specific area of the vesicourethral unit rather than on a specific etiology:

1 Storage:
   (a) detrusor tone
      - normal
      - increased
         - non-elastic
         - overactive
         - hyperreflexic
         - decreased
   (b) urethral closing mechanism
      - incompetent
         - bladder neck
         - external sphincter
         - non-reciprocal
         - periodic hypoactivity.
2 Evacuation:
   (a) detrusor contraction
      - normoactive
      - underactive
         - areflexic (non-reactive)
         - hypoactive (unsustained)
   (b) urethral closing mechanism
      - non-synchronous
         - bladder neck
         - external sphincter.

Improper storage may be related to an alteration in detrusor function or an inadequate urethral closure mechanism. The bladder may have increased tone secondary to loss of elasticity of the muscle, overactivity from excessive or unopposed sympathetic discharges, or hyperreflexia due to a CNS lesion above the sacral cord, the brainstem, or cerebral cortex that prevents the normal inhibitory centers from influencing the sacral reflex arc. Incontinence may occur with any one of these conditions despite a normal level of resistance in the bladder neck and urethra. Alternatively, incontinence may occur when the bladder neck and external sphincter areas do not provide adequate resistance during filling of the bladder or do not generate a reciprocal increase in outflow resistance as the bladder fills or abdominal pressure is raised. An injury to the spinal cord or nerve roots affecting the sympathetic, parasympathetic, or sacral somatic nervous system may alter both bladder neck and urethral sphincter tone. Periodic relaxation of the external urethral sphincter during filling of the bladder, the result of loss of CNS inhibition, may also lead to urinary incontinence.

Incomplete evacuation of the bladder may be due to a hypoactive or an areflexic detrusor muscle. A CNS lesion affecting the parasympathetic efferents may be responsible. However, non-synchronous relaxation of the bladder neck or external urethral

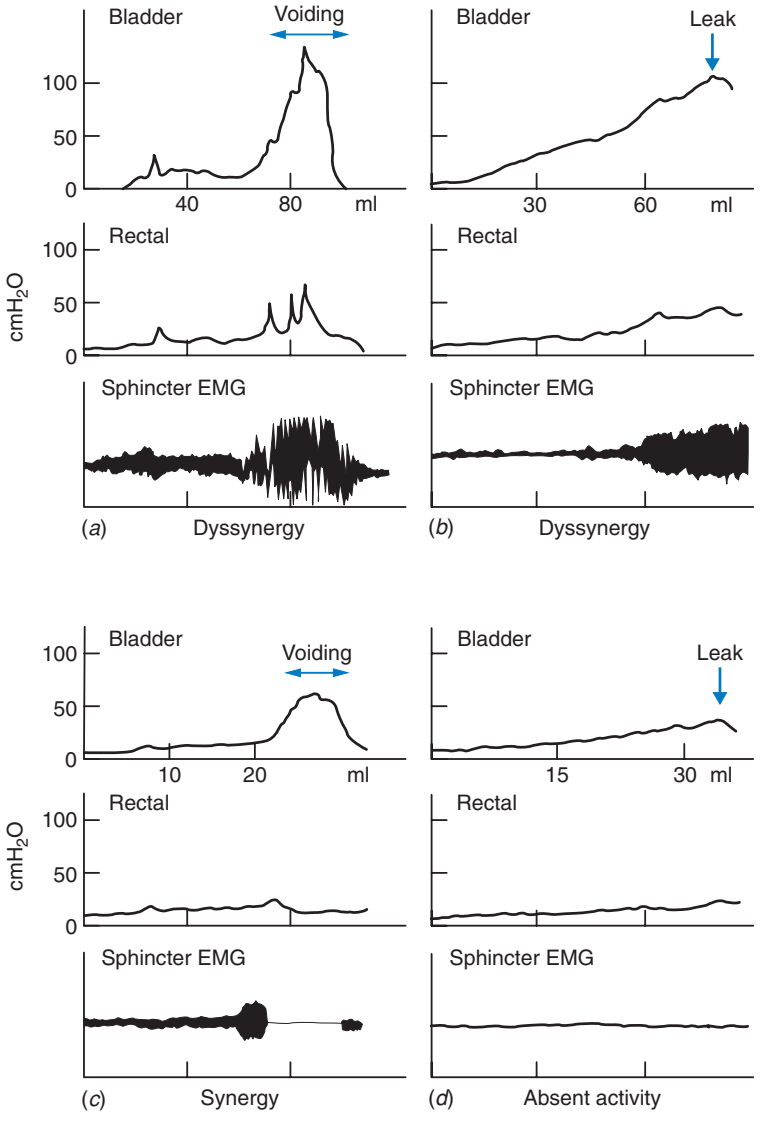

Figure 53.1 (*a–d*) Various patterns of urodynamic findings in newborns with myelodysplasia. Note that a hypertonic detrusor with a non-relaxing sphincter (*b*) is also labeled dyssynergy. (From Bauer.[13])

sphincter area mechanisms (dyssynergia) (Figure 53.1) resulting from a lesion in the CNS above the sacral cord, for example the pontine center or the cerebral cortex, can produce a similar effect. Myogenic failure occurs as the detrusor muscle hypertrophies and then decompensates owing to persistent bladder outflow resistance. Eventually, this mechanism may produce an overflow type of incontinence.

In general, medical management of neuropathic bladder dysfunction is based on the functional impairment produced by the specific neurourologic defect (Table 53.1). Lowering detrusor tone or abolishing uninhibited contractions with anticholinergic medications such as oxybutynin, tolterodine, trospium, glycopyrrolate, hyoscyamine, or propantheline, may enhance inadequate storage capacity. These drugs block cholinergic receptor sites in the detrusor muscle, diminishing its tone and suppressing involuntary contractions of the bladder. Other drugs, for example flavoxate, act directly on the smooth muscle cells and lower detrusor tone without affecting contractility. Failure of drug therapy to increase bladder capacity and lower detrusor tone results in the need for augmentation cystoplasty to enhance bladder storage capability. This procedure is appropriate as long as bladder outflow resistance is normal or increased.

If inadequate urethral resistance is the primary reason for impaired storage of urine, the bladder neck mechanism or the external sphincter area, or both, may be responsible. α-Sympathomimetic agents such as ephedrine sulfate, pseudoephedrine, and phenylpropanolamine stimulate α_1 receptors concentrated in the bladder neck area to enhance the tone of the muscles in this region. No drugs are commercially available that will increase the tone of denervated skeletal muscle in the external sphincter region.

Table 53.1 Drug therapy in neuropathic bladder dysfunction

Type	Minimum dosage	Maximum dosage
Cholinergic		
Bethanechol (Urecholine)	0.7 mg/kg t.i.d.	0.8 mg/kg q.i.d.
Anticholinergic		
Propantheline (Pro-Banthine)	0.5 mg/kg b.i.d.	0.5 mg/kg q.i.d.
Oxybutynin (Ditropan)	0.2 mg/kg b.i.d.	0.2 mg/kg q.i.d.
Glycopyrrolate (Robinul)	0.01 mg/kg b.i.d.	0.03 mg/kg t.i.d.
Hyoscyamine (Levsin)	0.03 mg/kg b.i.d.	0.1 mg/kg q.i.d.
Tolterodine (Detrol)	0.01 mg/kg b.i.d.	0.04 mg/kg b.i.d.
Trospium (Sanctura)	0.1 mg/kg b.i.d.	0.3 mg/kg b.i.d.
Sympathomimetic		
Phenylpropanolamine (alpha) (Ornade)	2.5 mg/kg t.i.d.	2.5 mg/kg b.i.d.
Ephedrine (alpha) (Ephedrine)	0.5 mg/kg b.i.d.	1.0 mg/kg t.i.d.
Pseudoephedrine (alpha) (Sudafed)	0.4 mg/kg b.i.d.	0.9 mg/kg t.i.d.
Sympatholytic		
Prazosin (alpha) (Minipress)	0.05 mg/kg b.i.d.	0.1 mg/kg t.i.d.
Phenoxybenzamine (alpha)	0.3 mg/kg b.i.d.	0.5 mg/kg t.i.d.
Propranolol (beta)	0.25 mg/kg b.i.d.	0.5 mg/kg b.i.d.
Doxazosin (alpha) (Cardura)	0.01 mg/kg q.d.	0.02 mg/kg q.d.
Smooth muscle relaxant		
Flavoxate (Urispas)	3.0 mg/kg b.i.d.	3.0 mg/kg t.i.d.
Dicyclomine (Bentyl)	0.1 mg/kg t.i.d.	0.3 mg/kg t.i.d.
Other		
Imipramine (Tofranil)	0.7 mg/kg b.i.d.	1.2 mg/kg t.i.d.

Incomplete emptying of the bladder may also be due to an areflexic bladder, unsustained detrusor contractions, or uncoordinated activity at the bladder neck or external sphincter area. α-Sympatholytic agents or skeletal muscle relaxants may facilitate emptying. Although conflicting reports have been published regarding the efficacy of bethanechol, it does seem to improve emptying of the bladder in most instances. It should be administered with α-sympatholytic agents because bethanechol also increases urethral resistance at the bladder neck. α-Sympatholytic agents such as phenoxybenzamine or prazosin act primarily in the bladder neck area, whereas diazepam and baclofen diminish skeletal muscle tone at the external sphincter region to lower outlet resistance to voiding.

Most neurologic conditions affecting vesicourethral function in children, including myelomeningocele, lipomeningocele, sacral agenesis, and occult lesions, are called congenital neurospinal dysraphisms:

1 Neuropathic:
- (a) spinal cord
  - (i) congenital
    - neurospinal dysraphism
    - other anatomic
  - (ii) acquired
    - trauma
    - tumor
    - infection
    - vascular
    - miscellaneous
- (b) supraspinal cord
  - anatomic/congenital
  - trauma
  - tumor
  - infection
  - vascular
  - degenerative
  - miscellaneous
  - temporary
- (c) peripheral
  - trauma
  - tumor
  - degenerative
  - Guillain–Barré syndrome.

2 Non-neuropathic:
- anatomic
- myopathic
- psychological
- endocrinologic
- toxic.

Occasionally, bladder dysfunction is seen in conjunction with other neurologic lesions. Cerebral palsy is an acquired non-progressive form of dysfunction as a result of a CNS insult occurring in the perinatal period as a consequence of cerebral anoxia from a variety of conditions.

Children without obvious neurologic disease may have a voiding abnormality on a functional or maturational basis. Most children gain urinary control before the age of 5 years. Persistent day and night incontinence without a prolonged period of dryness or the recurrence of nocturnal wetting lasting into puberty are indications for urodynamic evaluation in neurologically normal children. Although an overwhelming number have normal findings, a significant percentage may have a dysfunctional voiding state. The types of abnormality are discussed separately along with individual approaches to therapy.

Neurospinal dysraphisms

Myelodysplasia

The most common etiology of neuropathic bladder dysfunction in children is abnormal spinal column development. Formation of the spinal cord and vertebrae begins around the 18th day of gestation. The canal closes in a caudal direction from the cervical region, and is complete by 35 days. Although the exact mechanism causing a dysraphic state is unknown at present, numerous factors, including genetic influences,[14,15] have been implicated. The incidence has been reported to be 1 in 1000 births in the United States,[16] but there has been a definite decrease in this occurrence.[17] Two explanations are possible for this phenomenon: first, with the advent of prenatal screening, many families are electing to terminate their pregnancies when they have affected fetuses;[18] secondly, the addition of folic acid supplements to the diet of women of childbearing age has reduced the incidence of spina bifida by more than 50%.[19,20] In some cases, despite increased folic acid intake, women may still have a fetus with spina bifida owing to antibodies that develop to folate, which negates its salutatory effect.[21] If spina bifida is already present in one member of a family, there is a 2–5% chance of a second sibling being born with the same condition.[22] The incidence doubles when more than one family member has a neurospinal dysraphism (Table 53.2).

Table 53.2 Familial risk of myelodysplasia in the United States per 1000 live births

Relationship	Incidence
General population	0.7–1.0
Mother with one affected child	30–50
Mother with two affected children	100
Patient with myelodysplasia	40
Mother older than 35 years	30
Sister of mother with affected child	10
Sister of father with affected child	3
Nephew who is affected	2

Adapted from Kroovand et al.[23]

Pathogenesis

Myelodysplasia is an all-inclusive term used to describe the various abnormal conditions of the vertebral column that affect spinal cord function. More specific labels regarding each abnormality include the following:

- a meningocele occurs when just the meninges extend beyond the confines of the vertebral canal without any neural elements contained inside it
- a myelomeningocele implies that neural tissue, either nerve roots and/or portions of the spinal cord, have evaginated with the meningocele
- a lipomyelomeningocele denotes that fatty tissue has developed with the cord structures and both are protruding into the sac.

Myelomeningocele accounts for >90% of all the open spinal dysraphic states.[24] Most spinal defects occur at the level of the lumbar vertebrae, with the sacral, thoracic, and cervical areas being affected in decreasing order of frequency (Table 53.3).[25] An overwhelming number of meningoceles are directed posteriorly, but on rare occasions, the meningocele may protrude anteriorly, particularly in the sacral area. Usually the meningocele is made up of a flimsy covering or transparent membrane, but it may be open and leaking cerebrospinal fluid (CSF). For this reason,

Table 53.3 Spinal level of myelomeningocele

Location	Incidence (%)
Cervical–high thoracic	2
Low thoracic	5
Lumbar	26
Lumbosacral	47
Sacral	20

Adapted from Kroovand et al.[23]

urgent repair after birth is necessary, with sterile precautions being followed in the interval to closure. In 85% of affected children an associated Arnold–Chiari malformation is present; in such cases the cerebellar tonsils have herniated down through the foramen magnum, obstructing the fourth ventricle, and thus preventing the CSF from entering the subarachnoid space surrounding the brain and spinal cord.

The neurologic lesion produced by this condition can be quite variable. It depends on what neural elements, if any, have protruded with the meningocele sac. The bony vertebral level often gives little or no clue as to the exact neurologic level or deficits that are produced. The height of the bony level and the highest extent of the neurologic lesion may vary from one to three vertebrae in one direction or another.[25] There may be differences in function from one side of the body to the other at the same neurologic level, and from one neurologic level to the next, as a result of asymmetry of affected neural elements. In addition, 20% of affected children have a vertebral bony or intraspinal abnormality occurring more cephalad from the vertebral defect and meningocele, which can affect functional changes in those portions of the cord. Children with thoracic and upper lumbar meningoceles often have complete reconstitution of their spine in the sacral area and these individuals will frequently have intact sacral reflex arc function involving the sacral spinal roots. In fact, it is more likely for children with upper thoracic or cervical lesions to have just a meningocele and no myelocele, with no demonstrable loss of function. Finally, the differential growth rates between the vertebral bodies and the elongating spinal cord add a factor of dynamicism in the developing fetus that further complicates the picture.[26] Superimposed on all this is the Arnold–Chiari malformation, which may have profound effects on the brainstem and pontine center areas involved in the control over lower urinary tract function.

Thus, the neurologic lesion produced by this condition influences lower urinary tract function in a variety of ways and cannot be predicted just by looking at the spinal abnormality or the neurologic function of the lower extremities. This wide spectrum of dysfunction is evident when looking at babies with sacral level lesions.[27] Even careful assessment of the sacral area may not provide sufficient information to make a concrete inference. Therefore, urodynamic evaluation in the neonatal period is now performed at most pediatric centers in the United States and worldwide. This is because urodynamics not only provides a clear picture of the function of the sacral spinal cord and lower urinary tract but also has predictive value regarding babies at risk for future urinary tract deterioration and progressive neurologic change.[6,7,27–30]

Newborn assessment

Ideally, it would be best to perform urodynamic testing immediately after the baby is born, but the risk of spinal infection and the urgency for closure has not made this a viable option at this time. In a 1990 study, preoperative testing showed that fewer than 5% of children experience a change in their neurologic status as a result of the spinal canal closure.[31] Therefore, renal ultrasonography and a measurement of residual urine are performed as early as possible after birth, either before or immediately after the spinal defect is closed, with urodynamic studies delayed until it is safe to transport children to the urodynamic suite and place them on on their backs or sides for the test. For infants who cannot empty their bladder following a spontaneous void, intermittent catheterization is begun, even before urodynamic studies are conducted. The normal bladder capacity in the newborn period is between 10 and 15 ml; thus, an acceptable residue of urine is <5 ml. Other tests that should be performed in the neonatal period include a urine analysis and culture, and a determination of the serum creatinine level.[32]

Once the spinal closure has healed sufficiently, renal scintigraphy is performed to assess upper urinary tract function and drainage. VCUG is conducted if there is any element of hydronephrosis and/or the urodynamic study demonstrates risk factors for upper urinary tract deterioration. Thus, urodynamic studies fulfill several objectives:[6,7,29,33]

- They provide baseline information about the radiologic appearance of the upper and lower urinary tract, as well as the condition of the sacral spinal cord and the CNS.
- The studies can then be compared with later assessments, so that early signs of deteriorating urinary tract drainage and function, or of progressive neurologic denervation, can be detected.
- They help to identify babies at risk for urinary tract deterioration as a result of detrusor hypertonicity or outflow obstruction from detrusor–sphincter dyssynergy, which then allows prophylactic measures to be initiated before the changes actually take place.
- They help the physician to counsel parents with regard to their child's future bladder and sexual function.

Findings

Ten to 15 percent of newborns have an abnormal radiographic appearance to their urinary tract when first evaluated;[34] 3% have hydroureteronephrosis secondary to spinal shock, probably from the closure procedure,[35] whereas 10% have abnormalities that developed in utero as a result of abnormal lower urinary tract function in the form of outlet obstruction.

Urodynamic studies in the newborn period have shown that 57% of infants with myelomeningocele have bladder contractions. This is especially true in children with upper lumbar or thoracic lesions who have sparing of the sacral spinal cord, 83% of whom have detrusor contractions.[36] Forty-three percent have an areflexic bladder, and compliance during bladder filling is either good (25%) or poor (18%) in this subgroup.[7] EMG assessment of the external urethral sphincter demonstrates an intact sacral reflex arc with no evidence of lower motor neuron denervation in 47% of newborns, whereas partial denervation is seen in 24% and complete loss of sacral cord function is noted in 29%.[37]

Combining bladder contractility and external sphincter activity results in three categories of lower urinary tract dynamics: synergic; dyssynergic, with and without detrusor hypertonicity; and complete denervation (see Figure 53.1).[7,29] Synergy is characterized by complete silencing of the sphincter during a detrusor contraction or when capacity is reached at the end of filling. Voiding pressures are usually within the normal range. Dyssynergy occurs when the external sphincter fails to decrease, or actually increases its activity during a detrusor contraction or a sustained increase in intravesical pressure, as the bladder is filled to capacity.[38] Frequently, a poorly compliant bladder with high intravesical pressure is seen in conjunction with a dyssynergic sphincter, resulting in a bladder that empties only at high intravesical pressures.[28,29] Complete denervation is noted when no bioelectric potentials are detectable in the region of the external sphincter at any time during the micturition cycle or in response to a Credé maneuver or sacral reflex stimulation.

Categorizing lower urinary tract function in this way is extremely useful because it defines which children are at risk for urinary tract changes, who should be treated prophylactically, who needs close surveillance, and who can be followed at greater intervals without fear of deterioration. On initial assessment or subsequent studies, 71% of newborns with dyssynergic voiding had urinary tract deterioration within the first 3 years of life, whereas only 17% of synergic voiders and 23% with a completely denervated sphincter developed similar changes (Figure 53.2). The infants in the synergic group whose upper urinary tract deteriorated did so only after they converted to a dyssynergic pattern. Among the infants with complete denervation, the only babies who showed hydronephrosis were those who had elevated levels of urethral resistance, presumably due to fibrosis of the skeletal muscle component of the external sphincter. Thus, it appears that outlet obstruction is a major contributor to the development of urinary tract deterioration in these children (Figure 53.3). Bladder tonicity plays an important but somewhat less critical role in this regard,[6] although detrusor compliance seems to be worse in children with high levels of outlet resistance.[39] This combination of parameters (poor compliance and high outlet resistance) is very provocative for the development of hydroureteronephrosis,[40,41] whereas detrusor–sphincter dyssynergia is a significant factor in the onset of vesicoureteral reflux (VUR)[42] (see Figure 53.3). First Bloom and associates[43] and then Park and associates[44] noted an improvement in compliance when outlet resistance was lowered following gentle urethral dilation in these children; however, the reasons for this are unclear and the long-term effect of this maneuver on ultimate continence and upper urinary tract function remains uncertain. Another form of therapy advocated for high-risk children has been botulinum A toxin injected into the detrusor muscle to paralyze bladder activity and improve compliance. Despite an

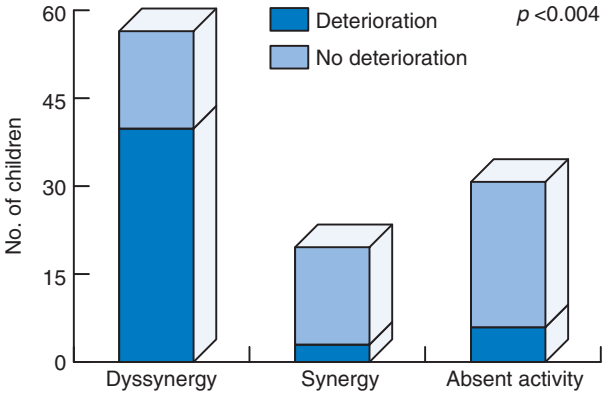

Figure 53.2 Urinary tract deterioration is related to outflow obstruction and most often associated with dyssynergy. Children with synergy converted to dyssynergy and patients with complete bladder denervation developed fibrosis with a fixed high-outlet resistance in the external sphincter, before any changes occurred in the urinary tract. (From Bauer.[13])

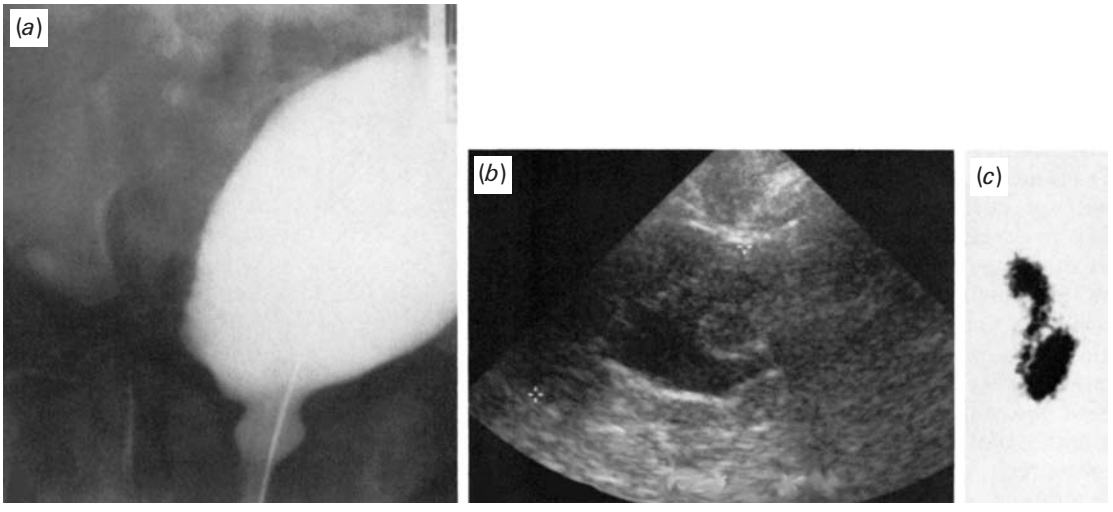

Figure 53.3 (*a*) Voiding cystourethrography in a newborn girl with dyssynergy and elevated voiding pressures demonstrated no reflux and a smooth-walled bladder. Her initial renal echogram was normal. She was started on clean intermittent catheterization and oxybutynin (Ditropan) but did not respond. Within 1 year, she had right hydronephrosis (*b*) and severe reflux on a radionuclide cytogram (*c*).

early excellent response, the effects are short-lived and repeated injections are necessary.[45]

Recommendations

Because expectant treatment has revealed that infants with outlet obstruction in the form of detrusor–sphincter dyssynergy or denervation fibrosis are at considerable risk for urinary tract deterioration, the idea of prophylactically treating the children has emerged as an important alternative to expectant therapy. When CIC is begun in the newborn period, it becomes easy for parents to master, even in uncircumcised boys, and for children to accept as they grow older.[46] Complications of meatitis, epididymitis, or urethral injury are rarely encountered, and symptomatic urinary infection occurs in fewer than 30%,[47] although asymptomatic bacteriuria can be seen in almost 70%.[48]

CIC alone or in combination with anticholinergic agents, when detrusor filling pressures are $>40\ cmH_2O$ and voiding pressures reach levels $>80–100\ cmH_2O$, has resulted in only an 8–10% incidence of urinary tract deterioration (Figure 53.4).[47,49,50] This represents a significant drop in the occurrence of detrimental changes compared with the group of children followed expectantly.[6,7,29] Oxybutynin hydrochloride is administered in a dose of 1.0 mg per year of age, every 12 hours, in order to help lower detrusor filling pressure. In neonates or children younger than 1 year of age, the dose is lowered to below 1.0 mg in relation to the child's age at the time and increased proportionately as the child approaches 1 year. No side effects were seen when oxybutynin was administered according to this schedule.[46,47] When a hyperreflexic or hypertonic bladder fails to respond to these measures, augmentation cystoplasty may be required. However, the need for this operative modality in children managed proactively has been substantially reduced to 17%, as compared with a 41% incidence in children followed expectantly[30,51] (see Figure 53.4). Furthermore, the use of vesicostomy drainage has been almost completely eliminated since this approach has been adopted.

Neurologic findings and recommendations

The neurourologic lesion in myelodysplasia is a dynamic disease process with changes taking place throughout childhood,[52–54] especially in early infancy,[37] and then at puberty,[55] when the linear growth rate accelerates again. When a change is noted on neurologic, orthopedic, or urodynamic assessment, radiologic investigation of the CNS often reveals: (1) tethering of the spinal cord; (2) a syrinx or hydromyelia of the cord; (3) increased intracranial pressure due to a shunt malfunction; or (4) partial herniation of the brainstem and cerebellum. Children with completely intact or only partially denervated sacral cord function are particularly vulnerable to progressive changes. MRI reveals anatomic details of the spinal column and CNS, but it is not a functional study. Therefore, when used alone, it cannot provide

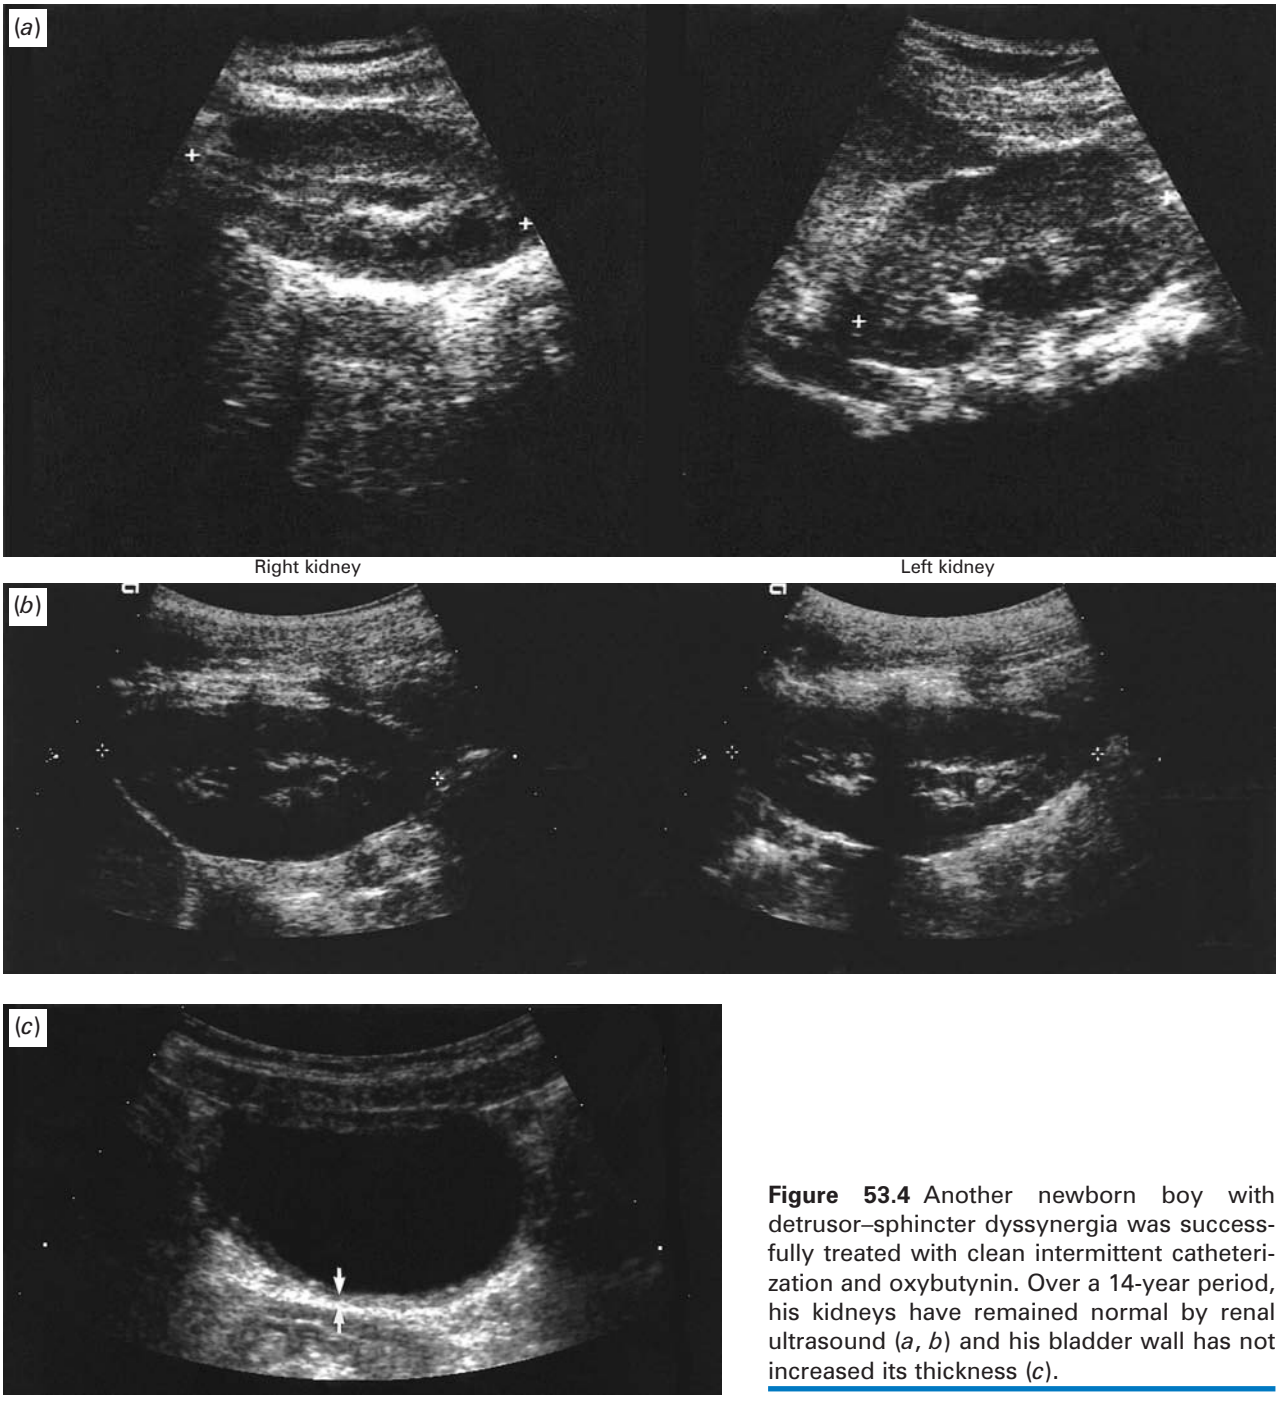

Figure 53.4 Another newborn boy with detrusor–sphincter dyssynergia was successfully treated with clean intermittent catheterization and oxybutynin. Over a 14-year period, his kidneys have remained normal by renal ultrasound (*a*, *b*) and his bladder wall has not increased its thickness (*c*).

exact information with regard to a changing neurologic lesion.

Sequential urodynamic testing on a yearly basis, beginning in the newborn period and continuing until 5 years of age, provides the means for carefully following these children to detect signs of change, thus offering the hope that early detection and neurosurgical intervention may help to arrest or even reverse a progressive pathologic process. Changes occurring in a group of newborns followed in this manner involved both the sacral reflex arc and the pontine–sacral reflex interaction[37,56] (Figure 53.5). Most children who change tend to do so in the first 3 years of life (Figure 53.6). Twenty-two of 28 children who exhibited a worsening in their neurologic picture underwent a second neurosurgical procedure: 50% had a beneficial effect from the surgery, with 11 of these 22 showing improvement in urethral sphincter function.[56]

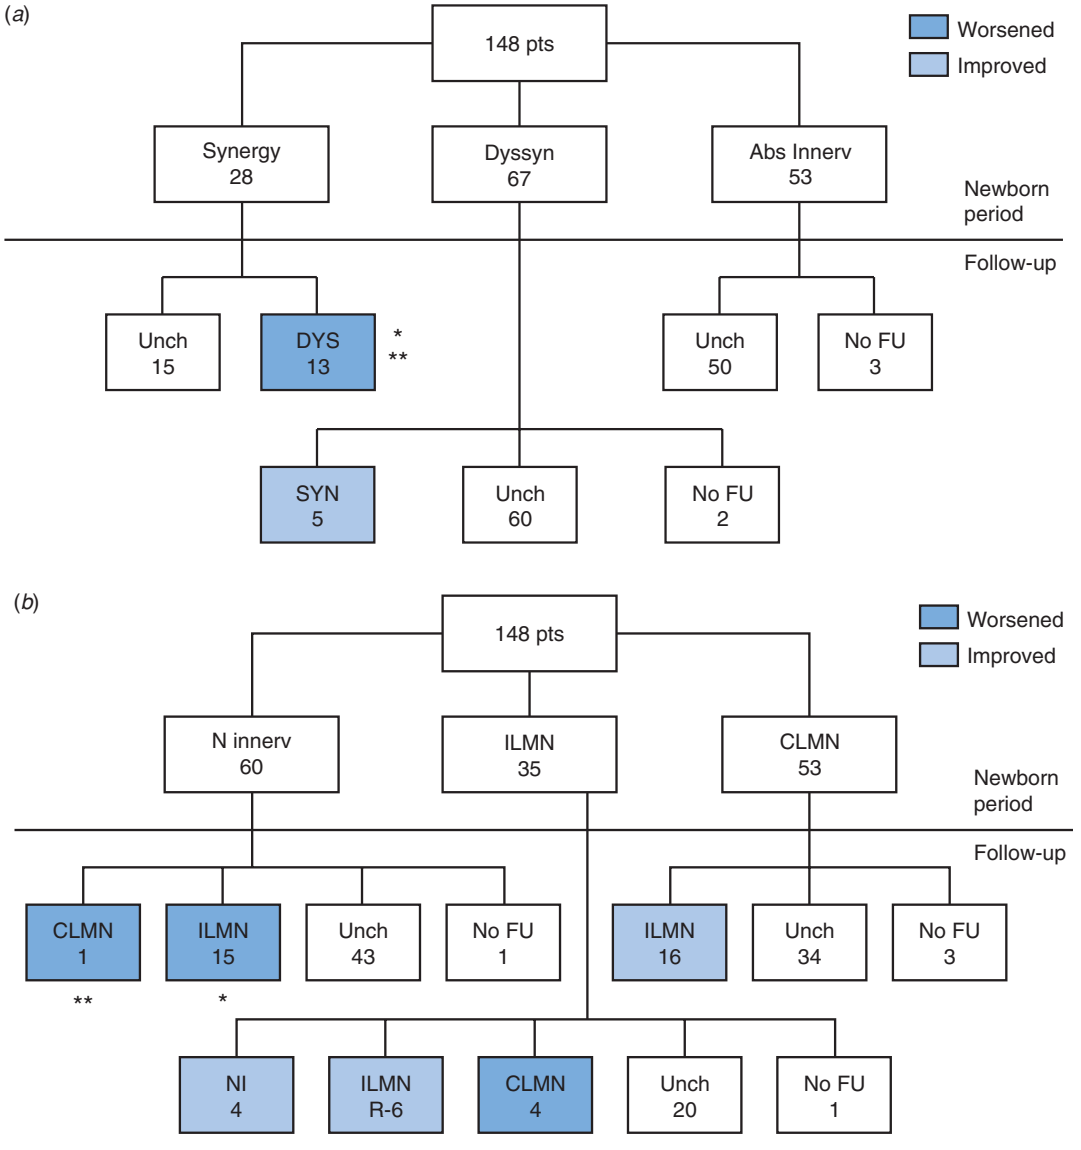

Figure 53.5 (*a*) Pontine–sacral reflux arc changes that occurred in a group of children with myelodysplasia followed with sequential urodynamic studies between the newborn period and 3 or more years of age. Dyssyn = dyssynergy; Abs Innerv = absence of innervation; Unch = unchanged; DYS = dyssynergy; FU = follow-up; Syn = synergy; * = one patient who changed from normal innervation to partial and then complete denervation; ** = four patients who changed from normal innervation to partial denervation. (*b*) Sacral reflex arc pathway changes that occurred in the same group of children. N innerv = normal innervation; ILMN = incomplete lower motor neuron; CLMN = complete lower motor neuron; Unch = unchanged; FU = follow-up; N = normal; * = four of 15 patients who changed from synergy to dyssynergy; ** = one patient who changed from synergy to dyssynergy.

As a result of these developments, all babies with myelodysplasia should be observed according to the guidelines set forth in Table 53.4. It is not enough to look at just the radiographic appearance of the urinary tract; critical scrutiny of the functional status of the lower urinary tract is important as well. In addition to the reasons cited above, it may be necessary to repeat a urodynamic study when the upper urinary tract dilates secondary to impaired drainage from a hypertonic detrusor or urinary incontinence occurs after a prolonged period of dryness on intermittent catheterization and medical therapy.

Management of reflux

VUR occurs in 3–5% of newborns with myelodysplasia, usually in association with detrusor hypertonicity and/or dyssynergia. It is rare to find reflux in

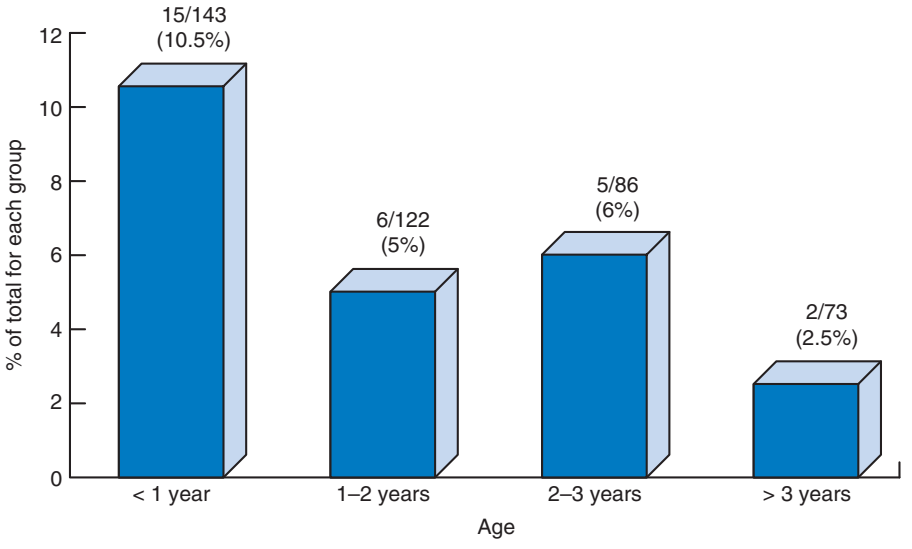

Figure 53.6 Propensity for deterioration in external urethral sphincter innervation is greatest in the first year of life, with a decreasing incidence noted subsequently. (From Bauer.[13])

Table 53.4 Surveillance in infants with myelodysplasia[a]

Sphincter activity	Recommended tests	Frequency
Intact – synergic	Postvoiding residual	Every 4 months
	IVP or renal echo	Every 12 months
	UDS	Every 12 months
Intact – dyssynergic[b]	IVP or renal echo	Every 12 months
	UDS	Every 12 months
	VCUG or RNC[c]	Every 12 months
Partial denervation	Postvoiding residual	Every 4 months
	IVP or renal echo	Every 12 months
	UDS[d]	Every 12 months
	VCUG or RNC[c]	Every 12 months
Complete denervation	Postvoiding residual	Every 6 months
	Renal echo	Every 12 months

[a] Until the age of 5 years.
[b] Patients on intermittent catheterization and anticholinergic agents.
[c] If detrusor hypertonicity or reflux already present.
[d] Depending on degree of denervation.
IVP = intravenous pyelography; echo = sonography; UDS = urodynamic study; VCUG = voiding cystourethrography; RNC = radionuclide cystography.

any neonate with a spinal cord lesion without dyssynergy or poor compliance.[49,57] If left untreated, the incidence of reflux in these at-risk infants increases with time until 30–40% are afflicted by 5 years of age,[57] with even higher levels noted in older children.[42]

In children with mild to moderate grades of reflux (I–III), who void spontaneously or who have complete lesions with little or no outlet resistance and empty their bladder completely, management consists of antibiotic prophylaxis to prevent recurrent infection. When these children have high-grade reflux (grade IV or V), intermittent catheterization is begun to ensure complete emptying. Children who cannot empty their bladders spontaneously, regardless of the grade of reflux, are catheterized intermittently to ensure complete emptying. Children with detrusor hypertonicity, with or without hydroureteronephrosis, are also treated with oxybutynin to lower intravesical pressure and ensure adequate upper urinary tract decompression. When managed in this manner, reflux resolves in 30–55% and renal function does not

become impaired.[46,57–61] Although bacteriuria can be seen in as many as 56% of children on intermittent catheterization, generally it is not harmful except in the presence of high-grade reflux because symptomatic urinary infection and renal scarring rarely occur with lesser grades of reflux.[58,62]

Credé voiding is to be avoided in children with reflux and a reactive external sphincter. Under these conditions, the Credé maneuver results in a reflex response of the external sphincter that increases urethral resistance and raises the pressure needed to expel urine from the bladder[63] (Figure 53.7). This has the effect of aggravating the degree of reflux and increasing upper urinary tract dilatation. Vesicostomy drainage[8,64] is reserved for (1) those infants who have such severe reflux that intermittent catheterization and anticholinergic medication fail to improve upper urinary tract drainage; or (2) those children whose parents cannot adapt to the catheterization program.

The indications for antireflux surgery are not very different from those for children with normal bladder function and include recurrent symptomatic urinary infection while on adequate antibiotic therapy and appropriate catheterization techniques, persistent hydroureteronephrosis despite effective emptying of the bladder and lowering of intravesical pressure, severe reflux with an anatomic abnormality at the ureterovesical junction, and reflux persisting into puberty. In addition, children with any grade of reflux who are being considered for implantation of an artificial urinary sphincter or any other procedure designed to increase bladder outlet resistance should have the reflux corrected at the time of or prior to the anti-incontinence surgery.

Jeffs et al[65] noted that antireflux surgery could be very successful in children with neuropathic bladder dysfunction as long as it is combined with measures to ensure complete bladder emptying. Since the advent of intermittent catheterization, success rates for antireflux surgery have approached 95%.[58,66–68] Unilateral reflux does not warrant bilateral reimplantation, because the incidence of contralateral reflux postoperatively is insignificant.[67] The endoscopic injection of Deflux (dextranomer microspheres in sodium hyaluronan solution) has altered the management of reflux in children with myelomeningocele but

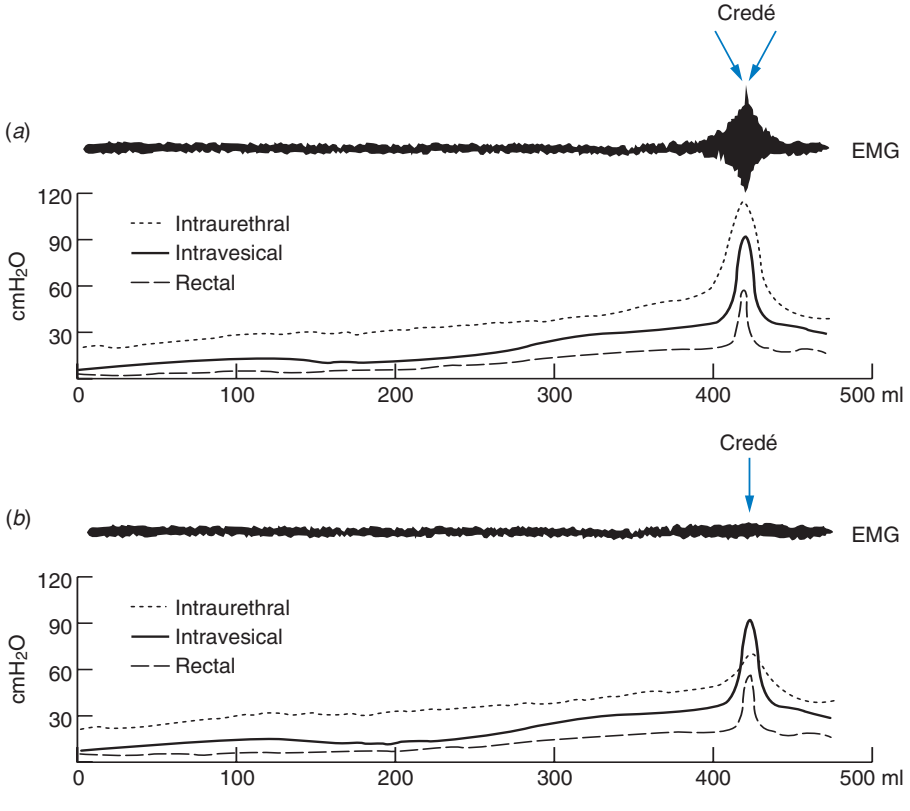

Figure 53.7 (*a*) When the external sphincter is reactive, a Credé maneuver produces a reflex increase in electromyographic (EMG) activity of the sphincter and a concomitant rise in urethral resistance, resulting in high voiding pressure. (*b*) A child whose sphincter is denervated and non-reactive will not have a corresponding rise in EMG activity, urethral resistance, or voiding pressure. A Credé maneuver here will not be detrimental. (From Bauer.[13])

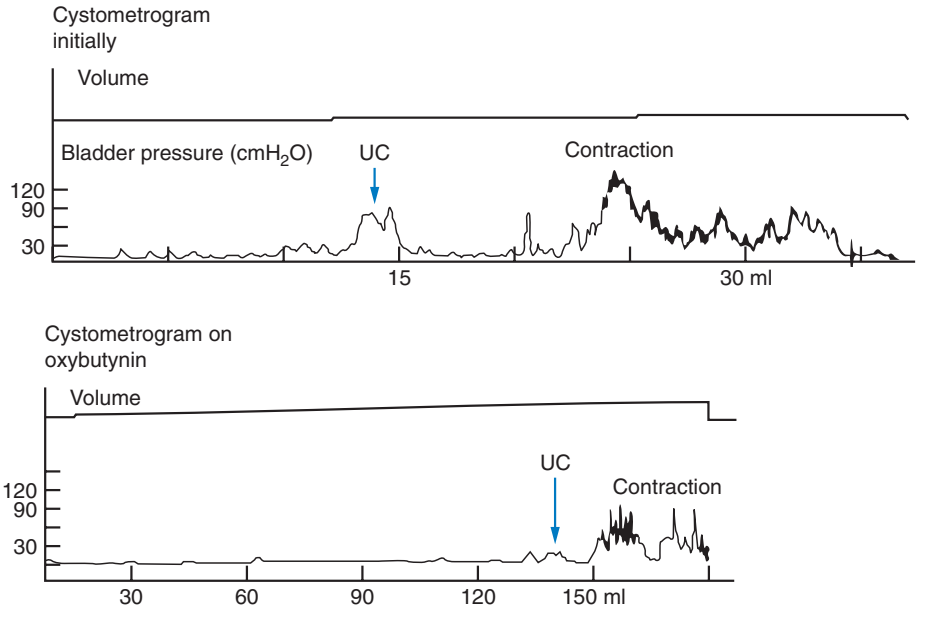

Figure 53.8 Oxybutynin is a potent anticholinergic agent that dramatically delays detrusor contractions and lowers contraction pressure, as demonstrated on these two graphs from a 6-month-old girl with myelodysplasia. UC = uninhibited contraction. (From Bauer.[13])

long-term salutary effects are yet to be appreciated.[69,70]

Continence

Urinary and fecal continence is becoming an increasingly important issue to deal with at an early age as parents try to mainstream their handicapped children. Initial attempts at achieving urinary continence include CIC and drug therapy designed to maintain low intravesical pressure and a reasonable level of urethral resistance (Figures 53.8 and 53.9). Although this approach can be conducted on a trial-and-error basis, it is more efficient to have exact treatment protocols based on specific urodynamic findings. As a result, urodynamic testing is performed if initial attempts with CIC and oxybutynin fail to achieve continence. Without urodynamic studies, it is hard to know whether (1) a single drug is effective, (2) the drug dosage should be increased, (3) a second drug should be added to the regimen, or (4) alternative methods of treatment, i.e. augmentation cystoplasty, should be contemplated.

If urodynamic testing reveals that urethral resistance is inadequate to maintain continence because there is either a failure of the sphincter to react to increases in abdominal pressure or a drop in resistance with bladder filling, then α-sympathomimetic agents are added to the regimen (see Table 53.1). Endoscopic treatment using various bulking agents has been employed to increase bladder outlet resistance. A positive response has been seen most notably with an areflexic good compliant bladder, but so far a truly long-lasting effect has not been demonstrated.[71–73]

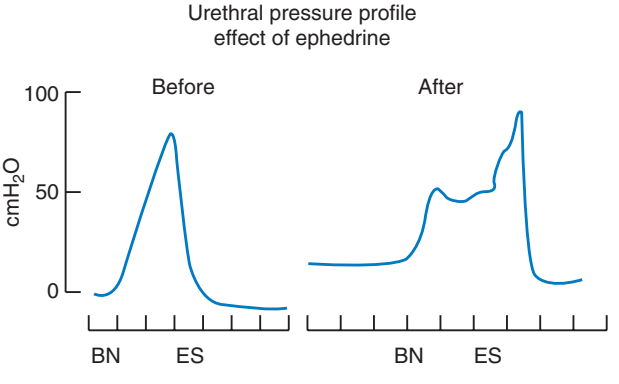

Figure 53.9 α-Sympathomimetic agents potentially have their greatest effect in the bladder neck region where the highest concentration of α-receptor sites exist. They can raise outlet resistance and improve continence in many individuals. (From Bauer.[13]) BN = bladder neck; ES = external sphincter function.

Fecal continence has become a very important social issue for these children as they reach their teenage years.[74] In addition to dietary maneuvers, intravesical bladder stimulation has helped with fecal continence,[75] but the most impressive results have come from the Malone antegrade continence enema or MACE procedure. A continent catheterizable conduit is created from the cecum to the anterior abdominal

wall using the appendix or a narrowed reconfigured small segment of bowel. The cecal end of the conduit is implanted in such a manner as to prevent leakage. An enema solution consisting of either GoLYTELY, saline, or tap water is instilled nightly or every other night, cleansing the distal bowel within a short time, and resulting in fecal continence for up to 2–3 days at a time. Older children readily become independent in managing their bowel function, which leads to improved self-esteem and sociability.[76]

Sexuality

Sexuality in this population has become an increasingly important issue to deal with as more and more individuals have reached adulthood and want either to marry or to have meaningful long-term relationships.[77] Few studies are available, however, that look critically at sexual function in these patients.

In one study, researchers interviewed a group of affected teenagers and reported that at least 28% of them had one or more sexual encounters, and almost all had a desire to marry and ultimately bear children.[77] In a more recent study,[78] 57 men were questioned regarding their sexual history: 41 (72%) had erections and 27 of them (66%) had ejaculations. Twenty men said they had had sexual intercourse but only 11 attempted to father children, of whom eight were successful. Overall, 12 men (21%) were married. Another study revealed that 70% of myelodysplastic women were able to become pregnant and have an uneventful pregnancy and delivery, although urinary incontinence in the latter stages of gestation and cesarean section were common.[79] In the same study, 17% of males claimed that they were able to father children. It is more likely for males to have problems with erectile and ejaculatory function because of the frequent neurologic involvement of the sacral spinal cord, whereas reproductive function in the female, which is under hormonal control, is not affected. However, the level of the neurologic lesion is not predictive of ultimate sexual function in men.[78]

As important as knowing what the precise sexual function is in an individual, sexuality or the ability to interact with the opposite sex in a meaningful and lasting way is just as important. Sexual identity, education, and social mores are issues that have been taken out of the realm of secrecy and are now openly discussed and taught to handicapped people.[80–82] Boys reach puberty at an age similar to that for normal males, whereas breast development and menarche tend to start as much as 2 years earlier than usual in myelodysplastic females. The etiology of this early hormonal surge is uncertain, but it may be related to pituitary function changes in girls secondary to their hydrocephalus.[83] The degree of sexuality attained by most is inversely proportional to the level of neurologic function.

Lipomeningocele and other spinal dysraphisms

Diagnosis

A group of congenital defects that affects the formation of the spinal column but does not result in an open vertebral canal has been labeled occult spinal dysraphisms,[84] and includes:

- lipomeningocele
- intradural lipoma
- diastematomyelia or split cord syndrome
- tight filum terminale
- dermoid cyst/sinus
- aberrant nerve roots
- anterior sacral meningocele (when occurring in conjunction with sacral agenesis = Currarino syndrome)
- cauda equina tumor.

These lesions may exist with no obvious outward signs. But 90% of the children manifest a cutaneous abnormality overlying the lower spine.[85] This may vary from a small dimple or skin tag to a tuft of hair, a dermal vascular malformation, or a very noticeable subcutaneous lipoma (Figure 53.10). In addition, on careful inspection of the legs, one may note a high arched foot or alterations in the configuration of the toes, with hammer or claw digits. Other signs include a discrepancy in muscle size and strength between the legs with weakness at the ankle, and/or a gait abnormality, especially in older children, as a result of shortness of one leg.[86–88] Absent perineal sensation and back pain are not uncommon symptoms in older children or young adults.[87,89,90] Lower urinary tract function is abnormal in 40% of affected individuals.[91]

The child may experience difficulty with urinary control (especially during the pubertal growth spurt), urinary retention, recurrent urinary infection, and/or fecal soiling after an initial period of dryness.

Findings

When these children are evaluated in the newborn or early infancy period, the majority have a perfectly normal neurologic examination. Urodynamic testing,

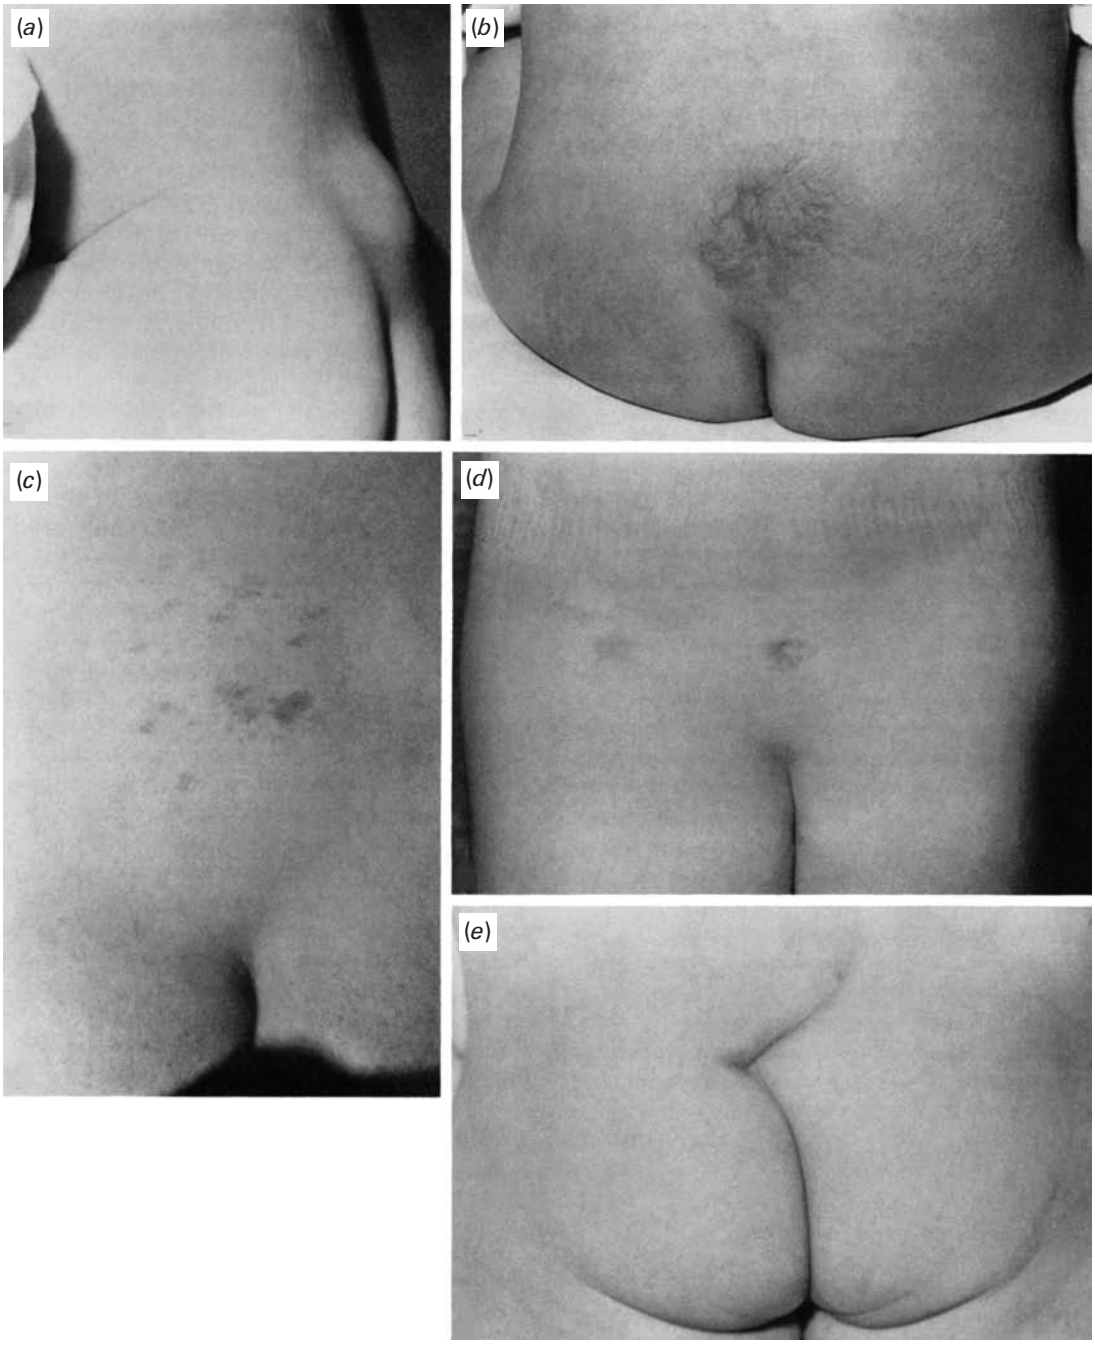

Figure 53.10 Cutaneous lesions occur in 90% of children with various occult dysraphic states. These lesions may vary from a small lipomeningocele (*a*) to a hair patch (*b*), a dermal vascular malformation (*c*), a dimple (*d*), or an abnormal gluteal cleft (*e*).

however, will reveal abnormal lower urinary tract function in about one-third of the babies younger than the age of 18 months[10,92] (Figure 53.11). These studies may provide the only evidence for a neurologic injury involving the lower spinal cord.[92–94] When present, the most likely abnormality is an upper motor neuron lesion characterized by detrusor hyperreflexia and/or hyperactive sacral reflexes, with mild forms of detrusor–sphincter dyssynergy being noted less often. Lower motor neuron signs with denervation potentials in the sphincter, or detrusor areflexia, occur in only 10% of very young children.

In contrast, practically all individuals in the group >3 years of age who have not been operated upon or have been belatedly diagnosed as having an occult dysraphism will have either an upper motor neuron and/or lower motor neuron lesion on urodynamic testing (92%) (see Figure 53.11), or neurologic signs

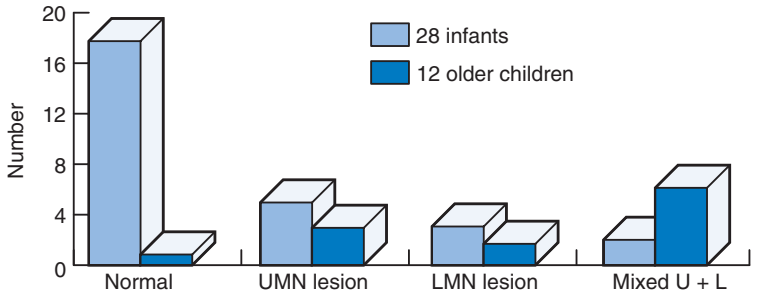

Figure 53.11 Most newborns with a covered spinal dysraphism have normal lower urinary tract function, whereas older children tend to have both upper and lower motor neuron lesions. UMN = upper motor neuron; LMN = lower motor neuron; U + L = upper and lower motor neuron.

of lower extremity dysfunction.[89,92,94–96] There does not seem to be preponderance for one type of lesion over the other (upper versus lower motor neuron); each occurs with equal frequency, and often the child manifests signs of both.[95,97]

Pathogenesis

The reason for this difference in neurologic findings may be related to (1) compression on the cauda equina or sacral nerve roots by an expanding lipoma or lipomeningocele,[98] or (2) tension on the cord from tethering secondary to differential growth rates between the bony and neural elements.[86] The overt stretching that invariably occurs when there is forcible flexion and/or extension of the spinal cord leads to changes in oxidation/reduction of cytochrome oxidase, most notably in the lumbosacral spinal neurons.[99] Under normal circumstances, the conus medullaris ends just below the L-2 vertebra at birth and recedes upwards to T-12 by adulthood.[100] When the cord does not 'rise' secondary to one of these lesions, ischemic injury may ensue.[99,101] Correction of the lesion in infancy has resulted in not only stabilization but also improvement in the neurologic picture in some instances (Figure 53.12). Sixty percent of the babies with abnormal urodynamic findings preoperatively reverted to normal postoperatively, with improvement noted in 30%, whereas 10% worsened with time. In the older child, there is a less dramatic change following surgery, with only 27% becoming normal, 27% improving, 27% stabilizing, but 19% worsening with time[92] (see Figure 53.12). The response to surgical untethering seems to be age related with infants being more likely to improve than older children.[94] Older individuals with hyperreflexia tend to improve, whereas those with areflexic bladders do not.[95,97,102] Finally, fewer than 5% of the children operated on in early childhood developed secondary tethering when observed for several years, suggesting that early surgery has both a beneficial and sustaining effect with these conditions.

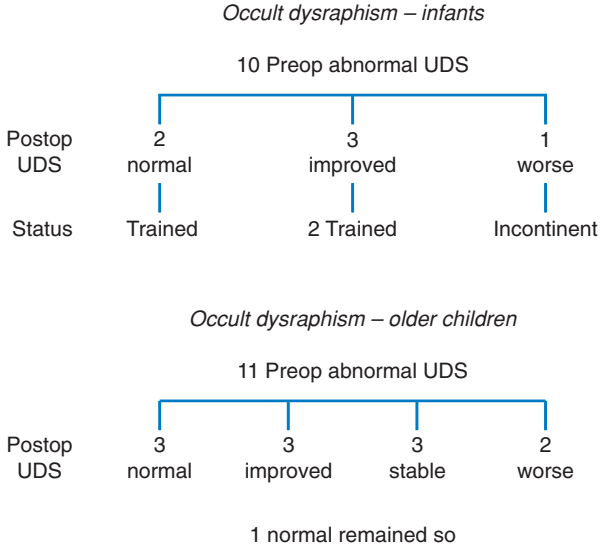

Figure 53.12 Potential for recoverable function is greatest in infants [6/10 (60%)] and less in older children [3/11 (27%)]. The risk of damage to neural tissue at the time of exploration to those with normal function is small [2/19 (11%), not shown]. UDS = urodynamic study.

As a result of these findings, it is apparent that urodynamic testing may be the only way to document that an occult spinal dysraphism is affecting lower spinal cord function.[92,103] Some investigators have shown that posterior tibial somatosensory evoked potentials are an even more sensitive indicator of tethering and should be an integral part of the urodynamic evaluation.[104] The implication of this recommendation is that early detection and intervention are both associated with a reversibility to the lesion that is lost in the older child.[98,101,105,106] and a degree of protection from subsequent tethering, which seems to be a frequent occurrence when the lesion is not dealt with expeditiously in infancy.[107]

Recommendations

Both MRI[108] and urodynamic testing should be conducted in everyone who has a questionable skin or

bony abnormality of the lower spine.[109–112] It is the most reliable way to detect a neurologic deficit involving the lumbosacral spinal cord initially, following surgical correction and as a means of predicting and identifying subsequent tethering, which can occur in 10–20% of children.[112]

If the child is younger than 4–6 months of age, ultrasonography may be useful to image the spinal canal before the vertebral bones have had a chance to ossify.[113,114] At this age there is good correlation between the ultrasound and MRI findings, but the latter gives much better definition of the lesion affecting the spinal cord.[115] Thus, ultrasound provides a good screening test, but MRI is the definitive study.

In the past, removing only the superficial skin lesions without dissecting further into the spinal canal to remove or repair the entire abnormality usually treated these conditions. Today, most neurosurgeons advocate laminectomy and removal of the intraspinal process as completely as possible without injuring the nerve roots or cord as soon as feasible after the diagnosis is made. They recommend this in order to release the tethering and to prevent further injury that might ensue with subsequent growth.[88,90,93–95,106]

Sacral agenesis

Sacral agenesis has been defined as absence of part or all of two or more lower vertebral bodies. Although the etiology of this condition is still uncertain, a number of factors have been implicated. Teratogenic factors may play a role in that insulin-dependent mothers have a 1% chance of giving birth to a child with this disorder. In addition, 16% of children with sacral agenesis have a diabetic mother,[116,117] although it may only have been gestational, insulin-dependent diabetes. Sacral agenesis has been reproduced in chicks when exposed as embryos to insulin.[118,119] Maternal insulin–antibody complexes have been noted to cross the placenta, and their concentration in the fetal circulation is directly correlated with macrosomia.[120] It is possible that a similar cause-and-effect phenomenon is occurring in sacral agenesis. Maternal drug exposure, i.e. minoxidil, has been reported to cause sacral agenesis.[121]

In familial cases of sacral agenesis associated with the Currarino syndrome (presacral mass, sacral agenesis, and anorectal malformation), deletions in chromosome 7 (7q) resulting in *HLXB9* genetic mutations have been found.[14] A mutation in *HLXB9*, a homeodomain gene of a 403 amino acid protein which appears to be responsible for neural plate infolding has been identified in 20 of 21 patients with familial and in 2 of 7 sporadic cases of Currarino syndrome.[122,123] Heterozygote carriers within these families have also been identified.[124] Thus, sacral agenesis may represent one point on a spectrum of abnormalities that encompasses sacral meningoceles and anorectal malformations.[125]

Diagnosis

The diagnosis is often delayed until failed attempts at toilet training bring the child to the attention of a physician. Sensation, including perianal dermatomes, is usually intact, and lower extremity function is normal.[126–128] Sacral vertebral bony ossification begins at 15 weeks, so it is possible to detect the abnormality after 18 weeks of gestation by prenatal ultrasonography and then confirm by fetal MRI.[129] Because these children have normal sensation and little or no orthopedic deformity involving the lower extremities (although high arched feet and/or claw or hammer toes may be present), the underlying lesion is often overlooked. In fact, 20% of children escape detection until the age of 3 or 4 years, when parents begin to question their ability to train their child.[117] The only clue, requiring a high index of suspicion, is flattened buttocks and a low short gluteal cleft[130] (Figure 53.13). Palpation of the coccyx will detect the absent vertebrae.[119] The diagnosis is most easily

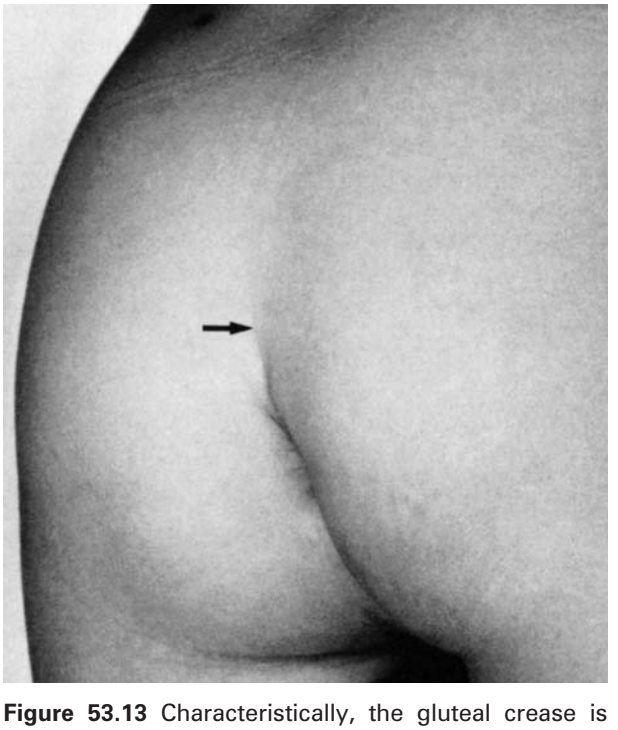

Figure 53.13 Characteristically, the gluteal crease is short and seen only inferiorly (below arrow) as a result of the flattened buttocks in sacral agenesis.

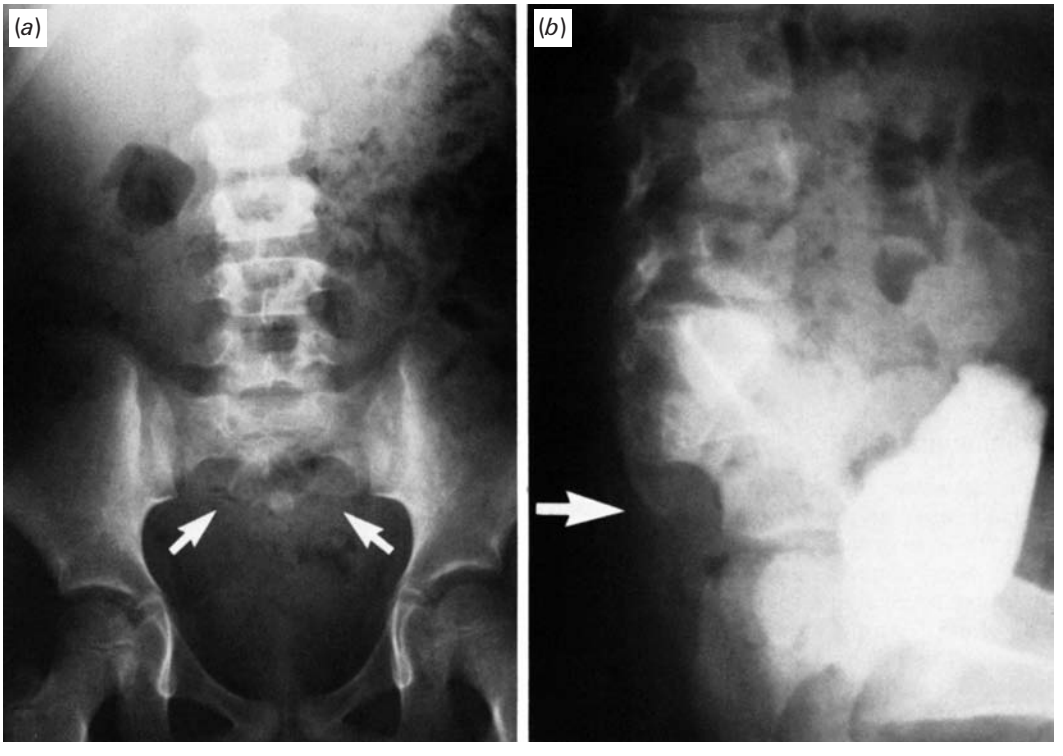

Figure 53.14 The diagnosis is easily confirmed on an anteroposterior (*a*) or lateral (*b*) film of the spine (the latter is performed if bowel gas obscures the sacral area) (arrows).

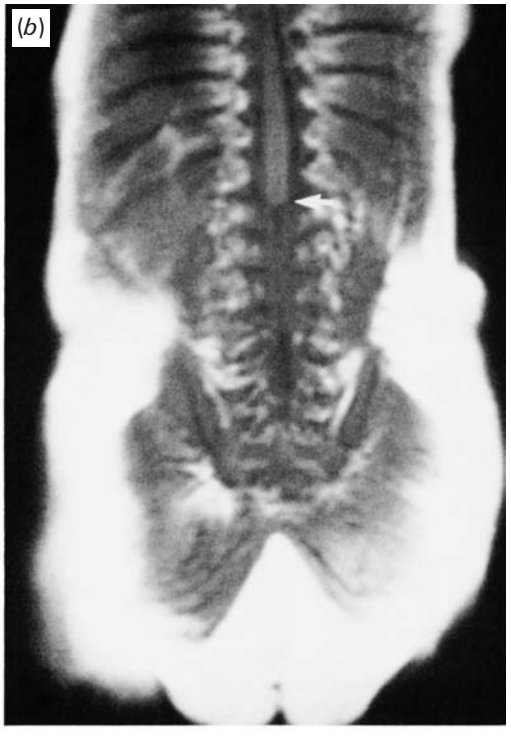
confirmed with a lateral film of the lower spine, because this area is often obscured by the overlying gas pattern on an anteroposterior projection[117,119] (Figure 53.14). MRI has been used to visualize the spinal cord in these cases, and a sharp cut-off of the conus opposite the T-12 vertebra seems to be a consistent finding[131] (Figure 53.15).



Urodynamic findings

When urodynamic studies are undertaken, almost an equal number of individuals will manifest an upper or lower motor neuron lesion (35% vs 40%, respectively), whereas 25% have no signs of denervation at all.[117] The upper motor neuron lesion is characterized by detrusor hyperreflexia, exaggerated sacral reflexes, absence of voluntary control over sphincter function, detrusor–sphincter dyssynergy, and no electromyographic evidence of denervation potentials in the urethral sphincter.[117,119,126,128] VUR occurs almost exclusively in children with hyperreflexia with or without dyssynergy.[132] A lower motor neuron lesion is noted when detrusor areflexia and partial or complete denervation of the external urethral sphincter with diminished or absent sacral reflexes are seen. The bladder is usually small and smooth-walled, with an open bladder neck a common finding.[132] The number of affected vertebrae does not seem to correlate with the type of motor neuron lesion present (Figure 53.16). The lesion usually appears to be stable and rarely shows signs of progressive denervation.

Recommendations

Management depends on the specific type of neurourologic dysfunction seen on urodynamic testing. Anticholinergic agents should be given to those children with upper motor neuron findings of uninhibited contractions, whereas intermittent catheterization and α-sympathomimetic medication may need to be initiated in individuals with lower motor neuron deficits who can neither empty their bladder nor stay dry between catheterizations. When anticholinergic medication is ineffective in controlling the hyperactive detrusor, augmentation cystoplasty may be required to attain an adequate organ for urinary storage. Failure of α-sympathomimetic agents may require either endoscopic injection of bulking agents or even artificial urinary sphincter implantation to increase bladder outlet resistance. The bowel manifests a similar picture of dysfunction and needs as much characterization and treatment as the lower urinary tract. Anorectal manometry has identified abnormalities in the internal anal sphincter and in vol-

untary anal sphincter squeeze pressure, leading to weakness of the muscle and concomitant fecal incontinence.[133] It is important to identify these individuals as early as possible so that they can be rendered continent and out of diapers at an appropriate age, thus avoiding the social stigmata of fecal and/or urinary incontinence.

Associated conditions

Imperforate anus

Imperforate anus is a condition that can occur alone or as part of a constellation of anomalies that has been called the VATER or VACTERL syndrome.[134] This mnemonic stands for all of the organs that possibly

can be affected (V = vertebral, A = anal, C = cardiac, TE = tracheo-esophageal fistula, R = renal, L = limb). This may be part of a spectrum of hindgut abnormalities that includes sacral agenesis and even a presacral mass or meningocele recently labeled as Currarino syndrome,[123] which has genetic implications.[14] Urinary incontinence is not common unless the spinal cord is involved or the pelvic floor muscles and/or nerves are injured during the imperforate anus repair.[135] A plain film of the abdomen and an ultrasonic image of the spine and kidneys are obtained in the neonatal period in all children regardless of the

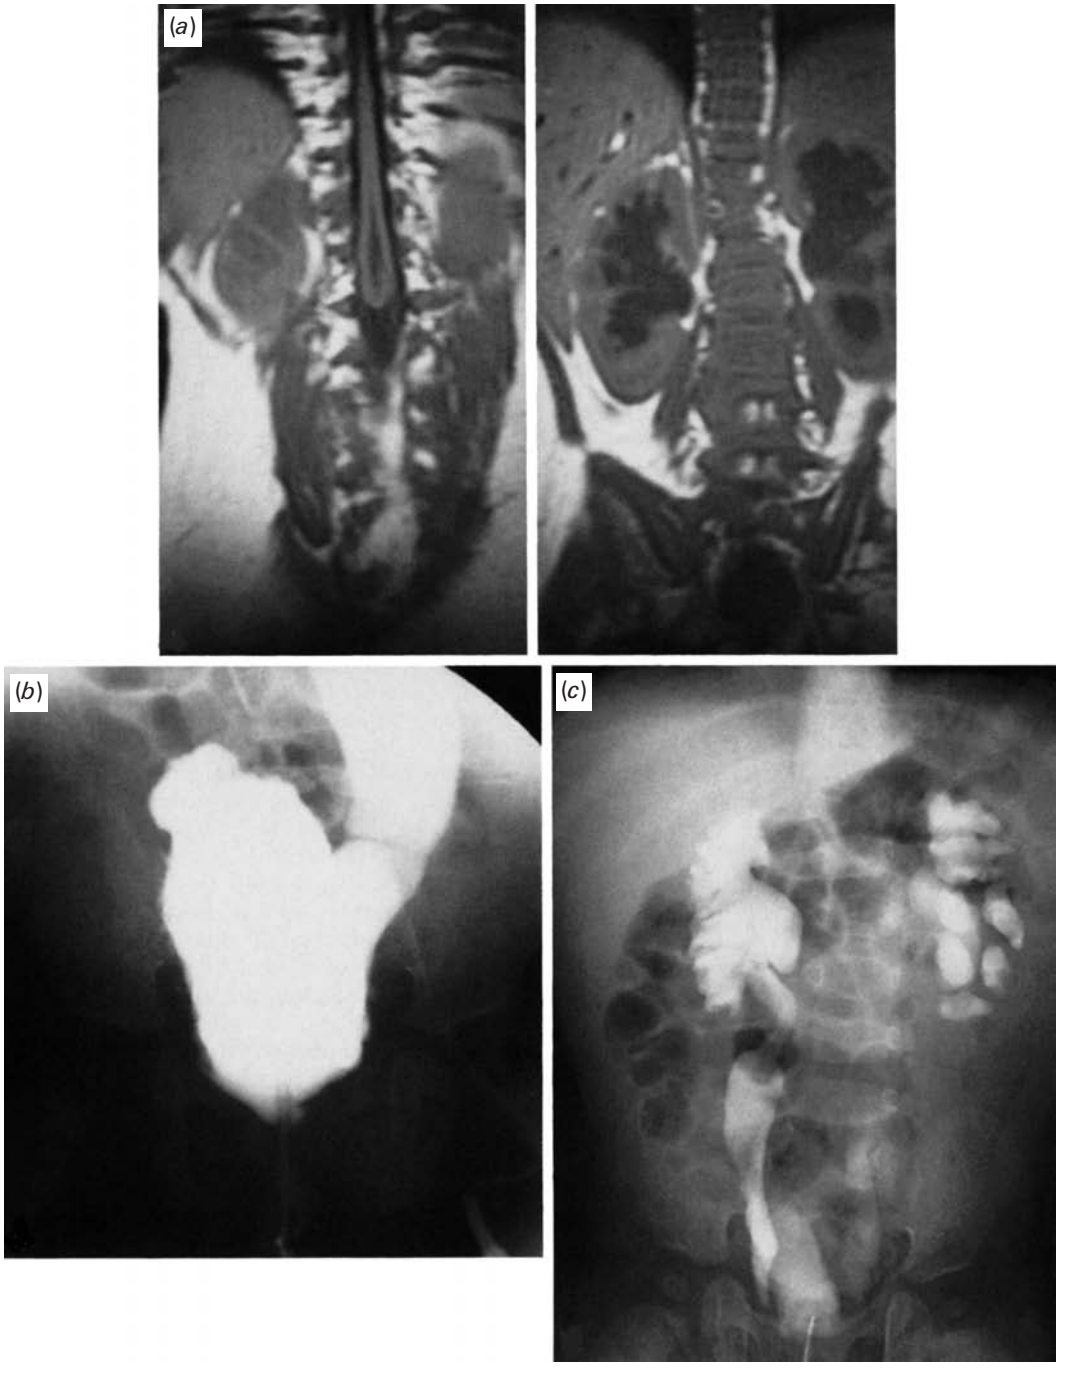

Figure 53.17 (*a*, right and left) This 1-year-old girl with an imperforate anus and bony vertebral abnormalities has bilateral hydronephrosis and a tethered cord on this magnetic resonance imaging scan. (*b*) Her voiding cystourogram reveals significant trabeculation and reflux on the left, whereas her excretory urogram (*c*) demonstrates bilateral hydronephrosis secondary to the reflux on the left and a ureterovesical junction obstruction on the right. Her urodynamic study manifested detrusor hypertonicity and dyssynergy.

level of the rectal atresia, once the child has either stabilized or has had a colostomy performed.[136–138] Vertebral bony anomalies often signify an underlying spinal cord abnormality. Because the vertebral segments have not fully calcified at this time, ultrasonography can readily image the spinal cord. Any hint of an abnormality on these studies or the presence of a lower midline skin lesion overlying the spine warrants an MRI to delineate any pathologic intraspinal process[139] (Figure 53.17). If radiographic images demonstrate an abnormality, urodynamic studies are conducted soon thereafter. Urodynamic studies are also indicated before repair in the child with a high imperforate anus who has undergone an initial colostomy. Abnormal findings may provide a reason to explore and treat any intraspinal abnormality in order to improve the child's chances of becoming continent of both feces and urine. In addition, they furnish a baseline for comparison, especially if incontinence should become a problem in the future, particularly in those children needing extensive surgery for their imperforate anus.

EMG studies of the perianal musculature at this time help to define the optimal location for the future anus. Before the Peña operation, which uses a posterior midline approach, was developed to correct a high imperforate anus, rectal incontinence was thought to be due to an injury involving the pelvic nerves that innervate the levator ani muscles.[140–142] Because the dissection is confined to the midline area, this procedure has reduced the chance of traumatizing the nerve fibers that course laterally and around the bony pelvis from the spine to the urethral and rectal sphincter muscles. Despite careful dissection techniques, 37% of patients still have long-term problems with fecal incontinence.[143] Urodynamic and perianal EMG studies are repeated after the imperforate anus repair, if fecal and/or urinary continence has not been achieved by a reasonable age or if urinary incontinence develops secondarily.

Thirty to 70 percent of these children have a spinal abnormality even though they may not have any other associated anomalies.[144,145] The incidence of neurovesical dysfunction is related to the presence (64%) or absence (31.5%) of a sacral bony defect. Similarly, the level of the anal atresia determines the incidence of bladder dysfunction, with supralevator atresia having a higher risk (70%) than infralevator (35%) lesions.[138] Boemers et al[146] found impaired lower urinary tract function in 24% of 90 children; all but one had a sacral bony abnormality, suggesting an even closer association of dysfunction with abnormal bony spinal development. This abnormality may range from tethering of the spinal cord secondary to an intraspinal dysraphism, which produces an upper motor neuron type of dysfunction involving the bladder and external urethral sphincter, to an atrophic abnormality of the conus medullaris, which leads to a partial or complete lower motor neuron lesion involving the lower urinary tract.[147] In these circumstances, urinary and fecal incontinence might be the child's only complaints. Because lower extremity function may be totally normal, an examination of the legs alone can be misleading.[145] In one review, 20% of children with neuropathic bladder dysfunction and imperforate anus had a normal bony spine, suggesting that postnatal spinal ultrasonography should be performed in all newborns with imperforate anus.[148]

Central nervous system insults

Cerebral palsy

Etiology

Cerebral palsy is a non-progressive injury to the brain in the perinatal period that produces a neuromuscular disability or a specific symptom complex of cerebral dysfunction. Its incidence is approximately 1.5 per 1000 births but may be increasing as more smaller and younger premature infants are surviving in intensive care units. It is usually due to a perinatal infection or period of anoxia (or hypoxia) that affects the CNS.[149,150] It most commonly appears in babies who were premature, but it may be seen following a seizure, infection, or intracranial hemorrhage in the neonatal period.

Diagnosis

Affected children have delayed gross motor development, abnormal fine motor performance, altered muscle tone, abnormal stress gait, and exaggerated deep tendon reflexes. These findings can vary substantially from being very obvious to exquisitely subtle with no discernible lesion present unless a careful neurologic examination is performed. Among the more overtly affected individuals, spastic diplegia is the most common of the five types of dysfunction that characterize this disease, accounting for nearly two-thirds of the cases.

Findings

Most children with cerebral palsy develop total urinary control. Incontinence is a feature in some, but

Table 53.5 Lower urinary tract function in cerebral palsy[a]

Type of dysfunction	No. (%)
Upper motor neuron lesion	49 (86)
Mixed upper and lower motor neuron lesion	5 (9)
Incomplete lower motor neuron lesion	1 (2)
No urodynamic lesion	2 (3.5)

[a] The study comprised 57 children.

the exact incidence has never been truly determined.[151,152] In a recent survey of questionnaires sent to over 600 families with an affected child aged 4–18 years, 23.5% had persistent urinary incontinence.[153] When urinary continence was achieved, its development was delayed when compared with normal children of similar age. With further analysis of the data, 80% of children with spastic diplegia, 54% with tetraplegia, and 38% with low intellectual capacity attained continence. The presence of incontinence was related in part to the extent of the physical impairment because the physical handicap prevents the individuals from reaching the toilet before they have an episode of wetting. If the children are intellectually handicapped they either do not recognize the need to void or relate this fact to caregivers early enough to be toileted.[153] Some children have such a severe degree of mental retardation that they are not trainable, but the majority have sufficient intelligence to learn basic societal protocol with patient and persistent handling. Continence is achievable, albeit at a later than expected age, with diurnal continence being attained first and nocturnal continence occurring within the subsequent year.[153] Therefore, urodynamic evaluation is reserved for children who appear trainable and do not seem to be hampered too much by their physical impairment, but who have not achieved continence by later childhood or early puberty.

One review of urodynamic studies, performed in 57 children with cerebral palsy (Table 53.5),[152] revealed that 49 (86%) of the children presented with the expected picture of a partial upper motor neuron lesion type of dysfunction, with exaggerated sacral reflexes, detrusor hyperreflexia, and/or detrusor–sphincter dyssynergia (Figure 53.18), even though they manifested voluntary control over voiding. Six of the 57 (11%), however, had evidence of both upper and lower motor neuron denervation with detrusor areflexia and/or abnormal motor unit potentials on sphincter EMG assessment (Table 53.6). When their

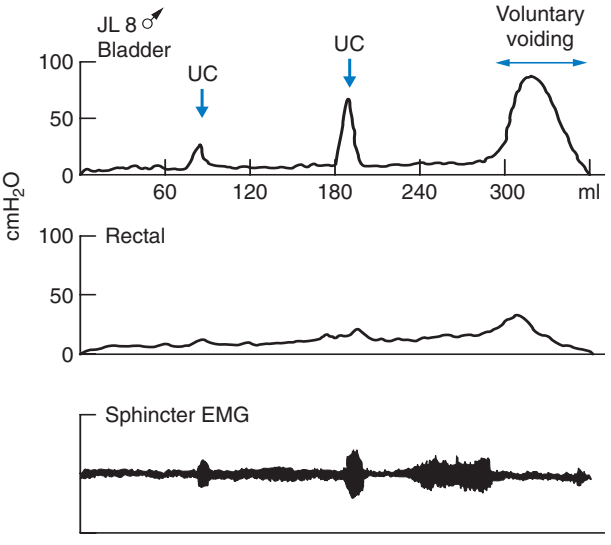

Figure 53.18 An 8-year-old boy with spastic diplegia has a typical partial upper motor neuron lesion-type bladder with uninhibited contractions (UCs) associated with increased sphincter activity but normal voiding dynamics at capacity. Wetting is due to these contractions when unaccompanied by the heightened sphincter activity. EMG = electromyography. (From Bauer.[13])

records were analyzed on a retrospective basis, most of the children who exhibited these latter findings had experienced an episode of cyanosis in the perinatal period (Table 53.7). Thus, a lower motor neuron lesion may be seen in addition to the expected upper motor neuron dysfunction.

In a more recent review of 29 children with cerebral palsy undergoing urodynamic studies,[154] including 23 who had incontinence and/or urinary infection and six who were asymptomatic, urodynamic studies demonstrated poor compliance in 21 of the 23 symp-

tomatic and two of the six asymptomatic children. In the same study, uninhibited contractions were found in all symptomatic and five of six asymptomatic children, and high leak point pressure in 16 of 23 and four of six symptomatic and asymptomatic children, respectively. VCUG revealed bladder trabeculation in 58% and VUR in 9% of symptomatic, and trabeculation in 50% but no reflux in asymptomatic children. In a meta-analysis of all published reports of urodynamic findings in children with cerebral palsy, detrusor overactivity was seen in 80%, dyssynergy between the bladder and sphincter in 5%, and normal function in only 12%.[152,154–156] From these reports it is apparent that urodynamic studies can be very revealing in all children, whether or not they have urinary symptoms,[154] but are especially useful if frequent toileting or initial anticholinergic treatment fails to improve incontinence, the child develops urinary infection, or renal ultrasonography reveals hydronephrosis.

Recommendations

Treatment usually centers around abolishing the uninhibited contractions with anticholinergic medication, but residual urine volume must be monitored closely to ensure complete evacuation with each void. Intermittent catheterization may be required for those who cannot empty their bladders. Selective dorsal sacral rhizotomy has helped with spasticity and incontinence, with only <5% developing incontinence if careful mapping of dorsal sacral nerve roots is identified.[157,158]

Traumatic injuries to the spine

Despite the exposure and potential for a traumatic spinal cord injury, this condition is rarely encountered in children; the incidence in Sweden is 2.6 cases per million children per year.[159] When an injury does occur, it is most likely to happen as a result of a motor vehicle accident (24–52%), a gunshot wound, or a diving incident.[159–162] Infants are more prone to an injury from a motor vehicle accident (71%), toddlers and children secondary to a fall (48% and 34%, respectively), and adolescents due to a sport-related event (29%).[161] It has also occurred iatrogenically following surgery to correct scoliosis, kyphosis, or other intraspinal problems as well as congenital aortic arch anomalies or patent ductus arteriosus.[160,163] Newborns are particularly prone to hyperextension injuries during a high forceps delivery.[164,165] The lower urinary tract dysfunction that ensues is not likely to be an isolated event but, rather, is usually associated with loss of sensation and paralysis of the lower limbs. Radiologic investigation of the spine may not reveal any bony abnormality, even though momentary subluxation of osseous structures due to the high elasticity of vertebral ligaments can result in a neurologic injury.[166] This has been labeled spinal cord injury without radiologic abnormality or SCIWORA, and can account for up to 38% of spinal cord injuries in children.[162] Myelography and computed tomography (CT) will show swelling of the cord below the level of the lesion, central disk herniation, spinal stenosis, or contusion.[164,165,167] Often, what appears initially as a permanent lesion turns out instead to be a transient phenomenon. Although sensation and motor function in the lower extremities may be restored relatively soon, the dysfunction involving the bladder and rectum may persist for a considerable period.

If urinary retention occurs immediately following the injury, an indwelling Foley catheter is passed into the bladder and left in place for as short a period of time as possible, until intermittent catheterization can be started safely on a regular basis.[168,169] When the child starts voiding again, the timing of catheterization can be such that it is used as a means of measuring the residual urine volume after a spontaneous void. Residual urine volumes of 25 ml or less are considered safe enough to allow for a reduction in the frequency and even cessation of the catheterization program.[169] If there is no improvement in urinary tract function after 4–6 weeks, urodynamic studies are conducted to determine whether or not this condition

is the result of spinal shock or actual nerve root or spinal cord injury. Detrusor areflexia is not uncommon under these circumstances.[170] EMG recording of the sphincter often reveals normal motor units without fibrillation potentials, but absent sacral reflexes and a non-relaxing sphincter with bladder filling, a sign that transient spinal shock has occurred.[170] The outcome from this condition is guarded but good, inasmuch as most cases resolve completely as edema of the cord in response to the injury subsides, leaving no permanent damage.[170,171]

Most permanent traumatic injuries involve either the upper thoracic or cervical spinal cord, but some affect the cauda equina region. The sacral cord injury most likely produces a lower motor neuron deficit of the striated sphincter that usually leads to low-pressure bladder emptying with little risk of upper urinary tract deterioration. However, it probably necessitates medical and/or surgical therapy to achieve continence. On the other hand, upper spinal cord injuries produce an upper motor neuron-type lesion with detrusor hyperreflexia and detrusor–sphincter dyssynergia. The potential danger from this outflow obstruction is obvious.[172] Substantial residual urine volumes, detrusor hypertonicity, high voiding pressure, high-pressure reflux, urinary infections, and their sequelae are the leading cause of long-term morbidity and mortality in spinal cord-injured patients. Urodynamic studies will identify those patients at risk.[169] Even if the child is continent and voiding to completion or requires intermittent catheterization to empty, it is imperative to measure detrusor compliance, the presence of hyperreflexia, and actual voiding pressures (if appropriate) to determine the potential risk for hydroureteronephrosis and/or reflux.[173] Early identification and proper management may prevent the signs and effects of bladder outlet obstruction before they become apparent on X-ray examination of the urinary tract.[174–176]

Functional voiding disorders

Urinary incontinence is defined by the ICCS as the uncontrolled leakage of urine; it can be continuous or intermittent, occurring during the daytime or nighttime. Continuous incontinence means leakage of urine all the time and denotes the probability of an ectopic ureter. It is abnormal at any age because even infants have a degree of cortical control over bladder emptying, void in reasonably spaced intervals, and stay dry between voidings. Daytime or diurnal incontinence may be on an urgent or sudden basis, associated with stress activity such as coughing or running, or occur just after voiding (only in girls, resulting from the vaginal trapping of urine during voiding that drips out afterwards). Nocturnal incontinence or enuresis means the leakage of urine while asleep at an age when urinary control is expected. It is difficult, however, to say when this should occur. Studies of large groups of children have provided some guidelines for expectations, but there are no absolute milestones for the individual child.[177,178] Girls tend to become trained before boys, and daytime continence is achieved before nighttime control. It is rare to achieve control before 18 months of age.[179] Thereafter, urinary control is gained by approximately 20% of children for each year of life up to 4.5 years, with a smaller percentage of the population attaining complete continence every year after that. By the age of 10, about 5% of children still have some nocturnal wetting, but this diminishes to 2% after puberty.[180] Recently, evidence has come to light that there may be a genetic basis for the development of urinary control.[181–183]

The evaluation of the incontinent child begins with a comprehensive history. The history includes details of any family history of enuresis, the mother's pregnancy, including the presence of maternal insulin-dependent diabetes mellitus, stage of gestation at the time of delivery, Apgar scores at birth, or difficulties occurring peri- or early postnatally, and developmental milestones such as school performance. History of fine and gross motor incoordination, previous continence, social setting and sibling interaction, parental expectations, and characterization of the wetting episodes are also important. If there is a suspicion of an ectopic ureter in a girl (normal voiding, but constant dampness), then renal and bladder ultrasonography is performed. Boys who have a question of bladder outflow obstruction (urgency or urge incontinence with enuresis beyond the age of 5 years) are evaluated by voiding cystography. One group of clinicians has developed a comprehensive questionnaire that accurately identifies and quantifies children with abnormal voiding patterns and has been used successfully in determining responses to therapy.[184] The indications for performing urodynamic studies are as follows: any suspicion of a neurologic condition, diurnal incontinence with no associated pathology, fecal and urinary incontinence at any age, persistent voiding difficulties long after a urinary infection has been treated, recurrent urinary infection despite continuous antibiotics, and bladder trabeculation and/or 'sphincter spasm' on VCUG (Figure 53.19).

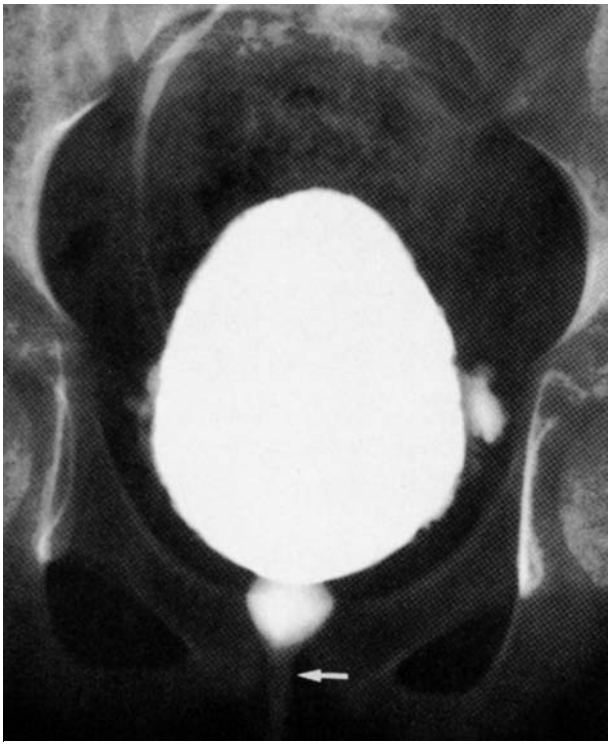

Figure 53.19 This 10-year-old girl with recurrent urinary tract infections has spasm of the sphincter during voiding, with narrowing in the distal urethra, demonstrated on this voiding cystourethrogram (arrow). Note grade II/V right-sided reflux.

When urodynamic studies are performed on a group of children who have these findings without an obvious systemic neurologic disorder, a spectrum of voiding pattern abnormalities emerges:[185]

- small-capacity bladder
- detrusor overactivity
- infrequent voider–lazy bladder syndrome
- psychological non-neuropathic bladder (Hinman syndrome).

Classification and a detailed description of these disorders help one to understand and treat each condition specifically.

Small-capacity hypertonic bladder

Children with recurrent urinary infection without an anatomic abnormality may have symptoms of voiding dysfunction, including frequency, urgency, urge incontinence, staccato or intermittent voiding, nocturia and/or enuresis, and dysuria, long after the infection has cleared. Sometimes, persistence of these symptoms with their associated abnormal voiding dynamics can lead to repeated infections.[186]

An inflammatory reaction in the bladder wall may produce an irritability that affects the sensory threshold and increases the need to void sooner than anticipated. If the detrusor muscle is affected as well, the increased irritability may lead to overactivity of the muscle and eventually to poor compliance.[155] When children attempt to hold back urination because it is either painful or inappropriate to void, they may actually tighten or only partially or intermittently relax the external sphincter muscle during voiding. This retention may result in a functional outflow obstruction that disrupts the laminar flow pattern that normally exists[186–188] (Figure 53.20). This stop-and-start (staccato) voiding (Figure 53.21) is a prominent pattern of dysfunction in girls leading to recurrent infection[189] because bacteria can be carried back up into the bladder from the meatus as a result of the 'milk-back' phenomenon occurring within the urethra when urination is interrupted in this manner.[190] Theoretically, if unrecognized or left untreated in young girls, this may become the forerunner of interstitial cystitis seen in many adult females and may even be the precursor of prostatitis in males.

Radiologic investigation often reveals a normal upper urinary tract, but the bladder may be small and have varying degrees of trabeculation on excretory urography or a thickened wall on ultrasonography.[185,191] During the voiding phase of cystourethrography, the posterior urethra may show signs of intermittent dilatation at its upper end, with a uniform narrowing occurring toward the external

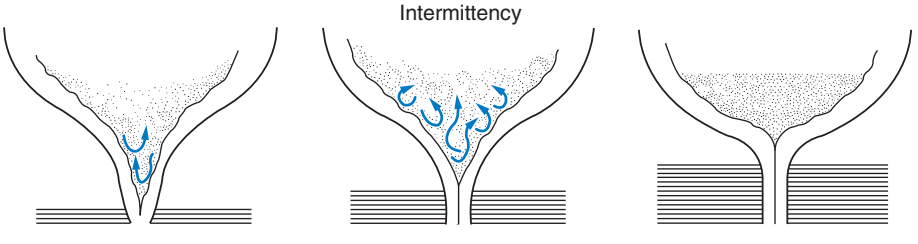

Figure 53.20 Non-laminar flow secondary to periodic tightening and relaxation of the external sphincter leads to eddy current and the 'milk-back' phenomenon, which can carry bacteria colonized at the urethral meatus up into the bladder and cause infection of the residual urine.

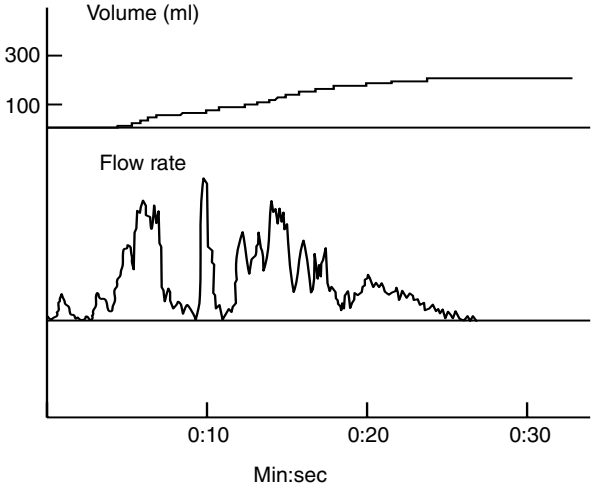

Figure 53.21 Staccato voiding is seen in this 8-year-old girl with recurrent infection.

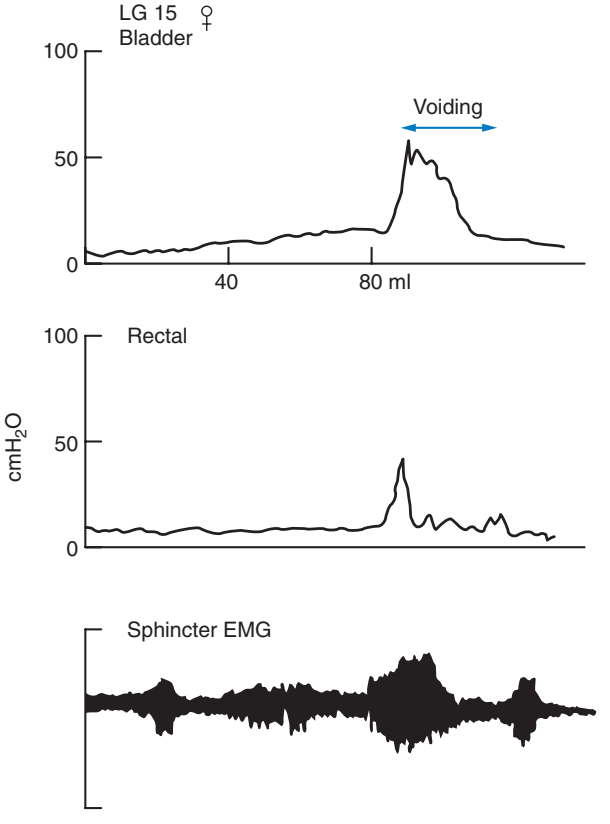

Figure 53.22 This urodynamic picture in a teenage female with recurrent infections reveals a small-capacity bladder and a hypertonic sphincter that relaxes only partially during voiding. EMG = electromyography.

sphincter region. In girls, this 'spinning-top' deformity has raised the question of an obstructed meatus[187,188] (see Figure 53.19), whereas in boys, it has often been mistaken for posterior urethral valves. This appearance is due to failure of complete relaxation of the external sphincter and persistence of a relative obstruction at the distal end of the posterior urethra in an attempt by the child to suppress voiding[192] and has no correlations with meatal size.

Urodynamic studies demonstrate a bladder of small capacity (when adjusted for age) and elevated detrusor pressure during filling[185,188] (Figure 53.22). At capacity, the child has an uncontrolled urge to void that may not be suppressed despite tightly contracting the external sphincter. The bladder contraction is usually sustained, with pressures reaching higher than normal values. Emptying may not always be complete despite these high pressures. The baseline sphincter EMG activity is normal at rest, but there may be complex repetitive discharges (pseudomyotonia)[193] or periodic relaxation of the muscle during filling, contributing to the sense of urgency or actual incontinent episodes. During a voluntary void, the sphincter may relax intermittently or even completely at first, but then contract in response to discomfort, preventing complete emptying[186,194] (see Figure 53.22).

Treatment is based on trying to eliminate the recurrent infections, minimize any possible environmental influences that predispose the individual to infection, and improve the child's voiding pattern and bathroom habits. Girls should learn to take showers instead of baths, or at least to bathe alone without other siblings, wipe from front to back, try to completely relax when they void so that a steady stream is produced, and take the time to empty completely each time they urinate.[186] Biofeedback training to teach these children to relax the sphincter when they void has been used with success.[195–198] In addition to antibiotics, antispasmodic/anticholinergic agents are administered for periods ranging from 6 to 9 months.

Detrusor overactivity

Children with long-standing symptoms of daytime frequency, urgency, or sudden incontinence and squatting, in addition to nocturia and/or enuresis, may have detrusor overactivity. Vincent's curtsy, a characteristic posturing by these children in an attempt to prevent voiding, is a commonly described behavior pattern.[199,200] One or more of the child's parents or siblings often have a history of delayed control over micturition. These affected family members may compensate for their own abnormality by displaying continued daytime frequency or nocturia, or both. Although the child's physical examination may be normal, hyperactive deep tendon reflexes in the lower and/or upper extremities, tight heel cords,

ankle clonus, posturing with a stress gait, or difficulty with tandem walking, and mirror movements (similar motion in the contralateral hand when the individual is asked rapidly to pronate and supinate one hand) may be evident. Left-handedness, left-footedness, or left-eyedness in a family in which all other members are right-handed may signify crossed dominance from a previously unrecognized perinatal insult. Attention deficit disorders, poor writing ability and/or incoordination, and learning difficulties are more commonly encountered in these children as well.[201,202] Carefully questioning parents about perinatal events or reviewing birth history records may uncover such an insult that has affected the CNS system and caused these findings. The DVSS or dysfunctional voiding symptom score devised by the group in Toronto has been successfully used in identifying and treating children with subtle effects of such insults.[184]

X-ray evaluation usually reveals no abnormality other than a mildly trabeculated or thick-walled bladder. Urodynamic studies demonstrate premature contractions of the bladder during filling, which the child may or may not sense and/or abolish by increasing the activity of the external urethral sphincter[185,194] (see Figure 53.18). Alternatively, periodic relaxation of the sphincter, the initial phase of an uninhibited contraction, that leads to a sense of urgency or to an episode of leaking, may be the only clue to an overactive bladder (Figure 53.23). During filling, capacity may be reached sooner than expected, at which time

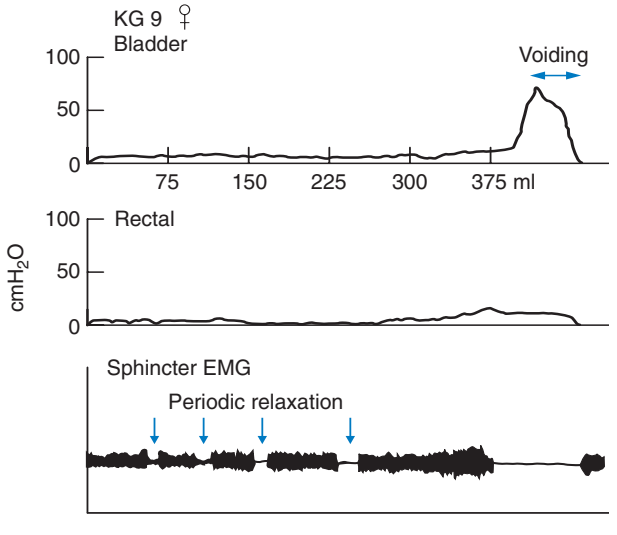

Figure 53.23 Some children only manifest periodic relaxation of the sphincter without a rise in detrusor pressure as an early phase of a hyperreflexic bladder producing urgency and incontinence. EMG = electromyography.

a normal detrusor contraction occurs with a sustained relaxation of the sphincter, resulting in complete emptying. Some children will not be able to suppress this contraction even though the bladder has not been filled to its intended capacity. Sometimes, detrusor overactivity may only be elicited following a cough or strain, or when the child assumes a change in posture.[200] The overactivity is thought to be responsible for the symptoms.[203]

These findings may be the result of a cerebral insult, however mild, in the neonatal (or even prenatal) period, but they are linked more commonly to delayed maturation of the reticulospinal pathways and the inhibitory centers in the midbrain and cerebral cortex. Thus, total control over vesicourethral function may be lacking.[179,180,204] Several investigators have found a similar urodynamic picture in a significant number of adults with nocturnal enuresis and/or daytime symptoms.[205] Parents who exhibit the same behavior pattern as their children may have a genetically determined delayed rate of CNS maturation.[182]

On occasion, children with profound constipation develop detrusor overactivity that leads to urinary incontinence.[206] The etiology of this condition is unclear, but treatment of the bowel distention has resulted in a dramatic improvement in the bladder dysfunction.[207]

Sometimes, repeated urinary infection may produce an identical urodynamic picture. Detrusor overactivity occurs as a result of the inflammatory response in the bladder wall that irritates the receptors located in the submucosa and/or detrusor muscle layers.[208] Therefore, these children should be screened for infection. It has been postulated that an overactive detrusor may lead to inappropriate voiding. The child realizes what is happening, and tightens the sphincter to reverse this process, which shuts the distal urethra first and the bladder neck second, causing the 'milk-back' phenomenon and the potential for urinary infection, as presented in the previous discussion, to occur.[190,208]

Anticholinergic medications alone or in combination have been used successfully to manage this condition.[200] Oxybutynin has been highly successful with tolterodine somewhat less so, primarily due to underdosing, but the latter is better tolerated than the former and constipation is less of an issue.[209,210] Recently, biofeedback training using computer technology has been employed successfully in achieving continence and in reducing the need for medication in children refractory to anticholinergic medication.[196–198,211] If infection is present, it should be

eradicated and antibacterial prophylaxis should be employed.[155,185,212–214]

The infrequent voider–lazy bladder syndrome

Most children urinate four or five times per day, and defecate daily or at least every other day. Some children, primarily girls, may void only twice a day, once in the morning (either at home or after they are in school), and again at night.[215] It is not uncommon to find children who do not void at all while in school. These children exhibited normal voiding patterns as infants, but after toilet training, they learned to withhold micturition for extended periods. As a result, a few develop a fear of strange bathrooms or mimic their mother's pattern of infrequent urination and defecation.[185] Others have experienced an aversive event or had an infection associated with dysuria around the time of training, which led to the infrequent pattern of micturition. Some children are excessively neat or have a fetish for cleanliness that causes them to avoid bathrooms. Often, they only void enough to relieve the pressure to urinate and do not empty their bladder completely. The decrepit conditions in many school bathrooms predispose children, mainly girls, to limit the number of times that they use these facilities during the school day; consequently, they become infrequent voiders all of the time.

The infrequent voiding and incomplete emptying produce an ever-increasing bladder capacity and a diminished stimulus to urinate.[190] The chronically distended bladder is at risk for urinary infection and/or overflow or stress incontinence. Sometimes, these signs are the first manifestations of the abnormal voiding pattern. When the child is carefully questioned, the aberrant micturition is easily detected. More often, the problem is diagnosed following VCUG or radionuclide cystography performed for an assessment of urinary tract infection. A larger than normal capacity (for age) and/or a high residual urine volume on initial catheterization is noted. When the child is questioned about voiding habits, this infrequent pattern of elimination is detected[190] (Figure 53.24). The cystogram, however, usually reveals a smooth-walled bladder without reflux.

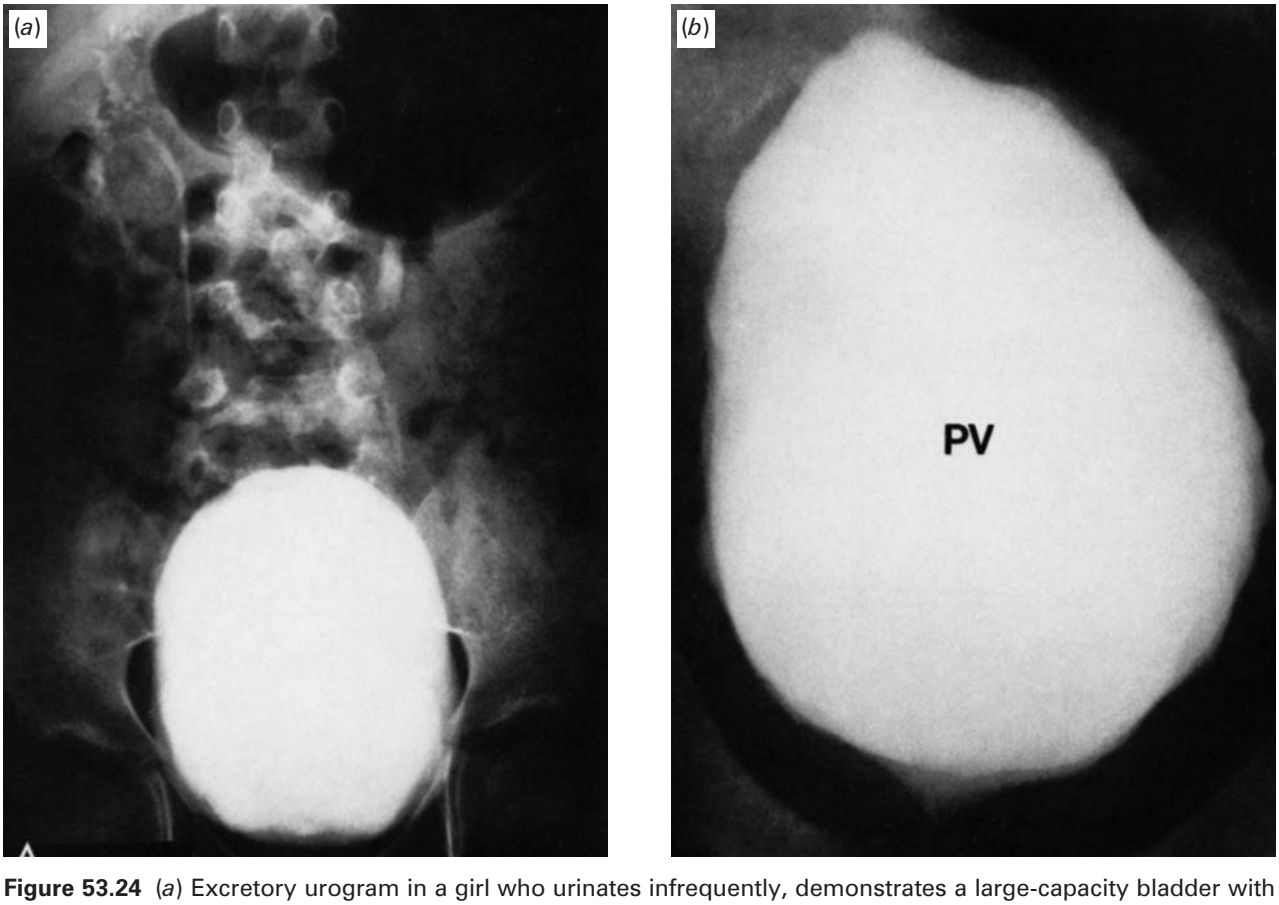

Figure 53.24 (*a*) Excretory urogram in a girl who urinates infrequently, demonstrates a large-capacity bladder with a normal upper urinary tract. (*b*) Her postvoiding (PV) residual is quite large.

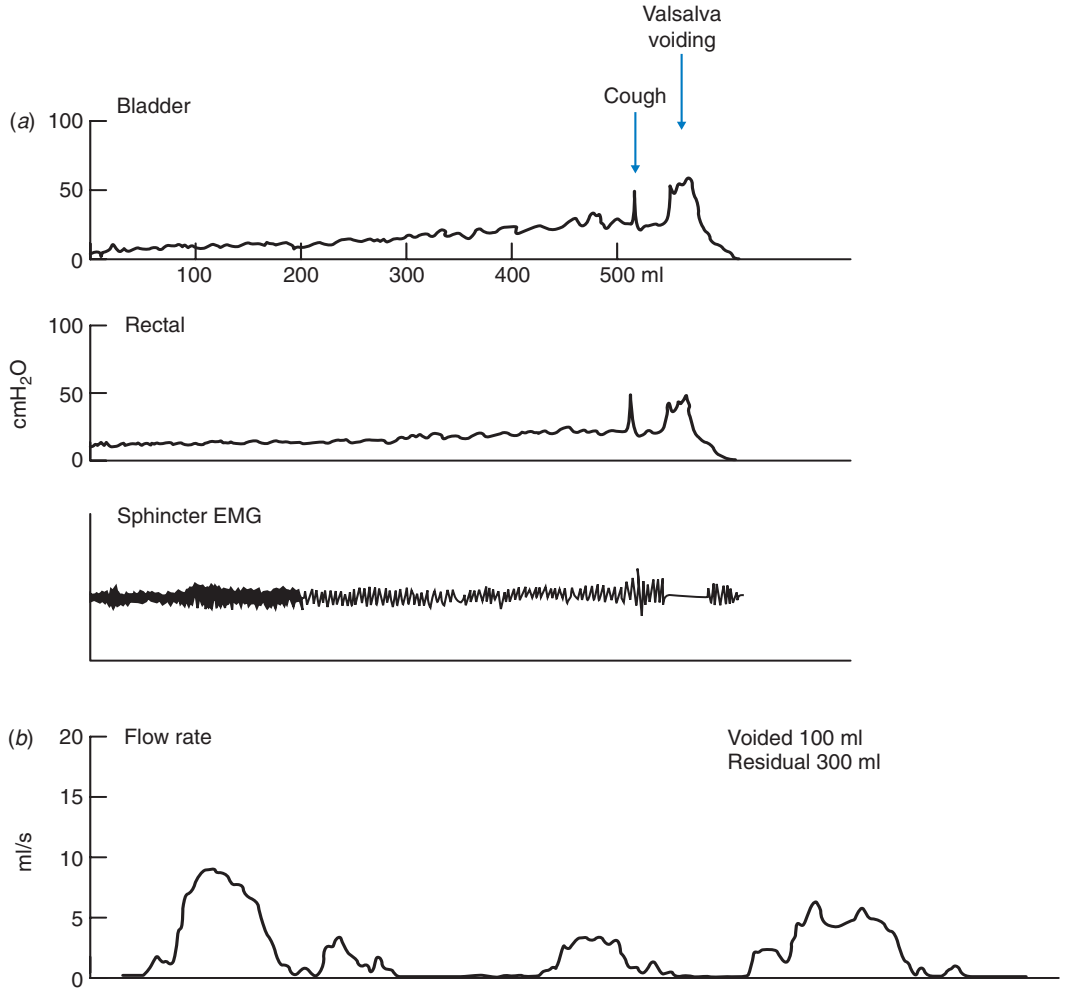

Figure 53.25 (*a*) Urodynamic evaluation reveals a very large-capacity, low-pressure bladder. The girl empties entirely by straining after relaxing the sphincter with no apparent detrusor contraction. EMG = electromyography. (*b*) Her intermittent urinary flow rate is characteristic of this effort to empty and leads to a considerable volume of residual urine.

Urodynamic studies demonstrate a very large-capacity, highly compliant bladder with either normal, unsustained, or absent detrusor contractions[185] (Figure 53.25a). Straining to void is a common form of emptying. Sphincter EMG reveals normal motor unit potentials at rest and normal responses to various sacral reflexes, bladder filling, and attempts at emptying. The urinary flow rate may be intermittent, with sudden peaks coinciding with straining, or it may be normal but short lived, secondary to an unsustained detrusor contraction.[190] Unless strongly encouraged, the child will not completely empty the bladder during voiding[185] (Figure 53.25b). This picture is consistent with myogenic failure from chronic distention.[216]

Changing the child's voiding habits is the first approach to therapy.[217] Keeping to a rigid schedule of toileting and encouraging children to empty each time they void are mandatory.[195] Behavioral therapy techniques to encourage compliance are helpful. Rarely, intermittent catheterization may be necessary to allow the detrusor muscle to regain its contractility and ability to empty.[218] Antibiotics are needed when urinary infection is present and are continued until the voiding pattern improves.

Psychological non-neuropathic bladder (Hinman syndrome)

Hinman[219] described an apparent 'syndrome' of voiding dysfunction that mimics neuropathic bladder disease but may be a learned disorder. At first, this syndrome was believed to be caused by an isolated neurologic lesion,[220–222] but now it is felt to be an

acquired abnormality.[185,219,223,224] It is produced by an active contraction of the sphincter during voiding, creating a degree of outflow obstruction. Some investigators think that this phenomenon may be the result of persistence of the transitional phase of gaining control in which the child learns to prevent voiding by voluntarily contracting the external urethral sphincter.[194,223] Others believe that this pattern results from the child's normal response to uninhibited contractions.[203] This behavior becomes habitual because the child has difficulty in distinguishing between involuntary and voluntary voiding; as a consequence, the inappropriate sphincter activity occurs all the time.[185] Jayanthi et al[225] reported similar findings in a group of younger children, newborn to 30 months of age and Bauer et al[226] noted these same findings in five newborns and children under 1 year of age. All were managed by either vesicostomy, urinary diversion, or intermittent catheterization, with spontaneous improvement after vesicostomy closure or urinary undiversion in some.

In general, the children have urgency, urge and/or stress incontinence, infrequent voluntary voiding, intermittent urination associated with straining, recurrent urinary infection, and irregular bowel movements, with fecal soiling in between.[185] Most striking is the similarity in the pattern of family dynamics that is disclosed on carefully observing and questioning.[224] The Hinman syndrome has been applied to many children with any degree of voiding dysfunction, but it should only be diagnosed as such when many of the following conditions are present:

1 Clinical features:
   - day and night wetting
   - encopresis/constipation/impaction
   - recurrent urinary tract infections
   - parental characteristics
     - domineering/exacting
     - divorce
     - alcoholism
     - punishments (mental and physical) inflicted for wetting
   - previous surgery
     - ureteral reimplantation
     - bladder neck plasty
     - diversion.
2 Radiologic features:
   - hydronephrosis, with or without pyelonephritis
   - reflux: III/V in degree
   - large-capacity, trabeculated bladder
   - large residual urine volume
   - posterior urethra sometimes dilated with narrowing at external sphincter
   - heavily loaded colon.
3 Urodynamic features:
   - elevated detrusor filling and voiding pressures
   - ineffective detrusor contractions
   - high resting sphincter EMG
   - unsustained sphincter relaxation during voiding
   - large residual volume.
4 Treatment (individualized):
   - bladder retraining
     - behavioral modification
     - double voiding
     - biofeedback techniques for sphincter relaxation
     - intermittent catheterization
   - drugs
     - oxybutynin
     - tolterodine
     - trospium
     - glycopyrrolate
     - flavoxate
     - bethanechol
     - prazosin
     - diazepam
     - α blockers
   - bowel reregulation program
     - stool softeners
     - bulking agents
     - laxatives, enemas.

The parents, especially the father, tend to be domineering, exacting, unyielding, and intolerant of weakness or failure. Divorce and alcoholism are common threads that only exacerbate the situation. Wetting is perceived as immature, defiant, and/or purposeful behavior that the parents feel must be counteracted with stern reprimands. The children are often punished, both mentally and physically, for their ineptness. Confusion, depression, and withdrawal for fear of wetting with its added punitive response become the children's prevalent attitudes because they do not know how to, nor can they prevent this provocative behavior. They try to withhold urination and defecation further by keeping the sphincter muscle tight, aggravating the situation. Thus, wetting becomes more commonplace, and abdominal pain from chronic constipation is likely.

X-ray evaluation reveals profound changes within the urinary tract. Hydroureteronephrosis with or without pyelonephritic scarring from recurrent infection occurs in two-thirds of the children[185] (Figure

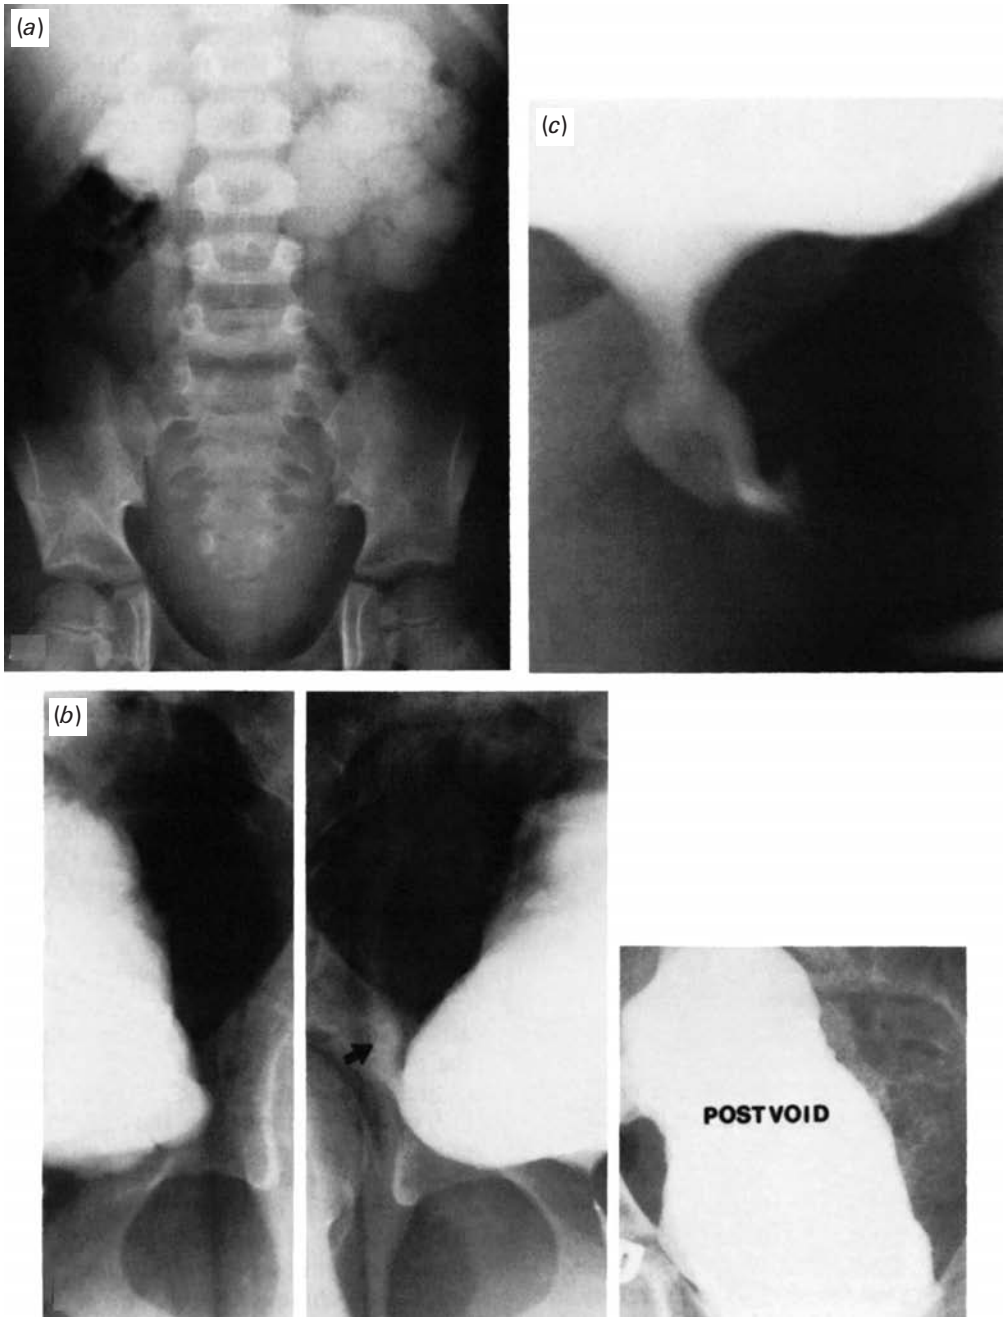

Figure 53.26 (*a*) Excretory urogram in a 14-year-old male with daytime and night-time incontinence and encopresis. Note the impression of a faintly opacified distended bladder. (*b*) His voiding cystourethrogram reveals trabeculation, mild right vesicoureteral reflux (arrow), and a large postvoiding residual urine volume. (*c*) A film during voiding demonstrates intermittent relaxation of the external sphincter area.

53.26). Fifty percent have severe VUR. Nearly every child has a grossly trabeculated, large-capacity bladder with a considerable postvoiding residual urine volume (see Figure 53.26b). Voiding films show either persistent or intermittent narrowing in the region of the external sphincter in almost half of the children (see Figure 53.26c). Finally, the scout film from the excretory urogram displays considerable fecal material in the colon, consistent with chronic constipation and a normal vertebral column.

Urodynamic studies demonstrate a large-capacity bladder with poor compliance, an overactive detrusor, and either high-pressure or ineffective detrusor contractions during voiding[185,214] (Figure 53.27a). Sometimes, Valsalva voiding is needed to empty the bladder. The urinary flow rate is often intermittent as

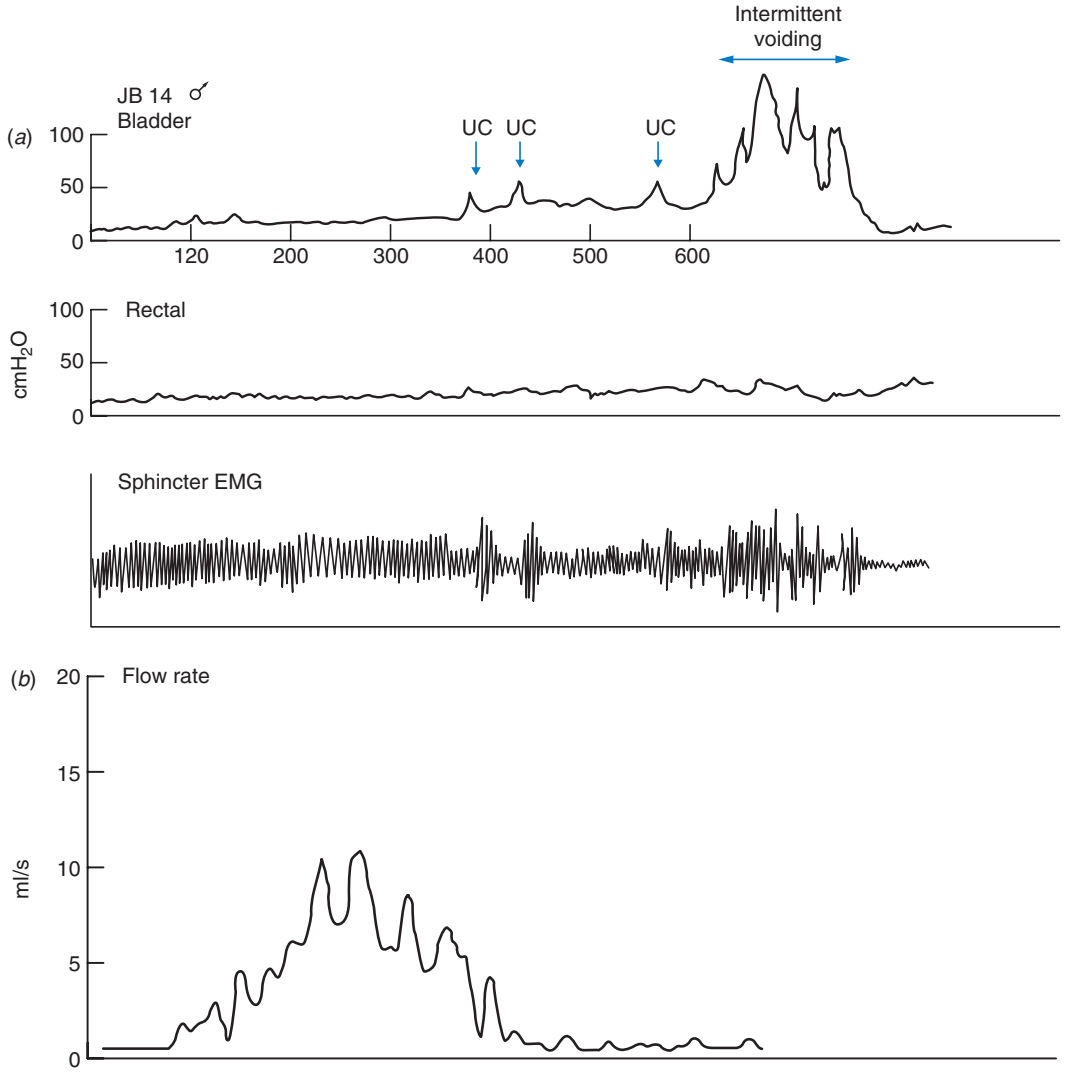

Figure 53.27 (*a*) Uninhibited detrusor contractions (UC) and increases in external urethral sphincter electromyography (EMG) activity are noted as the bladder is filled. During voluntary voiding, very high bladder pressures (>100 cmH_2O) are generated owing to increased activity and then intermittent relaxation of the external sphincter. (*b*) The urinary flow rate reflects the voiding pattern seen on urodynamic evaluation.

a result of the failure of the external sphincter to relax completely throughout voiding (Figure 53.27b). The bethanechol supersensitivity test may be positive; in the past, this response led to the belief that these children had neuropathic bladder dysfunction.[221] EMG recordings, however, reveal normal external urethral sphincter innervation and exclude the possibility of a sacral spinal cord lesion. The sphincter fails to relax completely and may actually tighten episodically once voiding commences;[194] this finding, along with the premature contractions, suggests an upper motor neuron lesion, but usually, no other signs are present to confirm this urodynamic hypothesis. MRI has failed to reveal any intraspinal process as a cause for the voiding dysfunction in these children.[227]

The dyssynergy created by the incoordination between the bladder and sphincter muscles leads to high voiding pressures initially and, later, to ineffective detrusor contractions.[194] Depending on which point of the spectrum one is at, a low or intermittent flow rate and either a minimal or significant postvoiding residual urine volume is noted.

Before this 'syndrome' was recognized and the pathophysiology elucidated, many children underwent multiple operations to improve bladder emptying and correct VUR. Failure of these procedures to succeed led to urinary diversion in a number of instances. Some of these individuals were eventually able to be undiverted at an older age after they outgrew the conditions that caused their dysfunction in the first

place.[228] Today, an entirely different approach is taken. Treatment is focused on improving the child's ability to empty the bladder and bowel and alleviating the psychosocial pressures that contribute to the aggravation of the voiding dysfunction.[195,227] A frequent emptying schedule accompanied by biofeedback techniques to relax the sphincter during voiding,[196,198] anticholinergic drugs to abolish detrusor overactivity, and improved bowel emptying regimens are instituted.[185] Despite these measures, intermittent catheterization may be needed in children who fail to respond and in those individuals who require immediate decompression of their upper urinary tract.[218,229] In some cases, the outflow obstruction may have produced severe renal damage and even chronic kidney failure, which must be managed accordingly.

Psychotherapy is an integral part of the rehabilitative process to re-educate both the child and the parents in appropriate voiding habits. Punishments are stopped and a reward system is initiated in order to improve the child's self-image and confidence.[195] This comprehensive urotherapy approach provides the best means for rehabilitating the child's lower urinary tract and for preserving and maintaining renal health.[230]

Diurnal and nocturnal enuresis

54

Mark Horowitz and Rosalia Misseri

Diurnal enuresis

In the infant, a simple reflex controls bladder function without input from the supraspinal centers. A full bladder elicits a detrusor contraction via a signal that is sent along afferent pathways to the spinal cord, which then triggers the appropriate motor response and simultaneous relaxation of the external sphincter muscles. In the absence of an anatomic obstruction, this allows for low-pressure bladder emptying without resistance to flow. The adult pattern of urinary control evolves over time and continence is first achieved by voluntary constriction of the external striated sphincter and later by supraspinal inhibition of the voiding reflex. The adult pattern of voiding is characterized by the absence of bladder contractions during bladder filling and relaxation of the external sphincter just before and throughout bladder emptying. Bladder capacity increases over time to permit the bladder to function as an adequately sized reservoir. In the first 2 years of life, one can predict the bladder's capacity by multiplying the patient's weight in kilograms by 8 to estimate the capacity in milliliters. After 2 years of age, bladder capacity can be accurately estimated and expressed by the formula:

bladder capacity (in ounces) = age (in years) + 2.[1] Multiplying this value by 30 gives the amount in milliliters.

Most children achieve day and night control by 4 years of age. The sequence of development of bowel and bladder control is:

- nocturnal bowel control
- daytime bowel control
- daytime urinary control
- nocturnal urinary control.

There are numerous causes for incontinence including neurological, anatomic and functional, but in children incontinence is most often secondary to problems at the level of the bladder, bladder neck and external striated sphincter, or any combination.

Incontinence may be either diurnal, nocturnal, or both. Patients with daytime incontinence often begin having symptoms 3–6 months after achieving urinary control. Children who are not yet able to inhibit the voiding reflex, stay dry by voluntarily contracting their external sphincter during uninhibited bladder contractions. In many children, persistence of this learned behavior leads to voiding dysfunction. This dyssynergia between the bladder and external sphincter results in high bladder pressures, during filling and emptying. These patients often void in stacatto or fractionated voiding patterns. Instability of the bladder, increased bladder wall thickness, high postvoid residual volumes (PVR), and recurrent infections are often the sequelae of this discordance between the bladder and sphincter. There is a strong association between dysfunctional voiding and urinary tract infections (UTIs), as well as vesicoureteral reflux. More severe forms of this disorder were described as the non-neurogenic neurogenic bladder or the Hinman syndrome.[2] Clinical features that originally characterized the Hinman syndrome included wetting during the day as well as at night with fecal retention and soiling, UTI, radiologic abnormalities of the bladder and/or kidneys, no demonstrable neurologic disease or bladder outlet obstruction and improvement after re-education and suggestive therapy. In addition to features seen in the Hinman syndrome, the Ochoa syndrome is associated with an unusual inversion of facial expression with smiling and a hereditary transmission. In both the Hinman syndrome and Ochoa syndrome upper tract damage may occur.

Urinary frequency and small voided volumes are most often secondary to bladder instability that is either primary, or secondary to the bladder sphincter dysynergia. Patients with primary instability

(sometimes referred to as the urge syndrome) have bladder overactivity without any voiding phase problems. Primary instability is commonly seen after a viral or bacterial infection somewhere other than the bladder where the bladder becomes a secondary target. These children experience the urge to void several times an hour and the symptoms resolve spontaneously.

Giggle incontinence (enuresis risoria) is the involuntary loss of urine induced by laughter. The urine is normal and the upper tracts are not affected. Chandra et al reported on a large cohort of children with giggle incontinence, of which 95% had concomitant dysfunctional voiding symptoms.[3] They concluded that detrusor instability contributes to the wetting. Therapy therefore should include timed voiding, anticholinergic therapy, and a bowel program. They reported an 89% remission rate within 10 weeks. Some have reported success with the use of methylphenidate (Ritalin) for the treatment of giggle incontinence.

Enuresis is only one of many symptoms seen in the complex of voiding dysfunction. Others include urinary frequency, urgency, urge associated incontinence, and other lower urinary tract symptoms (LUTS). Additionally, many patients with voiding dysfunction exhibit signs and symptoms of bowel dysfunction. The term dysfunctional elimination syndrome has been used to describe patients with bladder and bowel dysfunction.

Daytime urinary incontinence is a major source of concern for families and has potential to disrupt everyday life at home and school. Approximately 20% of children 4–6 years of age wet their pants, 3% wetting twice or more weekly.[4] As children get older the incidence of enuresis declines but society is less tolerant of the wetting. Pediatric urologists are second in line to treat children with this problem, often after treatment failure by the primary caregiver. Identifying the etiology of the symptoms helps to formulate a specific solution to improve the situation. It is important to remain minimally invasive and offer a treatment plan that is within reach of both the patient and the family, with minimal side effects.

Constipation and enuresis

Until proven otherwise, all patients with lower urinary tract disorders have constipation. Constipation is defined by the hard nature of the stool, the pain associated with its passage, or the failure to pass three stools per week.[5] Voluntary withholding of feces, most of the time caused by fear of painful defecation, is the most common cause of constipation. Encopresis or fecal soiling occurs when loose stool leaks per rectum after passing retained harder stool. Because of the close proximity of the bladder to the rectum, impacted stool in the rectum causes instability, which impedes bladder filling. Patients void smaller amounts with greater frequency. The frequency of bowel movements and consistency of the stool must be included in the history. Parents often know the voiding pattern of their children and the number of urinary and fecal accidents but have little knowledge of their children's frequency of bowel movements. Failure to diagnose and treat constipation often hinders the success of therapy for voiding dysfunction.

Loening-Baucke et al correlated resolution of voiding dysfunction symptoms with treatment of constipation.[6] Successful treatment of constipation leads to resolution of daytime incontinence in 89%, nighttime incontinence in 63% and UTI in 100% of patients. Recommendations included reconditioning the child's bowel movements with timed attempts to defecate, teaching proper toilet sitting positions, and modification of dietary habits. Initial therapy adds more fiber to the diet in the form of high-fiber foods, fiber additives, or laxatives that make bowel movements soft and easy to pass. The use of enemas, fecal disimpaction, and a variety of oral agents such as MiraLax (polyethylene glycol 3350), mineral oil, milk of magnesia, and sorbitol are often necessary for success.

Clinicians use a variety of regimens for the initial clean-out, where the goal is evacuation of retained stool;

1. Mineral oil alone (15–30 ml/kg/day up to 8 ounces once or twice daily for 3 days).
2. Hypertonic enemas and/or suppositories daily for 2–3 days.
3. Polyethylene glycol 3350 (MiraLax) orally, up to 1.5 g/kg/day to a maximum of 100 g for 3 days.
4. An enema each day for 2 days, followed by milk of magnesia 1 ml/kg/dose twice daily for 3 days.

Following the initial clean-out, a maintenance program helps keep the patient defecating on a regular basis. Stool softeners used for a prolonged period include:

- milk of magnesia (1–4 ml/kg/daily)
- mineral oil (2–6 ml/kg/daily)
- sorbitol or lactulose (0.7–3 mg/kg/daily)
- polyethylene glycol 3350 (0.27–1.42 mg/kg/daily).

Work-up

The history is the most important component in the evaluation of a patient with incontinence. A thorough, systematic approach is critical in defining the cause and directing the treatment. The astute clinician can eliminate most anatomic and neurogenic causes of incontinence through a careful history and physical. The following is a list of questions routinely asked of patients or families of children with daytime incontinence.

- How long has the wetting been a problem? We are more inclined to proceed with a full evaluation in a child who has been having accidents for several months than in one who has just recently become symptomatic. Acute onset of bladder instability often resolves spontaneously shortly after the onset of symptoms and does not require intervention.
- How significant is the wetting? Does the child soak through clothing or simply have damp underwear? Many parents are only concerned when soaking is severe enough to require a change of clothes, and consider dampness as either normal or inconsequential. Once children are mature enough to change their own clothes, parents may be less aware of the wetting problem. Dampness is often secondary to patients pulling up their garments before completing the voiding process. These children simply need coaching to encourage them to spend a extra few moments to empty their bladders before getting dressed. We instruct boys to shake their penis after voiding to prevent urine dripping into their underwear. Girls are encouraged to spread their legs and to pause an extra moment to allow for emptying of urine that pools in the vagina.
- How frequently does the child void? Some parents complain that their children go to the bathroom too often. On further questioning, these children state that they can sit through a movie or participate in a sporting event without going to the bathroom. A voiding diary for several days eliminates some of the confusion encountered when the parent's perception of the symptoms conflicts with that of the child. Together, the parent and child record the frequency of voiding, stooling, and hydration. It is sometimes easier for parent and child to record this data over a three-day weekend than during the week when the child is at school. The normal frequency of voiding in a child is 4–7 times per day or about every 2–3 hours. We define increased frequency as voiding more than 8 times per day or more frequently than every 1.5 hours. Infrequent voiding also contributes to recurrent bladder infections and lower urinary tract symptoms seen in children. Many children void only 2–3 times a day and often do not void upon awakening. The treatment for these children is simply a timed voiding schedule.
- Where is the child most symptomatic? Some children are fine at school where they void at least 2–3 times but experience urgency and accidents once they get home because they ignore the need to void while involved in other activities (watching television, playing with friends, playing computer games). Others wet at school because the teachers prevent the use of the bathroom. Some children are afraid to use public restrooms (lack of privacy, poor sanitary conditions, violence in the bathrooms). These children usually come home from school wet, but are able to stay dry at home where they have unlimited access to the bathroom.
- Has the child had associated UTIs? If so, we try to discern whether the child's symptoms followed or preceded an infection. In some cases, the voiding pattern (high PVR volumes and/or high-pressure voiding with turbulent flow) precipitates the infection. High PVR volumes correlate with the number of UTIs.[7] In others, inflammation following the infection results in abnormal voiding with wetting. Deciding who needs a voiding cystourethrogram (VCUG) to rule out vesicoureteral reflux is critical. Our approach has been to obtain a VCUG in all children with a febrile UTI and in all children with one or more infections while still in diapers. If we suspect the infection to be more consistent with cystitis secondary to high residual volumes, i.e. a 5-year-old girl with no history of prior infection who has symptoms consistent with voiding dysfunction and developed some dysuria with a resultant positive culture, a VCUG will not be obtained. This child is studied with a non-invasive flow/electromyelogram (EMG), and therapy is initiated to improve bladder emptying.
- Are the accidents habitual or situational? Stress at home or in the school may cause daytime accidents. In the social history it is important to elicit events such as the death of a friend or relative, parental separation or divorce, recent move to a new neighborhood, etc.
- Is the urinary flow pattern a continuous good urinary stream, or is it choppy and slow? Is there a straining pattern? Does the child feel completely empty after voiding? The clinician must suspect

anatomic conditions such as posterior urethral valves (PUV), meatal stenosis, and stricture disease when the stream is delayed or reduced. In the absence of anatomic conditions, detrusor sphincter dysynergia and primary bladder neck obstruction are the main culprits.

- How much fluid does the child consume over a 24-hour period? Both dehydration and overhydration may result in abnormal patterns and occasional wetting. Some children minimize fluid intake in an attempt to reduce the frequency with which they void.
- Other than incontinence, are there other LUTS? Many children complain of urinary urgency and others wet themselves without a warning or urge. In an attempt to stay dry, many girls either squat or sit on the heel of one foot (Vincent's curtsy) or cross their legs. This squatting behavior is a unique learned response to a sudden detrusor contraction and is an attempt to prevent or minimize urine loss. Boys sometimes grip their penis to stay dry.
- What is the appearance of the urine? Does it have a discrete smell? Dark yellow, strong-smelling urine indicates a relatively dehydrated state or the presence of infection. Children are encouraged to drink more or void with greater frequency. Any infection should be treated with the appropriate antibiotic. Cranberry and cherry juice (or tablets) may help to prevent infection. We suspect bacterial cystitis when symptoms include dysuria, cloudy, foul-smelling urine, and blood or mucus is visible in the urine.

A reliable symptom scoring system should provide accurate, objective, and scientific data that allow us to objectively assess treatment and follow-up of these patients.

We find that the dysfunctional voiding scoring system questionnaire (DVSSQ) is a helpful tool used for diagnosing and monitoring treatment of children with voiding dysfunction. Doubrava et al performed uroflow with pelvic floor electromyography (EMG) and PVR measurements on 51 patients with normal DVSSQ scores for gender.[8] The DVSSQ was able to predict a normal bell-shaped uroflow curve in 73% of patients; however, it correlated poorly with EMG patterns and PVR volumes. Of patients with normal DVSSQ, 65% had abnormal EMG patterns and there was poor correlation between uroflow curves and EMG patterns as well as between uroflow patterns and PVR values.

The dysfunctional voiding symptom score

Over the last month:

1. I have had wet clothes or wet underwear during the day.
2. I wet the bed at night.
3. When I wet myself, my underwear is soaked.
4. I do not have a bowel movement every day.
5. I have to push for my bowel movements to come out.
6. I go to the bathroom only once or twice a day.
7. I can hold onto my pee by crossing my legs, squatting, or doing the 'pee dance'.
8. When I have to pee, I cannot wait.
9. I have to push to pee.
10. When I pee it hurts.

Questions for parents to answer: Has your child experienced any of the following in the past year: new baby, new home, new school, school problems, abuse (sexual/physical), divorce/death, special events (birthday), accident, injury, any other stressful event?

Questionnaires are a practical method for measuring the magnitude of incontinence, and many exist for evaluating and following children with incontinence. Most take just a few moments to complete and augment the evaluation of children with daytime wetting. Use of a questionnaire helps prevent omission of parts of the voiding history. Sureshkumar et al developed a daytime urinary incontinence questionnaire using parent-reported data and demonstrated that it is reproducible.[9] The questionnaire was used in a prevalence survey of Australian primary school children to determine the magnitude of incontinence in those starting school. Farhat et al evaluates the performance of another instrument to quantify or grade the severity of abnormal voiding behaviors in children.[10] In this system, 10 voiding dysfunction parameters were used to assign a score of 0–3, according to prevalence; i.e. scores ranged from 0 to 30. These questionnaires and others help to identify patients with dysfunctional voiding and further direct their investigative studies and treatment.

Examination

Special attention to the evaluation of the abdomen, genitalia, and back is imperative in the evaluation of children with incontinence. Inspection of the lower back for evidence of skin discoloration, dimples, hair patches, subcutaneous lipomas, or spine defects may indicate the presence of an underlying spinal dysraphism. Asymmetry of the buttocks or motor tone of

the buttocks may also indicate the presence of neurologic disease. An absent or asymmetrical gluteal cleft suggests sacral agenesis. The neurologic examination includes careful attention to the lower extremities, including strength, sensation, reflexes, and assessment of gait. If a neurologic cause is suspected, strong consideration must be given to obtaining a magnetic resonance imaging (MRI) scan of the lumbosacral spine or requesting a full neurologic consultation. Patients with abnormalities such as tethered cord or lipomas often require neurosurgical intervention. Many patients with spina bifida occulta and a normal spinal cord will experience resolution of their enuresis with conservative management. Ritchey et al compared outcomes for enuretic children with spina bifida occulta to enuretic children with normal spine X-rays.[11] The majority of patients in both groups had resolution of the enuresis with conservative management and only a small percentage of children with spina bifida occulta required neurosurgical intervention.

Examination of the external genitalia may reveal the source of the problem. Boys with significant meatal stenosis may present with LUTS: mainly a decreased, often deflected stream, urinary hesitancy, and incontinence. Observation of the urinary stream and uroflowmetry may help assess the severity of meatal stenosis. Girls with labial fusion may present with LUTS, including dysuria, dribbling, and incontinence. Examination of the vaginal introitus may reveal a ureterocele or an ectopic ureter. Girls with continuous incontinence between normal voids may have an ectopic ureter. Rashes on the genital area or inner thighs may indicate constant exposure of the skin to urine and suggest constant drainage that may be due to an ectopic ureter. Girls with vaginal voiding often present with labiovulvar erythema and/or leukorrhea that may cause burning and itching. Chronic urine irritation leads to urea burns secondary to the action of skin bacteria on the urine.

When examining the child, it is important to inspect the child's undergarments. Some parents believe their child is always wet, and yet when the child is examined, their clothing is dry. When asked to explain this inconsistency, the parents often state that the child knew he or she was going to the doctor and voided several times that day. This is proof to both the child and parents that by going to the bathroom of regular intervals he or she can stay dry. Fecal stains suggest the presence of constipation or encopresis.

A urinalysis is obtained in all patients looking for infection, proteinuria, or glycosuria and if positive, a specimen is sent for culture and sensitivity. Catherized urines greatly improve the specifity of the culture and eliminate treatment for and further investigation of a UTI.

Uroflowmetry, because of its non-invasive nature, is the perfect instrument for revealing voiding disorders in pediatric patients.[12] We have the children void when they have a 'normal' desire to go. We measure peak flow rate, average flow rate, amount voided, and assess the shape of the curve. Voided amounts affect the peak and average flow rates. Patients with significant instability void very small amounts and this can underestimate their true flow rates.

Simultaneous measurement of uroflow rates and pelvic floor EMG tracings (flow/EMG) have been incorporated into the initial assessment of almost every patient we evaluate for daytime incontinence and bladder–kidney infections. The normal, coordinated flow curve is even and bell-shaped in the absence of pelvic floor activity (Figure 54.1). In contrast, a void with simultaneous pelvic floor contraction results in a ragged curve shape, the so-called staccato, interrupted, or irregular curve.[13] EMG studies typically show increased activity during voiding, instead of the expected relaxation (Figure 54.2). Non-invasive flow/EMGs can be performed regularly to monitor the child's response to therapy.

A bladder ultrasound is obtained to document PVR volumes and record bladder wall thickness and/or distal ureteral dilatation. When hydronephrosis is seen on prevoid images, resolution, improvement, or no change in the hydronephrosis is documented after the child voids. The upper tracts are usually normal in patients with voiding dysfunction and a renal sonogram is a quick, non-invasive, inexpensive screening tool to rule out other genitourinary anatomic anomalies.

Cystography is utilized to detect reflux in a child with a UTI. In addition to assessing grade and laterality, cystography provides information about bladder configuration, PVR volumes and urethral anatomy. Causes of bladder outlet obstruction such as PUV, urethral stricture and detrusor–sphincter dyssynergia, are clearly seen. Bladder instability can be detected when at least one of three well-defined radiologic signs are detected: bladder wall irregularity, elongation of bladder shape, and filling of the posterior urethra. The chances of identifying these signs are greatest if fluoroscopy captures images when unstable contractions occur. Opening of the bladder neck with variable degrees of filling of the posterior urethra is due to detrusor contraction, opening of the bladder

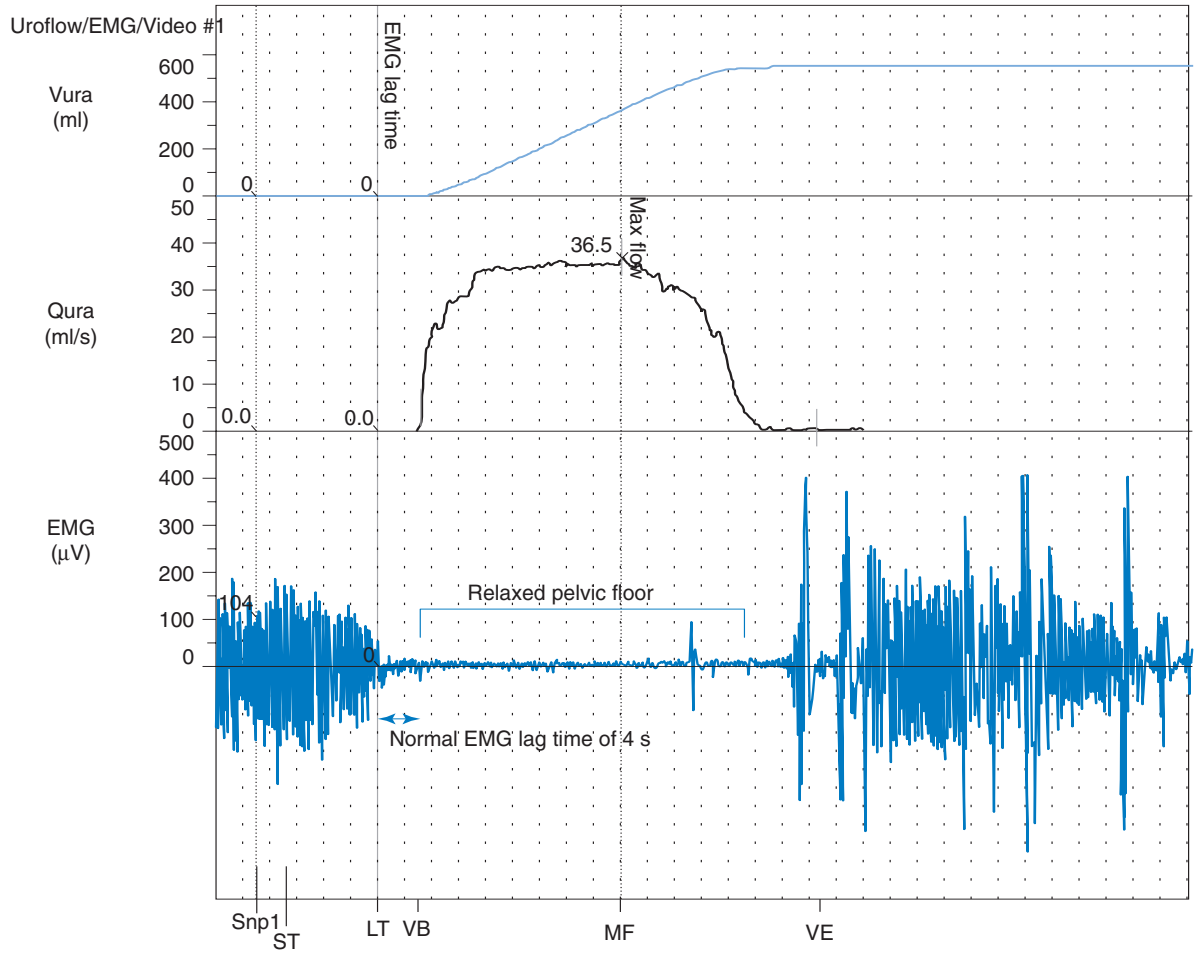

Figure 54.1 Normal voiding pattern. Electromyography (EMG) lag time of 4 seconds. Complete relaxation of pelvic floor muscles with voiding. Normal bell-shaped uroflow curve. Vura = volume of voided urine, Qura = urine flow, ST = start/stop, LT = lag time, VB = voiding begins, MF = maximum flow, VE = voiding ends.

neck, and simultaneous contraction of the external sphincter. Passerini-Glazel et al considered this process a typical and constant sign of bladder instability.[14]

Combs et al reported on the utility of pelvic floor EMG lag time in identifying children with detrusor instability.[15] Pelvic floor EMG lag time is the time interval between pelvic floor relaxation on pelvic floor EMG and the start of flow. Pelvic floor relaxation occurs 1–4 s prior to the start of a voluntary detrusor contraction and the start of flow. Urine flow that occurs instantaneously with or before relaxation of the pelvic floor indicates instability (Figure 54.3). Urodynamics confirms the presence of instability in all patients with a lag time that approaches zero or is in the negative range.

Kakizaki et al measured the internal diameter of the external urethral sphincter on VCUG in children with and without suspected voiding dysfunction to evaluate its diagnostic accuracy as a predictor of detrusor–sphincter incoordination.[16] A diameter <3 mm had satisfactory sensitivity and specificity for detecting detrusor–sphincter incoordination.

We have substituted video-urodynamics (VUDS) for the voiding cystourethrogram (VCUG) in patients being evaluated for febrile UTIs and associated LUTS and in patients not responding to conventional therapy. The advantages of VUDS are its ability to assess detrusor pressures during filling and emptying, monitor EMG activity of the pelvic floor and limit radiation exposure. Monitoring bladder pressure allows us to limit the use of fluoroscopy. We obtain images at the start of the study, two–three times during filling (usually at 25%, 50%, and 75% of expected capacity for age), and when unstable bladder activity on cystometry is seen. We then image during voiding and obtain a single image after completion of voiding to document PVR. In the presence of reflux, a 5 minute delayed KUB is obtained to document drainage of the upper tract.

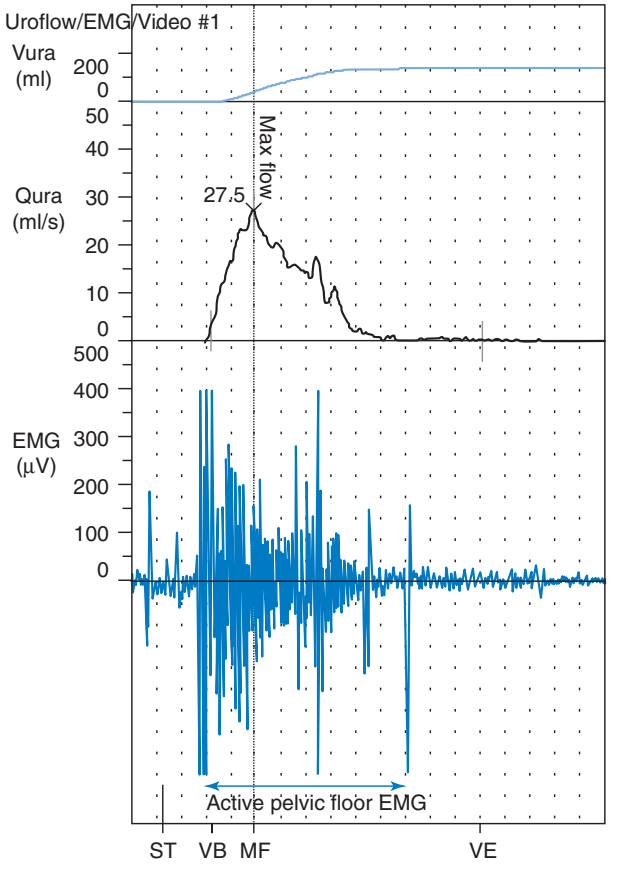

Figure 54.2 Type 1 dysfunctional voiding pattern. Persistent activity (non-relaxation) of pelvic floor muscles during voiding with a staccato uroflow curve.

Primary bladder neck dysfunction (PBND), PUV, urethral stricture and meatal stenosis are considered in boys with poor uroflow rates despite a relaxed pelvic floor. VUDS is obtained in these children to further define their problem.

Children with symptoms of bladder neck dysfunction exhibit narrowing at the bladder neck in addition to high voiding pressures and low flow rates with an obstructive pattern. Some children are able to maintain high enough voiding pressures to achieve normal flow rates. Studies typically show detrusor instability and high voiding pressures. In patients with a long history of LUTS, we may see impaired compliance and/or inefficient detrusor contractions. Urinary flow is often intermittent and there is often a prolonged opening time, which we define as the time between the start of a contraction and the start of urine flow. Pelvic floor EMG lag time correlates with the opening time seen on VUDS.[17] Prolonged pelvic floor EMG lag time associated with abnormal uroflowmetry is highly suggestive of PBND (Figure 54.4). There may be a disparity between peak pressure and peak flow.

Treatment options

The first step is to ask the child to void on a timed schedule. We instruct children to void every 2–3 hours during the day even if they do not have the urge. A multiple alarm watch is a helpful novelty to remind a child to go to the bathroom. We send a letter to school requesting permission for the child to use the bathroom every 3 hours. Timed voiding requires a great deal of cooperation from parents, teachers, and children. In addition to timed voiding, the child must spend at least 30 s to 1 minute voiding, and must relax to ensure efficient emptying. Rewards (stickers, gold stars, etc.) are given each time the child performs satisfactorily. We urge girls to pull their pants/skirts down to their ankles and sit with their legs apart. Commercial and domestic toilets are designed for adults, not for children. It is difficult for a child to void with a relaxed pelvic floor when sitting on a toilet that they are nervous about falling through. Vaginal voiding causes postvoid dribbling because the urine that enters the lower vagina leaks into the underwear when they stand up. Toilet seat adaptors and footstools should be available at both home and school. We instruct girls to sit backwards on the toilet (straddling the toilet seat) to help relax the pelvic floor muscles.

Patients with LUTS sometimes require drug therapy in addition to timed voiding. Patients with severe frequency and/or urgency often report little change with timed voiding alone. Anticholinergics act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by acetylcholine released from activated cholinergic (parasympathetic) nerves. Anticholinergic medications act mainly during bladder filling by decreasing urge and increasing bladder capacity. In the dose range needed for beneficial effect in the overactive bladder, there is little evidence for a significant reduction of the voiding contraction during bladder emptying.[18] Ditropan (oxybutynin) is a potent anticholinergic agent with strong independent smooth muscle antispasmodic activity at a site distal to the cholinergic receptor. In young children who cannot swallow pills, we initiate treatment with oxybutynin suspension 2–3 times/day. Children who can swallow pills are treated with the extended-release oxybutynin (Ditropan XL) once a day. Patients on oxybutynin experience a decrease in the frequency and intensity of uninhibited bladder contractions.

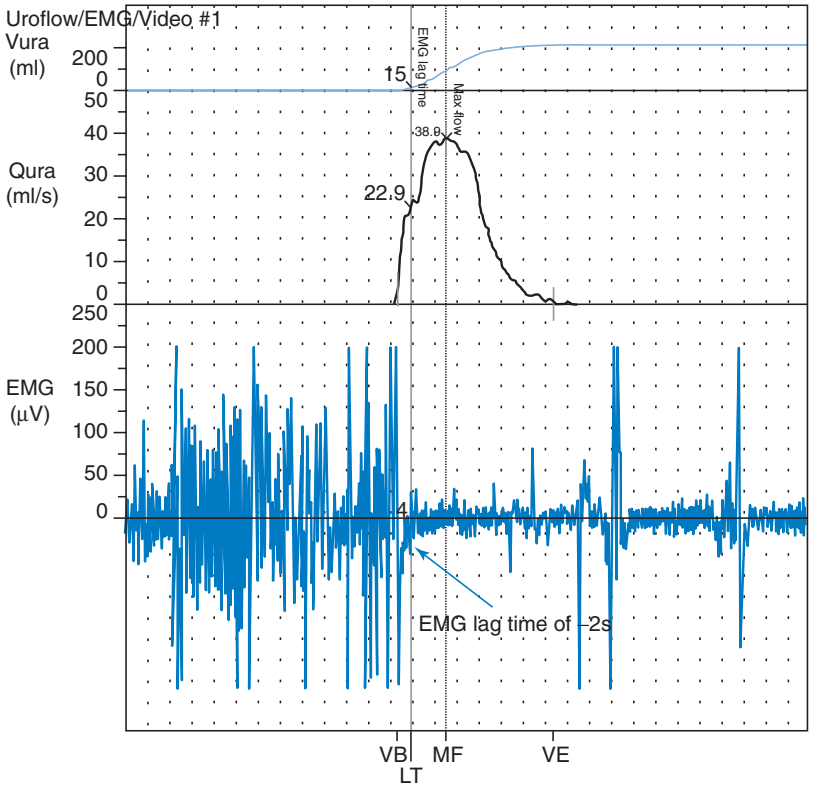

Figure 54.3 Type 2 dysfunctional voiding pattern (bladder instability). No lag time noted, which indicates initiation of flow prior to relaxation of pelvic floor muscle activity. For symbols, see caption to Figure 54.1.

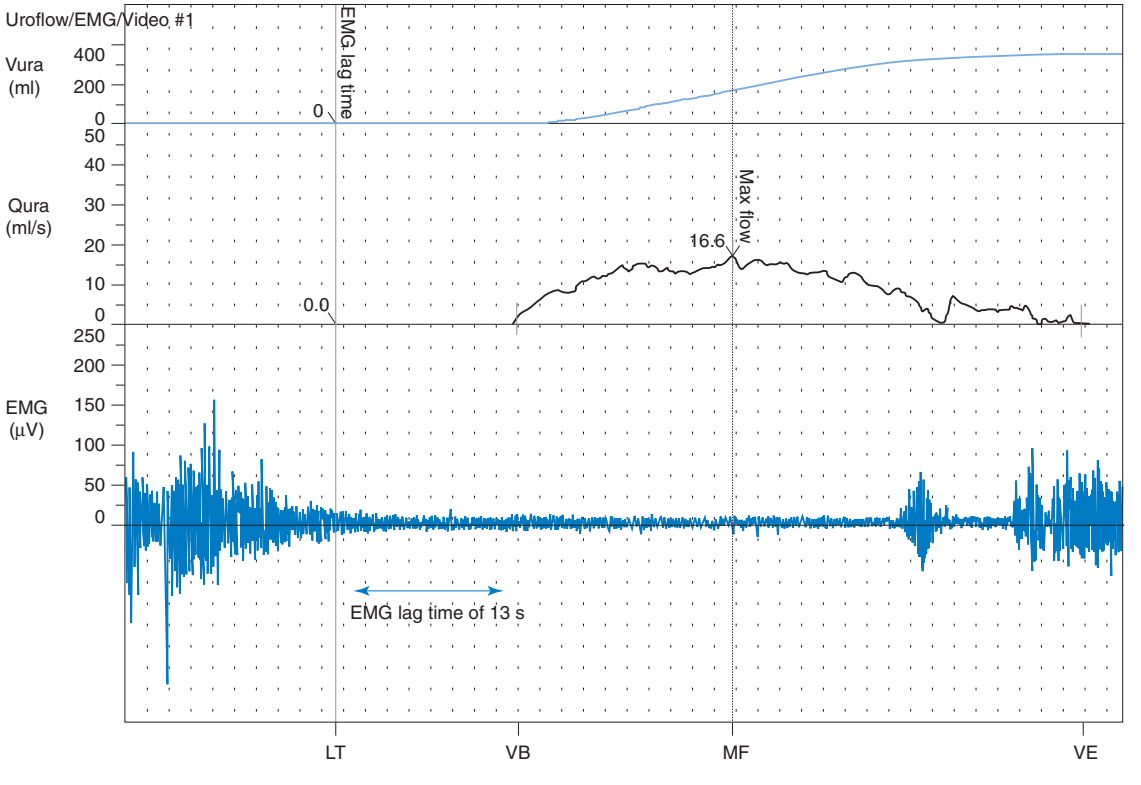

Figure 54.4 Bladder neck dysfunction. Lag time of 10 s (normal lag time = 2–4 s). Complete relaxation of pelvic floor muscles with voiding.

Reported side effects are more common in the summer months and include dry mouth and flushing. Oxybutynin decreases the body's natural ability to sweat, which can cause overheating in the very active child in extreme climates. Other side effects are dizziness, blurred vision, drowsiness and non-specific abdominal pain (cramping). The medication is more effective on an empty stomach, so we instruct the child to take oxybutynin either 30 minutes before or 1 hour after a meal. Severe frequency in the absence of burning, dysuria or incontinence is often self-limiting and can last for many months.

Wiener et al reported on long-term efficacy of simple behavioral therapy for daytime wetting in children.[19] Formalized management of bowel elimination was not included. There was improvement in daytime urinary control in 59.4% of patients, at a mean of 4.7 years after completion of therapy. Frequency and urgency demonstrated long-term improvement in 51% and 46% of patients, respectively. Assessment of symptoms during the first year after therapy revealed similar results, with 73% reporting improvement at 12 months. Behavioral therapy may lose some efficacy with time if return visits are not made to reinforce therapeutic interventions. It was concluded that simple behavioral therapy without biofeedback should be the first-line therapy for children with daytime incontinence.

Biofeedback is the use of modern instrumentation to provide better moment-to-moment information about a specific physiologic process that is under the control of the central nervous system but not clearly or accurately perceived. With biofeedback, patients can be made aware of and gain control over certain bodily functions. Biofeedback therapy is very successful in the treatment of voiding dysfunction and can be used alone or in combination with other treatment modalities discussed in this chapter. Biofeedback teaches the patient how to relax the pelvic floor muscles during voiding, thereby improving flow parameters and decreasing PVR volumes. To learn how to isolate the pelvic floor muscles, patients need to be both attentive and motivated. The success of biofeedback depends on patient and parent compliance and careful patient selection. Few patients are cured with a single session of biofeedback. Most require several sessions, the number being determined by improvement using clinical and urodynamic criteria. Each session starts with a review of the prior session, a review of symptoms with special emphasis on improvement or deterioration of LUTS and incontinence, and a review of current medications. Biofeedback is time-consuming for clinicians, children, and families, which may lead to problems with compliance.

Nelson et al reported on the use of biofeedback in 81 patients with voiding dysfunction in whom conservative management failed.[20] Of 73 patients with incontinence, 30% became dry, 49% improved, and 21% had no change after biofeedback. Recurrent UTIs resolved in 78% of patients. Non-invasive urodynamics after therapy showed a significant increase in maximum and average flow rate and a significant decrease in PVR volumes. Children were taught to void with a more normal flow pattern and greater voiding efficiency even in the absence of improving continence.

Herndon et al reviewed their experience with a conservative medical program and computer-assisted pelvic floor muscle retraining in patients with voiding dysfunction.[21] Patient compliance with the program was reported at 95% and subjective improvement was seen in 87% of the group. Predictors of failure included bladder capacity <60% of predicted volume and patient non-compliance. With adding medications, 83% of the non-responders improved.

Different methods of direct sacral nerve stimulation have been used to treat refractory lower urinary tract dysfunction in adults. The invasive nature of this procedure precludes it from use in children. In contrast, genital, anal, intravesical, and percutaneous tibial stimulation have been reported in children. However, these techniques require either genital manipulation, placement of an anal probe, bladder catheterization, or needle insertion, all considered somewhat invasive in children. De Gennaro reported on percutaneous tibial nerve stimulation in children and found it to be minimally invasive and feasible in children.[22] There was improvement in micturition symptoms, incontinence, flow rates, and PVRs with no adverse effects.

PBND is a new entity that has received much attention in the past few years. We define it using VUDS, by the constellation of prolonged opening time, incomplete bladder neck funneling, quiet pelvic floor EMG during voiding, and abnormal pressure flow parameters. As mentioned earlier, the diagnosis can be made with non-invasive uroflowmetry combined with pelvic floor EMG.

Clinicians now use α_1-adrenergic receptor-blocker (α_1-ANRB) therapy with greater frequency in patients with voiding dysfunction. Austin et al were one of the first groups to investigate the role of α blockers for the management of incomplete bladder emptying in children.[23] They looked at 17 children

with documented poor emptying as a result of various etiologies, including both neurogenic and non-neurogenic causes. With the use of an α_1-ANRB, bladder symptoms and/or emptying improved in 82% of patients and was well tolerated by most. Because of this success, they looked at a larger group of 55 patients with voiding dysfunction and poor bladder emptying.[24] There was an 88% reduction in the pretreatment PVR volume, with only 3 patients showing no change in PVR. There was improvement in diurnal continence in 83% of patients and urgency in 70%. They concluded that selective α_1-ANRB therapy might be used as either replacement for, or in addition to, biofeedback in patients with significant PVR volumes. At this time, α blockers have yet to be Food and Drug Administration (FDA) approved and are used off label.

Yucel et al compared the efficacy of biofeedback and α_1-ANRB therapy in children with PVR who had symptoms of incontinence, urgency, and UTIs.[25] There was no statistical difference between the two arms ($p > 0.05$) when looking at post-treatment reduction in PVR as the endpoint. Combined treatment of biofeedback and α_1-ANRB helped 83% of the children with refractory high PVR treated with either biofeedback or α-blocker therapy alone. Children with PBND respond well to α_1-ANRB. Donohoe et al used α_1-ANRB to treat 26 patients with PBND.[26] With α_1-ANRB, average and maximum flow rates improved from 5.5 to 12.6 ml/s and from 10.3 to 19.7 ml/s, respectively. PVR volumes decreased from 98.9 to 8.9 ml ($p < 0.001$). No patient experienced any major adverse side effects.

Diet can have a profound effect on voiding patterns, and dietary changes can alleviate symptoms associated with bladder dysfunction. Avoiding the '4 C's' (caffeine, chocolate, carbonated beverages, and citrus beverages) is an integral part of therapy, as they are known to cause urgency, frequency, and/or incontinence.

Clean intermittent catheterization (CIC) is a last option in a subset of patients that do not respond to standard treatment modalities. Alpert et al reported their experience with 20 patients requiring CIC.[27] CIC was an easy technique for 80% of the children to learn in a single visit and master in a short period. If necessary, CIC is used as a temporary measure until the patients learn to void correctly. If all these modalities fail, surgical intervention may be necessary. Augmentation cystoplasty with CIC provides a large-capacity, low-pressure, compliant bladder that allows for preservation of renal function and urinary continence. However, this is a long haul for a problem with no neurologic or anatomic etiology.

There are numerous approaches for the treatment of urinary incontinence in children. The aggressiveness of evaluation and intervention usually depend on the age of the patient, the chronicity of the problem, and other associated issues such as recurrent infections. A systematic review of randomized controlled trials led to the conclusion that there is a lack of proof for optimal treatment of pediatric incontinence.[28] Historically, antimuscarinic drugs have been the first line of treatment for urinary urgency, frequency, and urge-associated incontinence. Although they are associated with side effects that limit their use in some children, these drugs have undisputed effectiveness for the small numbers of children with overactive bladder that fail urotherapy. Children tolerate these medications better with the newer extended formulations. We sometimes use them in combination with other treatment modalities, including α_1-ANRBs, antibiotics, and bladder and bowel retraining. Newer, once daily, M_3 selective receptor antagonist agents are now available for the treatment of overactive bladder: with greater affinity for the M_3 receptors than the M_1 and M_2 receptors, there is less theoretical risk of central nervous system and cardiac side effects. The use of botulinum types A and B toxin injections into the detrusor muscle has been studied extensively for the treatment of incontinence from neurogenic causes. These treatments are safe, minimally invasive, and can be injected repeatedly, but to date have had no role in the treatment of non-neurogenic voiding disorders.

Summary

Voiding dysfunction is a common childhood problem. Use of a checklist for both the history and physical examination is highly recommended. Patience, diligence, and consistency are critical in the evaluation of these patients. Most children will respond to simple measures such as timed voiding and relaxation techniques to facilitate bladder emptying. In a select population of patients in whom single-modality therapy fails, we advise multiple-modality therapy, including timed voiding, biofeedback, and medications. In our experience, we treat almost all children successfully with combination therapy, frequently with no medication. The objective improvements we aim for are a decrease in PVR volumes, increased uroflow rates, and normalization of EMG patterns. Effective treatment also helps control the secondary complications of reflux, UTIs, and, in extreme cases, urinary tract deterioration.

Nocturnal enuresis

One of the most common urologic complaints in children is nocturnal enuresis (NE). Most children achieve night-time continence by 5 years old. The significance of NE is dependent upon the patient's age, the parents' and child's expectations, and the child's social situation.

Our understanding of the pathophysiology of NE has progressed greatly in recent years and we now know the disorder to be heterogeneous and genetically complex in nature. Abnormalities in nocturnal urine production, bladder reservoir function, arousability, molecular genetics, or a combination of these may be responsible for night-time wetting. This new understanding of NE has had enormous impact on both the diagnosis and treatment of the disorder. Nevertheless, we have much to learn and many controversies remain.

Definitions

In accordance with the International Children's Continence Society recommendations, we use the term primary nocturnal enuresis (PNE) to describe bedwetting in a child who has never had a dry period of >6 months. A child with secondary nocturnal enuresis is one that wets the bed but had previously been dry for at least 6 months prior.[29] Monosymptomatic nocturnal enuresis (MNE) describes bedwetting in children with no daytime urinary symptoms to suggest an underlying voiding dysfunction. Non-monosymptomatic or polysymptomatic nocturnal enuresis is used to describe nocturnal enuresis associated with bladder overactivity.[30]

Epidemiology

The overall prevalence of NE declines with age. By the age of 4 years, 20–25% of children frequently wet the bed. This decreases to 5–10% by the age of 7.[31–34] Fourteen percent of children between the ages of 5 and 9 years and 16% between 10 and 19 years will stop wetting the bed annually.[35] In this longitudinal cohort study, the authors followed 92% of 1129 children born in 1 year for 6 years, with PNE remission rates of approximately 15% per year.[35]

Although spontaneous cure occurs throughout childhood and adolescence, the problem may persist in 0.5–3% of the adult population.[36–39]

Although PNE is more common in young boys, by adolescence the incidence in males is equivalent to that in females.[40] The prevalence of NE is similar throughout the world.

Psychological impact

PNE may have a profound psychological and social impact on children and their families: enuresis may affect a child's normal activities and development; this, in turn, may affect the child's family.[41–43] There is some controversy regarding how enuresis affects self-esteem. A recent review concluded that there is no evidence that bedwetting leads to lower self-esteem.[43] Conversely, some studies have shown that children with NE have worse self-esteem and significantly more behavioral and psychological problems such as anxiety, depression, aggressiveness, and attention-deficit disorder when compared with normal age-matched non-enuretic patients.[41–43] After a successful cure, abnormal behavioral and psychological problems improve in some studies, possibly indicating that the problems are a result of the NE and not vice versa.[42,44,45] Surely, attaining dryness will not negatively impact a child's self-esteem. The child's age itself may change his/her attitude towards enuresis. Butler reported that younger children focus on the immediate consequences of enuresis, whereas older children are more likely to be affected by the social and emotional aspects of the condition.[46] Interestingly, comorbid psychiatric disorders are present in up to 75% of secondary nocturnal enuretics.[41,47] At least 46% of parents have some concern about NE, whereas 17% worry a great deal.[34,48]

In a study by Haque et al 1981, the mean anticipated age of dryness according to parents was 3.18 years. When asked for possible causes for their child's NE, parents believed that emotional problems (35.5%), heavy sleeping (38.2%), physical problems (21.4%), familial problems (28.9%), and small bladders (10.7%) may be responsible for their child's wetness.[49]

NE may also lead to punishment. Some mothers believe that their child is wetting on purpose and choose not to treat their children and may even punish them.[48] The reported rates of punishment in the 1980s were 37% in the UK and 35.8% in the United States.

Etiology

Family studies have repeatedly demonstrated high rates of relatives affected by enuresis. The risk for a child to be enuretic is 40% if one parent and 70% if both parents had been enuretic.[50] Early studies reported that 32% of fathers and 23.9% of mothers of children with enuresis were enuretic as children.[51]

Based on twin studies, the most common mode of transmission is autosomal dominant with high (90%)

penetrance.[52] Additionally, about 45% of patients with NE were found to have an autosomal dominant mode of inheritance.[53] Linkage analyses have been used in the study of NE and several loci have been identified; however, there is no clear association of any of the loci with any particular type of enuresis.[54,55]

Pathophysiology of nocturnal enuresis

One or more of several pathophysiologic mechanisms may cause NE.

Nocturnal polyuria

In two studies, Rittig and colleagues and Norgaard et al demonstrated abnormalities in the circadian rhythm of antidiuretic hormone (ADH) secretion in bedwetters.[56–58] In these children, urine production during sleep exceeds bladder capacity.[56,58,59] Children with NE associated with nocturnal polyuria will often wet in large quantities soon after going to sleep.[60,61] However, nocturnal urine production may vary considerably from night to night, and urine volume is significantly larger on wet nights compared with dry nights in enuretics.[62] Therefore, nocturnal polyuria is best evaluated during nights when enuresis is experienced.[63]

Based on the abnormalities in diurnal ADH production, desmopressin was introduced for the treatment of PNE. Response rates using desmopressin of approximately 70% have been reported by various studies.[58,64] Other factors that may also contribute to excessive nocturnal urine production are under investigation. These include an increase in the nocturnal release of other hormones that regulate solute excretion: e.g. angiotensin II, aldosterone, and atrial natriuretic peptide. Abnormalities of renal function may also contribute to PNE. A study examining renal function in enuretic children found decreases in free water and solute reabsorption in the thick ascending limb of Henle's loop.[65] Hypercalciuria, prostaglandin production, aquaporin II dysfunction, and sleep apnea may also play a role in the pathophysiology of nocturnal enuresis.[65–68]

Nocturnal urine production is approximately 50% of daytime production in early childhood.[69] This decrease in urine production is controlled by decreases in free water excretion secondary to nocturnal increases in the release of ADH and/or decreases in solute excretion related to the release of angiotensin II and aldosterone.[56,70]

Children with NE and increased nocturnal urine output generally have normal functional bladder capacity and a favorable response to treatment with desmopressin (DDAVP).[71]

Impairment in sleep arousal response

Problems with arousal must exist in order for a child to wet the bed. Enuretic children have poor arousability in response to acoustic stimuli, and specific brainstem dysfunction has been suggested.[72,73] In Wolfish's study, acoustic stimuli of up to 120 dB were successful in waking 39.7% of the control group and only 9.3% of enuretic patients. Enuretic boys are more difficult to arouse than age-matched controls.

Bladder dysfunction

Small functional bladder capacity and detrusor overactivity may play an important role in the pathophysiology of nocturnal enuresis.[63,74–77] Despite normal daytime voiding, approximately 30% of enuretic patients studied with simultaneous sleep electroencephalogram and cystometric monitoring had detrusor instability while sleeping at night.[78] In studies by Yeung et al[76] and Oredsson et al,[63] a majority of enuretic patients with symptoms refractory to treatment were found to have a small functional bladder capacity. When the results of cystometric studies obtained during the daytime were compared with those obtained during sleep, enuretic patients were categorized into two groups. The first group of patients had normal urodynamics and bladder capacity during daytime and marked detrusor instability, diminished nocturnal functional bladder capacity, and small volume voiding only after sleep at night. The second group of patients had abnormal daytime urodynamics associated with various types of occult underlying bladder dysfunctions and significantly reduced functional bladder capacity and small volume voids both day and night.[76,77] Additionally, up to 70% of adult patients with persistent PNE have been found to have detrusor instability and reduced functional bladder capacity.[79]

The incidence of significant anatomic and functional bladder abnormalities is low in primary MNE; however, patients with severe, treatment resistant enuresis and adults with new-onset NE may have an underlying abnormality that should be thoroughly investigated.[76,77,80]

Evaluation

To properly manage a child with PNE, one must determine possible causes for the condition. Is the

bedwetting a result of nocturnal polyuria (increased nocturnal urine production during sleep) or is it caused by a reduction in nocturnal functional bladder capacity? Although a good voiding history may identify these occult abnormalities, it is often after a failed course of desmopressin that the clinician becomes suspicious that nocturnal polyuria may not be the cause. These children will often improve with combination therapy such as enuretic alarm, urotherapy, and antimuscarinic agents, and/or desmopressin.

To avoid a delay in effective treatment, patients should have a detailed history and physical examination. A voiding diary is often useful. Occasionally, ultrasonography, uroflow, and even urodynamic studies may be indicated.

History

A careful history should include questions to help determine whether the enuresis is primary or secondary. The number and time at which night-time wetting occurs should be noted. Every effort should be made to rule out the possibility of an underlying voiding dysfunction. Clinicians should ask questions regarding daytime incontinence, urgency, frequency, posturing, infrequent voiding, and difficulties voiding. Additionally, questions not directly related to voiding include questions about fluid consumption, sleep habits, bowel habits, and clumsiness.

The answers to these questions may be useful in determining whether the NE is due to nocturnal polyuria or a diminished functional capacity. With careful questioning, and validated questionnaires, one can identify daytime voiding symptoms if present and appropriately adjust the treatment plan.

Voiding diary/frequency volume chart

It is difficult for most parents and children to answer questions regarding the number of episodes of nocturnal enuresis per week, to assess urinary frequency accurately, and to estimate voided volumes precisely. Hence, a voiding diary or frequency volume chart is extremely useful. Despite day-to-day variation, a voiding diary is an important tool in helping to determine the etiology of the NE, devising a treatment plan, and monitoring response to treatment. Optimally, a voiding diary should include a record of the child's fluid intake and urine output. Clinicians should also record the frequency and volume voided during the enuretic episode. Although debated as to clinical relevance, the functional bladder capacity is assumed to be the volume of the largest single void that occurs overnight.[81]

After analyzing various studies, Hjalmas and colleagues recommend a 2-day 3-night voiding record.[59,81,82] Because volumes of urine produced and storage capacity may vary from day to day, they suggest that a uroflow with measurements of PVR may be helpful to screen for dysfunction voiding.[81]

In children with secondary enuresis, a social and psychological history becomes important. Various factors may affect a child's voiding habits, including the family situation, the school environment, and other changes in the child's daily way of life. It is important to discuss the family's response to the child's enuresis. Children may feel punished by having to wear pull-ups. Siblings and other family members may ridicule them, further worsening the child's self-esteem.[81]

When children have extended periods of dryness, both parents and professionals should congratulate them. After a successful dry night, the child and parents will be encouraged. Not only does the child feel better for not wetting but also it becomes apparent to the parents that this is a condition that the child will outgrow. Parents are reassured that anatomic problems are unlikely to be the cause of the enuresis.

A thorough sleep history should be taken and it should be noted how much the child is sleeping when compared with other children of the same age.[83] Obstructive sleep apnea may contribute to the child's NE. Parents should be asked if the child snores, is a mouth breather, or has restless sleep. Teachers may have noted morning tiredness.

Non-monosymptomatic nocturnal enuresis

Hjalmas and colleagues describe complex bedwetting as non-monosymptomatic bedwetting.[81] These children have nocturnal enuresis that is refractory to therapy or is the result of anatomic or neurologic abnormalities. Here the challenge is to identify urologic causes for the wetting. As previously described, a thorough history aids this search. If dysfunctional storage or voiding is identified, the cause for the refractory night-time wetting may become treatable.

Further evaluations, including uroflow examinations, urodynamics, and radiographic evaluation of the upper tracts, often become necessary.

Physical examination

Anatomic and behavioral causes for enuresis may be eliminated with a thorough physical examination. When the child enters the examination room, the behavior and gait should be recorded. Possible signs

of neuropathic voiding dysfunction include abnormal gait, spinal deformities, and foot abnormalities, including asymmetry, high arched feet, or hammer toes. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks, and gluteal clefts are also important. Clinicians should also assess anal sphincter tone and perineal sensation and reflexes.

The clinician should then palpate the abdomen to identify a distended bladder and stool. If stool is palpated, the possibility of dysfunctional elimination syndrome should be considered.[84]

In boys, a genital examination may reveal an abnormal meatus, e.g. stenotic, hypospadiac, or epispadiac. The significance of these meatal abnormalities can be assessed with a voiding history. If the significance of the anomalies remains unclear, the clinician may decide to objectively measure uroflow.

Abnormalities of the female perineum that may contribute to abnormal voiding include the presence of labial adhesions, a urogenital sinus, ectopic ureteral orifices, or a hypospadiac urethral meatus. Some of these conditions may lead to dysfunctional voiding in girls.[85] Both girls and boys should be carefully examined for signs of sexual abuse.[86,87]

Laboratory tests

For a healthy child with monosymptomatic NE, laboratory tests rarely contribute to the evaluation and treatment of the condition. A urinalysis and urine culture may be considered to screen for UTI, diabetes mellitus, and diabetes insipidus.

Urodynamics and imaging

Urodynamic evaluation and upper tract imaging are necessary where there is a suspicion of neurological dysfunction or in a severely refractory patient.

Treatment

The clinician can develop a sound treatment plan only after carefully reviewing the child's history and physical examination. One must answer the following questions before treating the patient:

- Is an underlying voiding dysfunction present?
- Is bedwetting the only complaint?
- If the condition is truly monosymptomatic NE, does the child have increased nocturnal urine production (nocturnal polyuria) or a small functional bladder capacity?

The treatment of enuresis is based on its etiology,[60,88] and tailored to the individual child's needs.

Starting out

Before initiating therapy with an alarm or a medication, the clinician should review some basic guidelines with the child and parents. Educating the child about the problem will help compliance and promote success.[89] These guidelines include encouraging regular daytime voiding schedules, avoiding the intake of excessive food or fluid intake for several hours before bed, emptying the bladder before bedtime, and encouraging the child to get adequate amounts of sleep.[75,83] A low calcium and sodium dietary content of the afternoon and evening meals may also be useful.[67,90] Some parents find it useful to arouse and escort the child to the bathroom before they themselves proceed to sleep.

Additional motivational tools such as having children mark a calendar to signify wet and dry nights have been successful. Up to 18% of children may be cured with this type of program.[91]

Clinicians should be alert for comorbid conditions such as encopresis, constipation, and psychiatric disorders. Up to 72% of enuresis may be eliminated with treatment of these comorbid conditions.[92,93] If present, daytime voiding symptoms should be treated before initiating therapy for NE.[94,95]

For treatment of enuresis to be successful, the child and family must be motivated and the clinician must be prepared to be patient and supportive. Expectations should be realistic and one should not consider a relapse to be a complete failure. The child must be motivated to improve. If the child does not consider wetting to be a problem, the outcome of therapy may be poor, and waiting may be more appropriate. Children <6 years old are rarely interested in becoming dry at night. Parents should not punish the child who wets, but successes should be rewarded.

The condition may be treated using these simple guidelines alone. It is our practice to provide baseline counseling before the initiation of specific treatment in most enuretic children.

Alarm therapy

Currently available enuretic alarms are small devices that the child can clip to the undergarments and wear throughout the night, or the unit may be placed at the bedside. Alarms worn on the body are as effective as bedside alarms.[91] Although highly effective, the exact mechanism by which alarm treatment works is not

known. The behavioral modification is not classical conditioning, as the stimulus is a result of the behavior. Instead, the alarm appears to work by negative reinforcement or avoidance. The alarm awakens the child during voiding; the child must then get out of bed and finish voiding in the toilet or hold the urine until later.

Alarm therapy is successful treatment for bedwetting, with initial and long-term success rates of 70–90% and 50–70%, respectively.[96,97]

Evidence-based medicine teaches us that alarm therapy is amongst the most effective interventions for treating childhood NE. Several systematic reviews and meta-analyses report success rates of 65–70%, with a treatment duration of 5–12 weeks and stated relapse rates of 15–30% in the 6 months after treatment.[98–100] As efficacy improves with time, enuresis alarms may not be suitable in families unwilling to wait several months for improvement.[101]

Clinicians must discuss expectations and commitment to the alarm's use before deployment of the device. Alarm therapy requires a motivated child and family, and a significant effort and time. The alarm may not only interrupt the affected child's sleep but also that of the parents and other siblings. Once the alarm is activated, a parent will often have to awaken and get out of bed to assist the child to the bathroom to finish voiding, change the sheets and pajamas, return the child to bed, and reset the alarm. Often the child is not fully awake during this entire process. The parent, on the other hand, is fully awake and unless committed to the elimination of the wetting, may begin to resent the child.[102] Parental fatigue and intolerance may lead to discontinuation or early withdrawal from alarm therapy.[103]

When using the alarm, some physicians recommend biweekly follow-up to monitor therapy and provide encouragement to the child and the parent.[81] The family should continue to use the alarm for at least 1 month after a period of sustained dryness: although 29–66% of children may relapse, this does not preclude repeated use of the alarm.

Use of the alarm may affect arousal, overnight urine production, and nocturnal bladder capacity. Oredsson and Jorgensen reported increase of bladder capacity but no change in nocturnal urine output or vasopressin secretion.[63]

Butler has defined outcomes to aid in the evaluation of the effectiveness of alarm therapy:[104]

- initial success – a minimum of 14 consecutive dry nights within 16 weeks of alarm therapy
- relapse – two wet nights in 2 weeks
- continued success – no relapse within 6 months after initial success
- complete success – no relapse within 2 years after initial success.

Alarm therapy is widely believed to be the most effective therapy for NE, with the best long-term results.[105] In the meta-analysis by Houts et al, 62% of children were dry at the end of therapy, with 47% dry at follow-up.[106] Similar successes, with up to 77.9% dry, have also been reported, with the likelihood for 14 consecutive dry nights 13.3 times higher than without therapy.[93] Successes using alarm therapy are also considered more durable by some clinicians, as treatment using desmopressin and tricyclics has not been sustained once therapy has been withdrawn.[102] Long-term desmopressin treatment has also been shown to produce sustained improvement, although reported cure rates with the alarm are generally higher.[107,108]

A Cochrane review comparing alarm interventions considered 952 potentially relevant studies but found only 22 were of a quality sufficient to be analyzed. These were randomized controlled trials involving a total of 1125 children.[101] After analysis, the study concluded that comparative studies comparing alarms to pharmaceuticals are warranted before assuming alarm therapy to be effective.

Butler and Stenberg and Hjalmas et al have separately summarized predictors of poor response with the enuresis alarm: e.g. parental intolerance and annoyance and children with low self-esteem, behavioral problems, or lack of motivation. Other predictors of poor outcome are a family history of bedwetting, associated daytime wetting, lack of supervision, inconsistent use, family stress, psychiatric disorder in the child, failure to awaken in response to the alarm, unsatisfactory housing conditions, and more than one wetting episode per night.[81,97,103,109–112]

Pharmacologic treatment

Desmopressin (DDAVP)

Many patients with MNE lack the nocturnal rise of ADH, therefore causing an imbalance in the normal circadian variation in urine production. This results in the production of large quantities of dilute urine at night. When the amount of urine produced overnight exceeds the bladder capacity, NE will occur.[113] A study by Hansen and Jorgensen confirmed that nighttime urine production was reduced during desmopressin treatment.[114]

Arginine vasopressin (AVP or ADH) is a polypeptide produced in the hypothalamus and released from the pituitary gland. Its release is caused by hyperosmolality or a low effective circulating blood volume. The polypeptide's effect is on V_2 receptors of the collecting ducts and distal tubules to enhance water reabsorption.[115] It also is a potent vasopressor, through independent actions on V_1 receptors.

Desmopressin is an analog of vasopressin. Unlike ADH, this analog has increased antidiuretic activity without vasopressor activity. The half-life is 1.5–3.5 hours. Desmopressin is commercially available in an oral and intranasal formula. The usual dose is 0.2–0.6 mg orally or 10–40 μg intranasally at bedtime with immediate clinical effects. Fluid intake should be limited when the drug is used. A simple suggestion is to avoid drinking for 2 hours before bedtime and to limit fluid intake to 8 ounces after evening meal.

Desmopressin is regarded safe for use in children. In most cases, children tolerate the medication well, with few adverse reactions reported in short- or long-term use.[107,108] Klauber reported no serious adverse reactions in 516 cases.[116] In another study, only 6 of 242 children (2.5%) withdrew, as a result of very mild adverse events, during long-term intranasal treatment. All monitored clinical and laboratory parameters remained within normal limits in this study.[107]

The risk of water intoxication should be discussed with parents prior to initiating DDAVP therapy and, consequently, fluid intake during evening meal and before bedtime should be limited. In this case, hyponatremia results from a large amount of fluid intake while taking the drug.[117]

Although children with nocturnal polyuria and low nocturnal urine osmolality should respond best to DDAVP treatment, some studies have not found any differences in urine output, osmolality, or vasopressin secretion in responders and non-responders.[118,119]

Before labeling a child as a non-responder, it is important to know whether the child received the medication correctly. In children that do not respond to treatment with DDAVP, nocturnal hypercalciuria and hypernatriuria should be suspected.[67,90]

Predictors of good response to desmopressin therapy include larger bladder capacities,[75] older children,[120,121] fewer wet nights at presentation,[120,122] and normal functional bladder capacity.[119,121] Other predictors include primary as opposed to secondary NE,[123] only one wet episode during the night, enuresis that occurs during the first 2 hours of sleep,[119] a family history of NE,[124,125] and initial good response to the smallest dose of desmopressin used in the study (20 μg intranasal).[126]

Several controlled studies have demonstrated the effectiveness of desmopressin in the treatment of nocturnal enuresis,[56,127–129] regardless of the route of administration. Positive response (defined as >50% reduction of wet nights) was reported in 60–70% of patients.[58,64,107] A review of randomized trials comparing desmopressin with placebo found that desmopressin was better in 13 of the 14 studies.[64] Based on the Cochrane report by Glazener and Evans, patients treated with DDAVP were 4.6 times more likely to achieve 14 consecutive dry nights compared with placebo.[130] With a more selected population of children with primary NE, Caione et al found a 79% success rate after the administration of desmopressin.[131]

When DDAVP treatment is successful, we stop the drug for 1 week every 3 months to evaluate whether the problem persists. The annual cure rate in children treated with DDAVP is approximately 30%.[107] Permanent cure may increase to 74.5% by gradually discontinuing the drug and positively reinforcing dry nights over a 10-week period.[132]

Unfortunately, relapse after the cessation of treatment is common, and long-term treatment may yield a better response. Of 399 enuretic children recruited in the Swedish Enuresis Trial (SWEET),[107] 61% responded to desmopressin treatment initially, and of those responders, 61% were dry after 1 year of treatment. However, using an intent-to-treat analysis, only 19% of patients remained dry after the cessation of therapy.[107]

Desmopressin may be helpful in children that have failed alarm therapy or in families where motivation to use the alarm is lacking. In the short term, desmopressin produces more rapid improvement than alarm therapy. As children that do poorly with the alarm may do well with DDAVP, the converse may also be true.

Oxybutynin

The antimuscarinic agent oxybutynin is often used as part of combination therapy in enuretic children with a small bladder capacity, daytime incontinence, or detrusor overactivity. Oxybutynin should not be the first recommended therapy for a child with MNE. Yeung et al found that ≥ 30% of enuretic children refractory to therapy had detrusor overactivity at night.[77] When using oxybutynin, we recommend bladder training, since in unselected populations of children with NE, oxybutynin has not been effective

in randomized controlled studies.[133] Watanabe et al[134] reported a 67% success rate with oxybutynin in a group of children with bladder instability as a cause of their NE. Kass et al[135] reported a 90% success rate. The drug may also be considered in children with day- and night-time incontinence and for DDAVP non-responders. The efficacy may improve when combined with desmopressin.[136,137]

Tricyclic antidepressants

Tricyclic antidepressants such as imipramine were extensively used in the treatment of enuresis in the 1970s and 1980s. Imipramine has fallen out of favor for several reasons, including cardiotoxic side effects, risk of death with overdose, and its psychopharmacologic properties. The mechanism of action for this drug in the treatment of NE is unclear, although it may act by reducing detrusor activity and increasing bladder capacity secondary to anticholinergic and smooth muscle relaxant effects.

Additionally, it may enhance arousal and suppress rapid eye movement (REM) sleep or decrease urine production by a stimulating vasopressin release.[138,139]

Because of the lower efficacy and more dangerous side-effect profile of this drug compared with desmopressin (only 17% of children who were dry during treatment with imipramine remained dry 6 months after cessation of medication and alarm therapy), we only use it when all other management has failed.

Other therapies

Combination therapy

Some children with NE may have more than one cause for their condition. The most common combined cause of NE is lack of AVP with poor arousability. In these children, combined therapy may be more successful than a single therapy alone.

Studies using combined desmopressin and the enuresis alarm on unselected groups of children have been published. In study by Bradbury, 71 children were randomized to alarm plus desmopressin (40 μg) or alarm monotherapy for 6 weeks.[140] The combined therapy was more effective than the alarm alone, particularly where the child had severe NE and behavioral problems. Sukhai et al,[141] with a crossover design, randomized children into two treatment groups: i.e. alarm + desmopressin or alarm + placebo. The results suggested that alarm + desmopressin was better ($p = 0.05$) than alarm + placebo in treating NE. In a double-blind placebo-controlled study, Leebeek-Groenewegen et al,[142] examined 93 children with MNE. Children were treated with alarm + desmopressin or alarm + placebo for 9 weeks. Based on the results of this study, it was concluded that desmopressin does not result in higher cure rates and that combined treatment is not justified in all enuretic children at the outset of treatment.

For children with enuresis associated with bladder overactivity, a combination of bladder training coupled with anticholinergic therapy yields success rates of 67–100%.[78,135,137] Combination therapy with oxybutynin and desmopressin has also been found to be effective in this subgroup of patients.[131]

Behavioral therapies

Houts suggested that the addition of selected behavioral procedures produces better outcomes than alarm monotherapy.[143] Houts names four main behavioral procedures. These include arousal training, which reinforces waking and toileting in response to the alarm's trigger, and normalized voiding, which encourages children to increase their fluid intake and time their voiding during the daytime in an attempt to increase cognitive control over voiding. One other procedure, dry-bed training uses the enuresis alarm, and encourages the children to take responsibility for removing wet sheets and re-making the bed, and two waking schedules, to ease arousability from sleep.[144] However, Bollard and Nettelbeck[145] found that the enuresis alarm accounted for most of the success achieved through dry-bed training.

Alternative therapies

Numerous studies using traditional Chinese acupuncture and laser acupuncture for the treatment of NE have been published.[146,147] In a prospective randomized study comparing laser acupuncture with desmopressin in patients with nocturnal polyuria, laser acupuncture was found to be as efficacious as desmopressin.[147]

Treatment for non-responders

Absorptive nocturnal hypercalciuria may be responsible for NE in some children that remain non-responders despite therapy with DDAVP and anticholinergics. Pace et al demonstrated that some enuretic patients with hypercalciuria who failed to respond to DDAVP became desmopressin responders once they were treated with a low-calcium diet.[148]

Abnormalities in aquaporin 2 (AQP2) urinary excretion have been recently reported as another

possible cause of nocturnal enuresis.[67] Urinary AQP2 and hypercalciuria levels correlated with the severity of enuresis in children. Valenti et al further strengthened the association between AQP2 and hypercalciuria in a recent study.[149] Enuresis resolved in 80% of patients after 6 months of combined treatment with desmopressin and a low-calcium diet. Arginine vasopressin levels returned to normal, hypercalciuria resolved, and day/night AQP2 ratios returned to near normal levels. Based on these recent reports, Hjalmas and colleagues suggest that:[107]

> it may become mandatory to study the CaU/CrU ratio to determine if the enuretic patient is hypercalciuric or not, as a first step to a correct therapeutic strategy for nocturnal enuresis.

Conclusion

Despite advances in our understanding of NE, the condition remains complex. The key to success involves a motivated patient and family.

Operations for the weak bladder outlet

55

Anthony J Casale

Introduction

Surgery to correct urinary incontinence began in 1852 with a procedure to divert the ureters into the sigmoid colon of a boy with exstrophy.[1] Our understanding of the physiology and cause of urinary incontinence has grown slowly over the past century and more has been learned in the past 25 years than in prior medical history. Early surgeons did not have the necessary technology to define the physiology of the bladder neck but they were keen observers of anatomy. As early as 1906 the German surgeon Trendelenburg had suggested to divide the symphysis pubis to gain access for surgical narrowing of the bladder outlet in epispadias patients with the goal of improving urinary control.[2] Hugh Hampton Young was the first American urologist to identify the abnormal anatomy of the bladder neck as the cause of the patient's urinary incontinence and devise surgery to correct it in 1908. In 1919, Young presented his original procedure to provide continence in patients with bladder outlet incompetence.[3]

By examining these patients with early cystoscopes and at the time of open surgery, Young noted that the bladder neck and proximal urethra was enlarged and funnel shaped. The remainder of the bladder appeared healthy. He surmised that if he could restore the bladder neck and proximal urethra to a more normal appearance, then function would improve. He excised a wedge of mucosa from the posterior urethra and bladder below the trigone and narrowed the muscle with a single layer of sutures.

Since Young's bold procedure, surgery for the weak bladder outlet has progressed from the goal of re-creating normal anatomy to that of constructing continence mechanisms that bear no resemblance to the normal bladder outlet. Other developments in urinary tract reconstruction, such as intermittent catheterization, bladder augmentation, and continent catheterizable stomas, have made new procedures to repair the weak bladder outlet possible and offer solutions to problems that early surgeons saw as incurable.

After decades of becoming bolder in our approach to the bladder neck, the last few years have seen a realization of the limitations of reconstructive surgery to the bladder outlet and a turn to less aggressive and disruptive bladder surgery. Better understanding of the physiology of the bladder and stresses on the bladder outlet has led to a more selective approach to increasing bladder outlet resistance. Increased awareness of long-term negative consequences of altered anatomy and physiology have led surgeons to aspire to alter the bladder outlet anatomy only enough to achieve the desired result of socially acceptable continence.

Indications and evaluation

Urinary incontinence may be the result of bladder outlet inadequacy in conditions such as epispadias, exstrophy, cloacal exstrophy, traumatic injuries of the urethra and bladder neck, urogenital sinus, bilateral ectopic ureters, and neurologic conditions. Indications for bladder outlet surgery in these conditions include evidence that weakness of the outlet is a cause of incontinence and the failure of maximal medical therapy to correct the problem.

The bladder outlet includes the bladder neck and proximal urethra: together, they may be considered as a unit and normally function as a sphincter in both boys and girls. There is no identifiable anatomic sphincter but a mixture of smooth and striated muscle, intracellular matrix, and mucosal factors that combine to make up a functional sphincter.[4] Compression of the urethral lumen and the resultant outlet resistance depends on several factors. Among the components that make up the normal sphincter mechanism are smooth and striated muscle tone and

contractions, elastic properties of the urethra, mechanical forces transmitted from the abdomen, and structural support of the posterior urethral wall and bladder neck against which the urethra is compressed with increased abdominal pressure. The conditions that cause incontinence in children often present inadequacies in several if not all of these components.

In health, the bladder neck provides a variable resistance to the flow of urine through the urethra. The resistance is stable when the bladder pressure is low and increases as the pressure rises with bladder filling. It also increases reflexively with increased bladder pressure due to coughing or Valsalva's maneuver, and it decreases dramatically when the patient begins to void. For the bladder neck to maintain continence it must be able to generate pressure within the lumen that is greater than the pressure within the bladder at all times except during voiding.

There are several methods to evaluate the competency of the bladder outlet. Just as Young noted, the cystoscopic appearance of the bladder neck reflects its function. When viewing from the proximal urethra, the posterior lip of the bladder neck should be elevated above the level of the urethra and the base of the bladder. The bladder neck should close easily when fluid flow through the cystoscope is stopped. Although these observations are helpful, they are by no means completely reliable in predicting continence.

The bladder outlet may also be evaluated by imaging with a radiographic cystogram. A competent bladder outlet appears closed as the bladder is filled and contrast should not leak into the urethra. The incompetent bladder outlet may remain open and funnel shaped during the filling process or may open with Valsalva's maneuver or suprapubic pressure[5] (Figure 55.1). Lateral views of the cystogram may reveal the lack of adequate elevation and suspension of the posterior bladder outlet.

Urodynamic studies of the bladder are important in determining causes of incontinence. Bladder leak point pressure and sphincter electromyography (EMG) are commonly used to measure bladder neck function. Leak point pressure is simply the pressure within the bladder at which fluid begins to leak through the bladder outlet into the urethra. Sphincter EMG is the measurement of electrical activity of the striated muscle of the sphincter. The sphincter EMG is most helpful in evaluating coordination of the detrusor and sphincter and may be of some benefit to document neural innervation of the sphincter in incontinent children. It is seldom helpful in children who are candidates for bladder outlet surgery.

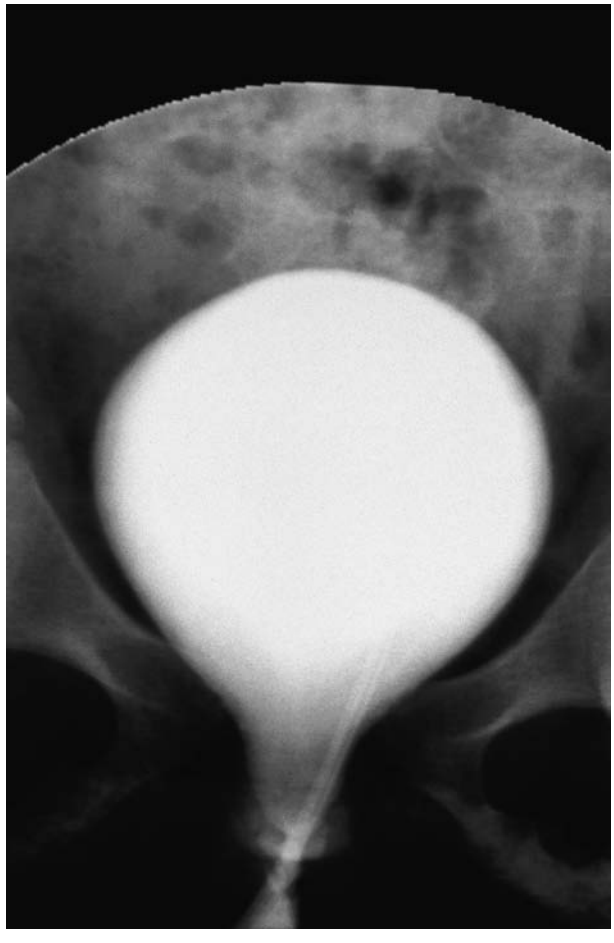

Figure 55.1 Voiding cystourethrogram of a patient with an open bladder neck during filling with contrast. The bladder neck is funneled during the entire study.

On the other hand, bladder leak point pressure is the most reliable objective study in incontinent children due to bladder outlet dysfunction. Low leak point pressures indicate incompetence of the bladder outlet and may cause incontinence independent of detrusor function. McGuire et al defined the importance of leak point pressure in children with myelodysplasia and neuropathic bladder when they found that high leak point pressures >40 cmH_2O resulted in upper tract deterioration due to reflux and hydronephrosis.[6] Children with pressures <40 cmH_2O were protected from such changes but were prone to leak urine easily owing to weak bladder outlet. They also found that the radiographic appearance of an open bladder neck did not correlate well with measured leak point pressures.

McGuire found that children with myelomeningocele have fixed bladder outlet resistance that is located distal to the bladder neck and does not vary with

filling or leaking. When these children were treated with intermittent catheterization and anticholinergic medications, patients with closed bladder necks on cystogram were uniformly continent whereas only 60% of those with an open bladder neck became continent. This finding was independent of leak point pressure, indicating its limits in predicting continence in all patients.

Leak point pressure should be measured with a small urethral catheter (5 or 7 Fr). The water should be infused with a pump rather than by gravity. The technique should be standardized for each measurement, since Decter and Harpster have demonstrated that measured values of leak point pressures in children vary with catheter size and with rate and method of infusion.[7] Patients should be encouraged to cough and sit or stand if possible to measure leak point pressures in a dynamic, more normal, setting. The volume at which leaking occurs is important because it reflects the functional capacity of the bladder and prognosis for continence.

Other urodynamic measurements are critical in diagnosing the cause of incontinence. Bladder pressures and volumes indicate storage capacity of the bladder and must be adequate for continence. Compliance may be considered the inverse of stiffness and is a helpful indicator of bladder adaptability. Poorly compliant bladders tend to produce higher pressures with lower volumes of urine, making patients more prone to upper tract deterioration and incontinence.[8] Detrusor measurements in children with completely incompetent bladder necks may be performed by inflating the balloon of a Foley catheter at the bladder neck and pulling it down to occlude the bladder outlet.[9] It is fruitless to consider treatment of bladder outlet incompetence unless the bladder itself has adequate volume and pressure characteristics for the storage of urine.

When evaluating incontinent children as candidates for bladder outlet surgery, a voiding/catheterizing diary can yield invaluable and practical information. Unlike radiographic and urodynamic examinations, these diaries represent the level of incontinence during normal activity. Some parameters, such as functional storage capacity of the bladder, may be quite different from values that hospital tests may imply. We have patients measure voided/catheterized amounts of urine obtained, the times that the bladder is emptied, when incontinence occurs, the degree of incontinence, and activities associated with leaking. This information, along with urodynamic data, examination by cystogram, and cystoscopy, may be needed to define the cause or causes of incontinence.

If incontinence is due to incompetence of the bladder outlet, the physician has two basic treatments available, medical and surgical. Medical treatment must always be exhausted completely before considering surgery. This is important not only because some patients will become dry with medical management alone but also because medical regimens requiring family and patient participation may demonstrate that the family is committed and willing to comply with similar catheterization and medicine schedules that necessarily accompany most surgical procedures to create continence. If the family can give medication and catheterize the child prior to surgery, it is likely that they will do so after bladder outlet surgery.

Medical therapy

Children found to have inadequate bladder outlet resistance may be treated with various non-surgical modalities. Some therapy helpful in incontinent adults has no role in children. Pelvic floor exercises, biofeedback, and electric stimulation of the bladder outlet have not been helpful in children with incontinence who suffer from anatomic and neuropathic conditions.

There are medications that have been effectively used to stimulate muscles of the weak bladder outlet. They include α-sympathomimetic agents such as ephedrine and ephedrine-like compounds that stimulate the large number of α-adrenergic receptor sites found in the proximal urethra and bladder neck and cause smooth muscle contraction.[10] These compounds produce troublesome side effects in some patients such as hypertension, anxiety, and palpitations. Results have not been reliable in this group of children because most have severe anatomic and neurologic defects at the bladder outlet. We have had little success with medical stimulation of the bladder outlet to improve continence.

Other non-surgical therapies include clean intermittent catheterization (CIC) to completely empty the bladder on a prearranged schedule. Intermittent catheterization remains the single most important contribution to the treatment of incontinence in children. In children with neuropathic bladder, intermittent catheterization alone will provide continence in 19–24%.[11,12] The addition of anticholinergic medications, which lower bladder pressures and inhibit detrusor contractions, to CIC programs raised the continence rates to 68–89%.[13,14] It is important to recognize that various authors have defined continence differently in the past. Whereas most patients gain

some social or daytime continence with medical therapy, complete dryness is possible in less than one-third. Even if bladder outlet function is marginal, continence may be improved by maximizing other aspects, such as bladder storage capacity, with medication and emptying the bladder regularly with catheterization.

Procedures to increase bladder outlet resistance

Once the bladder outlet has been identified as a cause of incontinence and medical therapy has been exhausted without acceptable improvement, the next options are surgical procedures to enhance bladder outlet resistance. This may be done by three basic surgical methods: procedures to change the suspension, support, or angle of the bladder outlet; procedures to compress the lumen of bladder outlet with either an external compression device or by injection of material under the mucosa; and procedures to reconfigure the bladder outlet into a more efficient continence valve.

Procedures to suspend the bladder outlet

For the past century inadequate support or insufficient elevation of the bladder neck and proximal urethra has been identified as a cause of urinary incontinence.[15] Inadequate suspension contributes to incontinence by making the bladder outlet too mobile, allowing it to descend into the pelvis. Normal suspension of the posterior bladder outlet is necessary to provide resistance from below to counter increased abdominal pressures from above and thus compress the lumen. Suspension of the bladder outlet may be accomplished in several ways, including procedures that fasten the existing periurethral fascia to the anterior pelvic wall and procedures that reinforce the posterior bladder outlet with a sling made of fascia or some other external material.

In 1949, Marshall, Marchetti, and Krantz (MMK) introduced a procedure to improve stress incontinence by surgically elevating and suspending the bladder neck and proximal urethra.[16] The procedure is based on sewing the anterior vaginal fascia just lateral to the urethra and bladder neck to the cartilaginous portion of the symphysis pubis (Figure 55.2). These

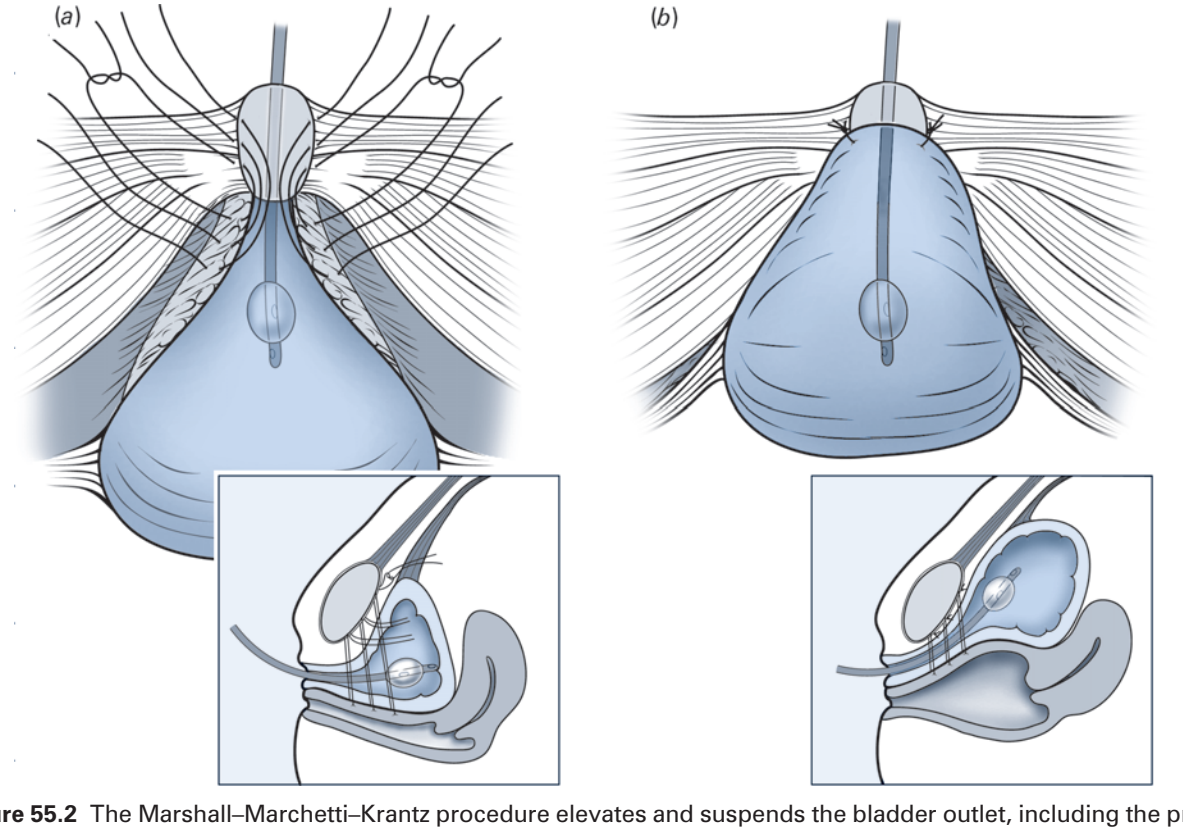

Figure 55.2 The Marshall–Marchetti–Krantz procedure elevates and suspends the bladder outlet, including the proximal urethra, by sewing the anterior vaginal fascia to the underside of the symphysis pubis. These are permanent sutures and re-create the posterior angle of the bladder neck. The concept of bladder neck suspension is still a cornerstone in incontinence surgery. (*a*) Placement of sutures between the anterior vaginal fascia and underside of the pubis. (*b*) Suspension and elevation of the bladder outlet.

sutures suspend and support the bladder outlet and recreate its posterior angle. The MMK procedure was for many years the gold standard of incontinence surgery and the concept is still critical in correcting these problems. Burch's procedure to suspend the bladder outlet from Cooper's ligament was another form of suspension that gained wide acceptance.[17] Both suspension surgeries produce cure rates in patients with pure stress incontinence of >90%.[18] Today, suture suspension of the bladder outlet in children is utilized usually as an adjunct procedure with other incontinence surgery and helps to produce continence in up to 88% of patients.[19,20]

Pereya (1959), Stamey (1973), and Raz (1981) developed procedures that were also designed to elevate and suspend the weak bladder outlet.[21–23] They supported and elevated the bladder neck using sutures from the perivesical and periurethral fascia to the rectus abdominal fascia. These procedures were clear advances because they could be done through small incisions using long needles to place the suspension sutures (Figure 55.3). The surgeons could confirm correct suture placement at the time of the procedure with the cystoscope and the patients suffered minimal discomfort.

McGuire improved on a concept introduced in 1911 by Goebell of suspending the bladder outlet with a sling of fascia or muscle.[24] McGuire developed a method of passing an isolated strip of rectus fascia beneath the bladder neck and reattaching it to the anterior abdominal wall at the insertion of the rectus fascia and the pubis[25] (Figure 55.4). Slings may improve continence by compressing the urethra, elevating the bladder outlet into the abdomen, or by providing a stable point against which the urethra is compressed during increases in abdominal pressure.

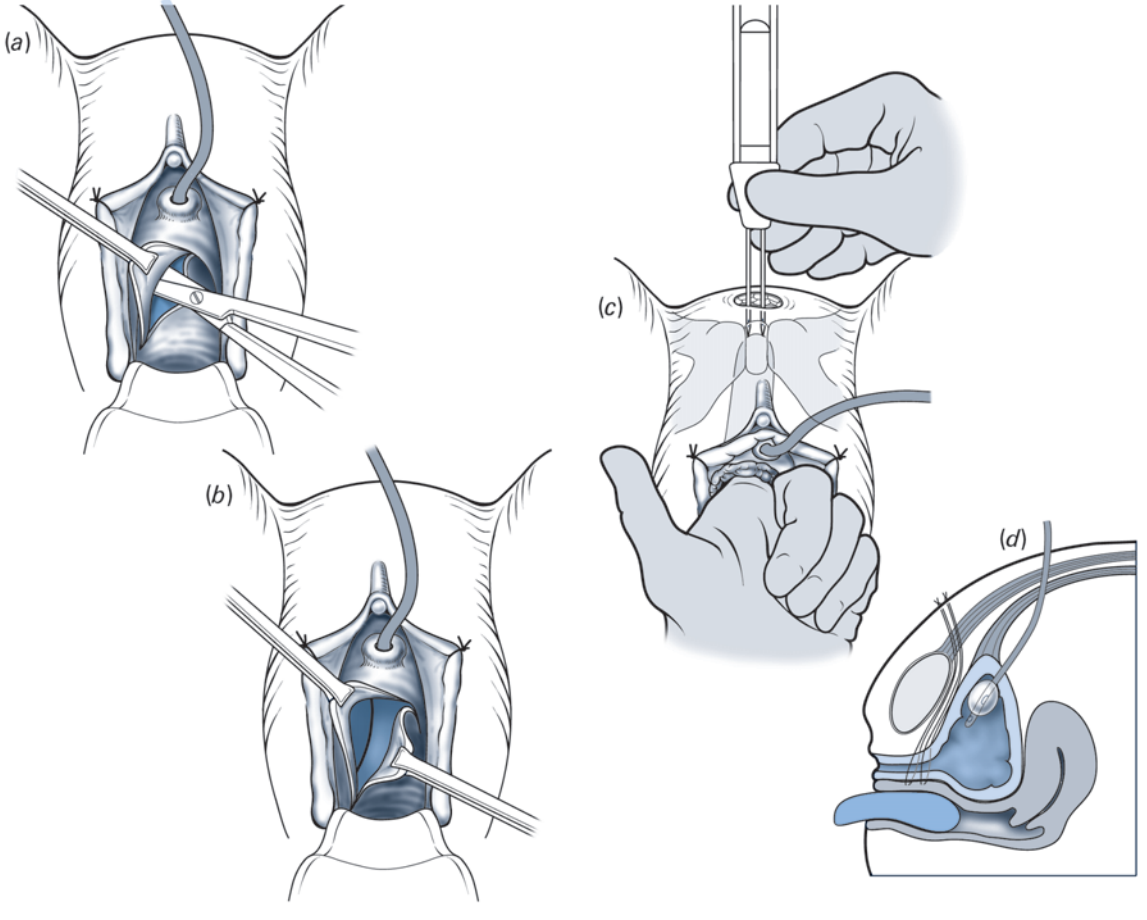

Figure 55.3 The Raz sling suspension uses long needles to pass permanent sutures from the anterior rectus fascia to suspend the bladder outlet from the anterior abdominal wall. The sutures support and elevate the bladder outlet and re-create the normal position and anatomy of the posterior bladder neck. They are dependent on the strength of the fascia surrounding the bladder neck and posterior urethra. (*a* and *b*) Exposure of the anterior vaginal fascia on either side of the bladder outlet. (*c*) Passing a needle from the anterior abdominal fascia to the vaginal incision in order to place sutures. (*d*) Suture suspension of the bladder outlet.

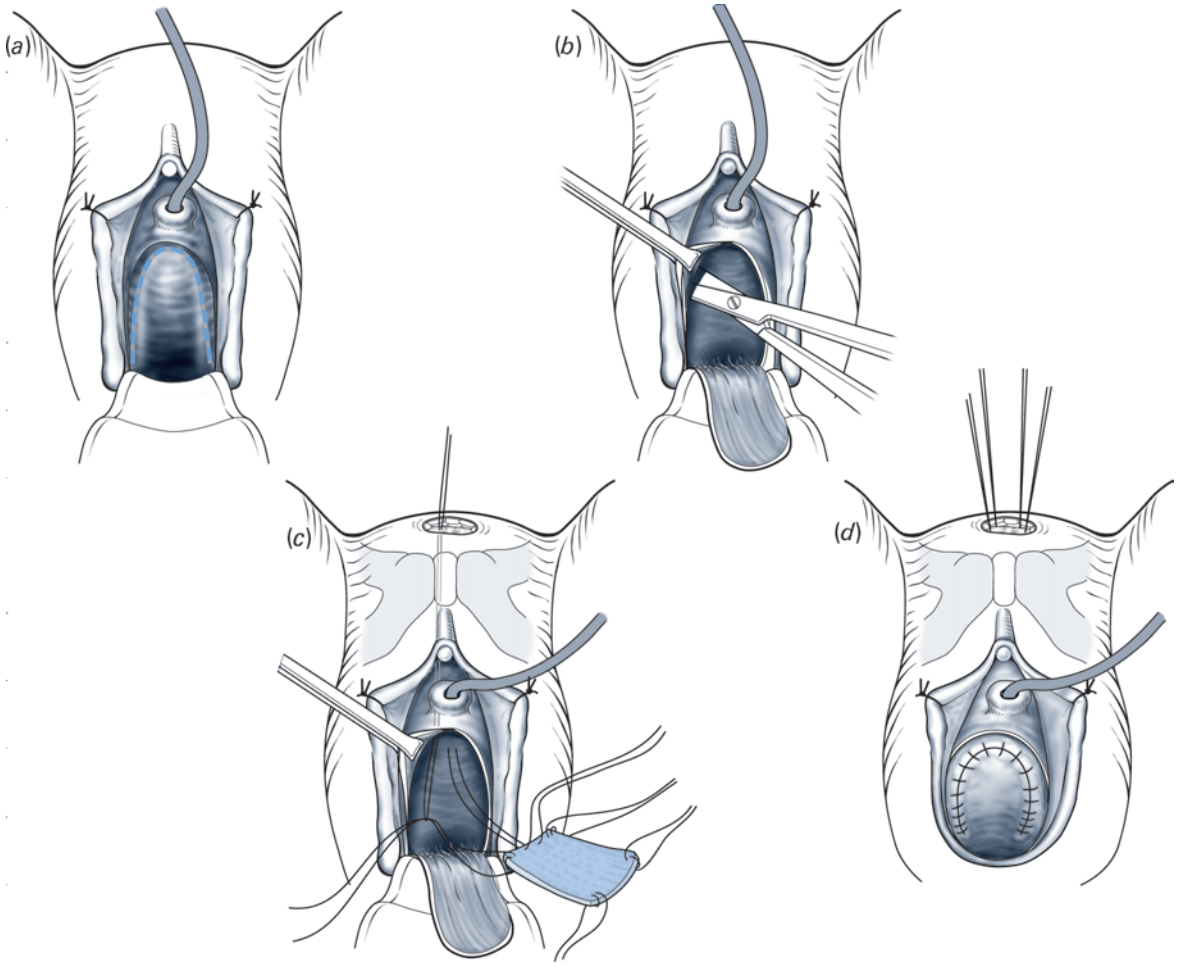

Figure 55.4 McGuire developed a suspension procedure that uses long sutures from the anterior abdominal wall to support a short strip of fascia. This fascia is passed posterior to the bladder outlet and supports and elevates the bladder outlet. This procedure provides more uniform support to the posterior bladder neck and does not rely on the native fascia around the bladder neck and urethra. (*a*) Vaginal incision to expose anterior vaginal fascia. (*b*) Dissection on either side of the bladder outlet. (*c*) Placement of the sling. (*d*) Sutures that elevate and suspend the bladder outlet.

This fascial sling and its variations have proven valuable for children with bladder outlet incompetence.[26] The use of fascia under the bladder neck is more reliable in these children than sutures alone, which must rely on the strength of the native fascia adjacent to the bladder neck and proximal urethra to hold the suspension sutures.

At the time of open surgery, the most popular form of sling suspension involves a long strip of rectus fascia that is passed around the bladder outlet and sewn to the anterior abdominal wall fascia on each side. This suspension depends completely upon the fascia to support the bladder outlet and is done entirely through a lower abdominal incision (Figure 55.5).

Slings may also be placed transvaginally in girls, just as is done in adults with good results.[27] This procedure would seem to be limited somewhat by the age of the child and size of the introitus. It is a useful approach in adolescent girls who are not undergoing simultaneous bladder reconstruction.

Bladder neck suspension, usually in the form of a rectus fascia sling, has been most helpful in girls with myelomeningocele on intermittent catheterization.[28] The female urethra is more easily manipulated in this way and results have been good in this population, with continence rates of 78–90%.[29–31] The success rate in males in our hands has been considerably less than in females when suspension is used alone, although some authors report good experiences.[32–34] The combination of slings with other bladder neck surgery, such as narrowing the outlet, has been successful for some surgeons.[35] In

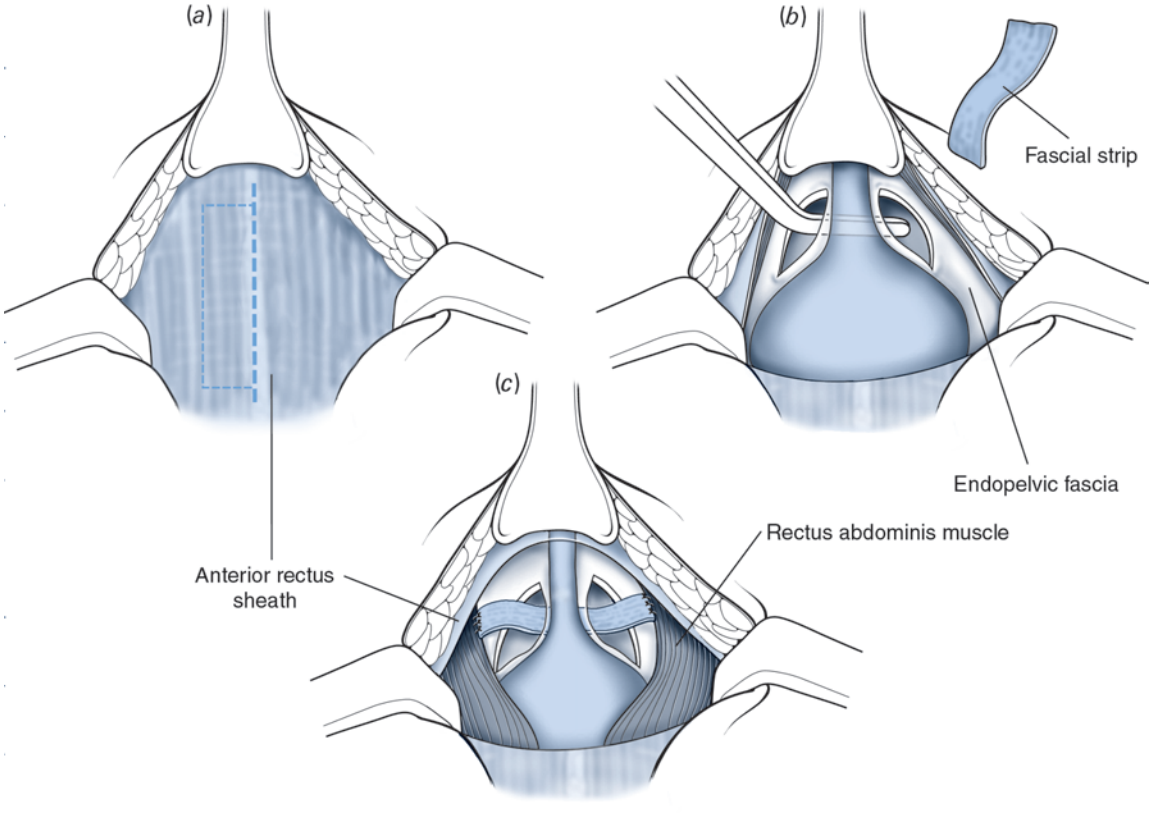

Figure 55.5 Fascial slings may be harvested from the anterior rectus fascia at the time of open surgery and used to suspend the bladder outlet from the anterior abdominal wall. (*a*) A single strip of fascia can be taken from the lateral aspect of a midline incision and (*b*) passed behind the bladder outlet. (*c*) Each end of the sling can then be sewn to the anterior rectus fascia on each side to elevate and support the bladder neck and urethra.

the author's experience the one group of patients who most often fail sling suspension are males who subject their bladder outlet to very high pressures that result from physical activity such as ambulation and play.

Fascial sling suspension of the bladder outlet is not without complications. Decter has reported erosion of the sling into the bladder and late degeneration of detrusor compliance after sling placement.[36] Often patients have difficulty catheterizing through the urethra after sling placement owing to the altered angle of the urethra. We have also witnessed the sling break during physical activity, acutely returning the child to a state of incontinence. There has been concern about the effects of slings on erectile function in males with spina bifida, but this function appears to be preserved in over 90% in one series of 14 patients.[37] Like many other procedures to improve bladder outlet resistance, augmentation cystoplasty has often been required to provide a large low-pressure reservoir for optimal continence.

Slings made of exogenous material have been introduced at various times and include true synthetic and processed biologic material such as porcine small intestinal submucosa. The early-generation pure synthetics such as silicone rubber and Gore-Tex have a high risk of erosion into the urinary tract and are not in common use today.[38] A new generation of material is available, including synthetic polypropylene mesh tape. This material has been useful in adult stress incontinence and has a much lower risk of erosion than prior synthetic materials.[39,40] The use of newer synthetic mesh slings has yet to be documented in children but its use in full-grown adolescents would seem to be promising.

The processed porcine biomaterial, small intestinal submucosa, has been in use for some time and has similar efficacy for producing continence. It offers an off-the-shelf replacement for rectus fascia, thus shortening surgical time and simplifying abdominal wall closure at the time of reconstruction.[41]

Procedures to compress the weak bladder outlet

Surgery to compress the bladder neck externally can take one of two forms: variable or fixed. Since the

normal bladder neck offers variable outlet resistance, this form is the most desirable, so that the resistance can be relaxed to allow voiding or easy catheterization. The artificial urinary sphincter developed by Scott in 1972 has been valuable in the management of incontinence for many years.[42]

Artificial urinary sphincter

The artificial urinary sphincter is a hydraulic device that is composed of three parts: an inflatable cuff that surrounds and compresses the bladder neck or bulbous urethra; a pressure-generating balloon; and a pump control module (Figure 55.6). The artificial sphincter gives the patient the ability to deflate the cuff and reduce the compression of the bladder neck at will. The pump is placed in the scrotum or labia and the entire device is contained within the body. Continence rates are close to 90% after placement of the device.[43–45]

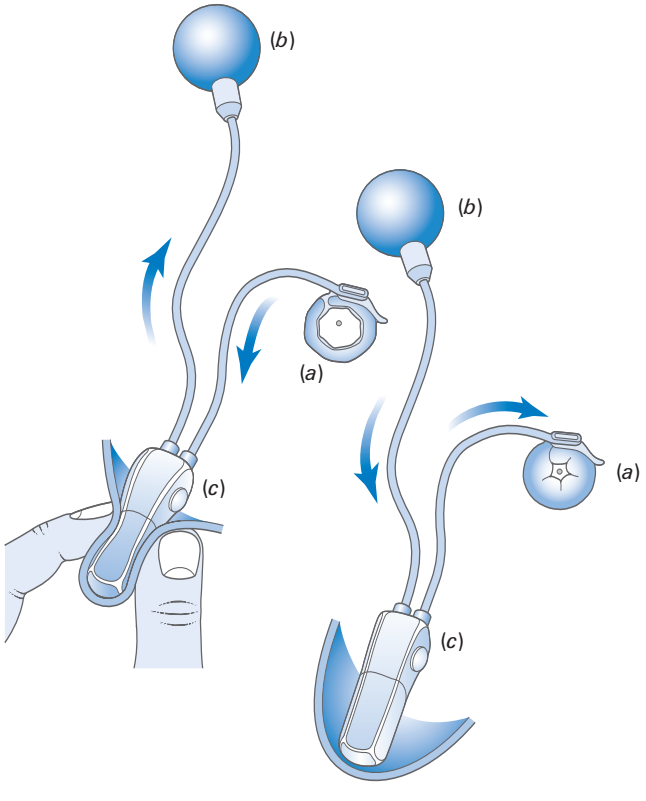

Figure 55.6 The artificial urinary sphincter is a mechanical device composed of three components: (*a*) an inflatable cuff, (*b*) a pressure-regulating reservoirballoon, and (*c*) a control pump. It functions by using hydraulic pressure to inflate the cuff, which compresses the urethra and provides continence. By squeezing the pump (implanted in the scrotum or labia), the patient can manually deflate the cuff and allow voiding or catheterization through the urethra. The pressure in the balloon then restores pressure throughout the system and reinflates the cuff in 3 minutes.

The bladder neck is the preferred site of placement in children (Figure 55.7). The usual minimal age for placement of artificial sphincters is 6 years for boys and 8 or 9 years for girls.[46] The pressure exerted on the urethra is regulated by the balloon/reservoir and most children need 61–70 cmH_2O pressure to safely control the bladder outlet. The device is not activated immediately, as cuff pressure immediately after surgery may cause erosion of the cuff into the bladder. The sphincter may be activated after 6–8 weeks with less risk of erosion.[47]

Initially, there were concerns that performing intermittent catheterization through the implanted sphincter could cause damage to the tissue compressed by the cuff and lead to erosion. Sphincters were only placed in patients who could void, but as many as 50% of children cannot void efficiently after sphincter placement, making catheterization necessary.[48] Barrett and Furlow reported a series of children with neuropathic bladders who could not void after artificial sphincter surgery and found that intermittent catheterization could be performed safely if the cuff was deflated to pass the catheter.[49,50] Continence was good and no patients suffered erosion due to catheterization. It appears that the ability to void may deteriorate with time, particularly in boys with neurogenic bladder. Gonzalez et al reported that 74% of patients followed for a mean of 8 years after sphincter placement required intermittent catheterization.[44] Upsizing the sphincter cuff size in adolescent boys who suffer delayed voiding failure after sphincter placement has not been successful in restoring the ability to void.[51]

Historically, there has been a higher rate of reoperation with artificial sphincters than with bladder outlet reconfiguration.[52] This rate appears to be improving with better technique and newer devices. Kryger et al reported an average of 0.03 revisions per year with the newest model and 70% of children who had sphincters placed since 1987 have not required revision.[53] The long-term (7–10 years) survival of the artificial sphincter in children in two large series is approximately 80%, with most being lost to the complications of device infection and erosion.[45,54] Eventually, all devices will wear out and fail, requiring replacement, but if complications can be avoided the mean survival of the new devices in children is over 12 years.[43] The newest model (AS 800), with a narrow backing cuff, was developed in 1988. It had a

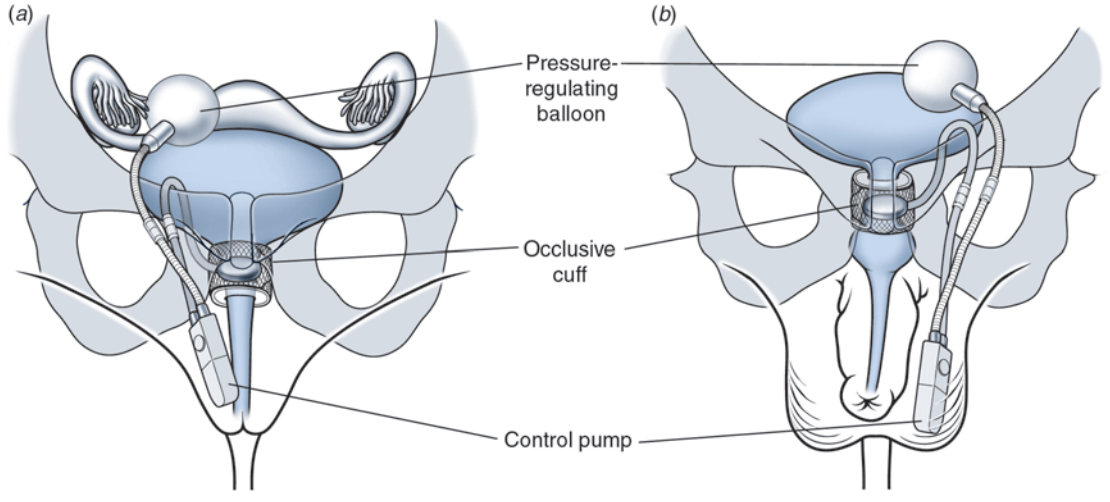

Figure 55.7 (*a*) Artificial urinary sphincter components in a female with the pump implanted in the labia. (*b*) Artificial urinary sphincter components in a male with the pump implanted in the scrotum. Both examples show the cuff implanted around the bladder neck.

mechanical failure rate of 7.6%, a non-mechanical failure rate of 9%, and a sphincter survival rate of 92% in 184 adult patients with a mean follow-up of 40.8 months.[55]

Roth and others reported an important complication of artificial sphincter placement in 1986 when they discovered that some patients suffered late deterioration of the upper urinary tracts.[56–58] This deterioration was due to two factors: a failure to void efficiently in some patients and the new development of detrusor hypertonicity in others. Deterioration of detrusor function after sphincter placement occurs in as many as 20% of patients and there is currently no reliable method to predict which patients will undergo these changes or the timetable for risk.[54,59] Because of this threat it is necessary to follow patients with artificial sphincters with upper tract imaging and urodynamics, as needed indefinitely after placement of the sphincter.

Augmentation cystoplasty, as either a simultaneous or later procedure with artificial sphincter placement, is necessary in approximately 30% of children.[44,60] Augmentation increases storage volume and decreases storage pressures of the bladder due to poor compliance or hypercontractatility of the detrusor. Augmentation may be performed at the same time as sphincter placement but has been associated with an increased risk of device infection if colon and small bowel are used for the augmentation.[61] Apparently, augmentation with stomach does not present an increased risk of infection in simultaneous sphincter placement.[62]

Patient selection for artificial urinary sphincter is important. Although there has been an increased risk of erosion with girls who had prior bladder neck surgery, Bosco et al have demonstrated that the risk to girls and boys is similar if they have not had prior bladder surgery.[63] The condition of the bladder outlet that will be compressed with the cuff is critical, and prior bladder neck surgery or excessive scarring increases the risk of erosion and infection.[64] Castera et al have reported that prior bladder neck surgery also impacts the continence rate after sphincter placement, resulting in only 37.5% continence in this group.[65]

The artificial urinary sphincter is the only method of producing variable bladder outlet resistance and thereby allowing volitional voiding. Its main indication today is in children who have the ability to void prior to surgery and the potential to do so after placement of the device. Use of the artificial sphincter in patients who require augmentation and intermittent catheterization offers little advantage over other methods to increase bladder outlet resistance.

Bladder outlet wraps

There have been a few attempts to compress the bladder neck with a fixed resistance and these have usually been in conjunction with bladder neck reconstruction surgery. Silicone rubber sheaths have been placed around the narrowed bladder neck, but in early series over 60% eroded into the lumen and required removal.[66] Quimby et al presented a large series of 94 patients treated with silicone sheaths used in conjunction with a Young–Dees–Leadbetter (YDL) bladder neck reconstruction. The authors continued to

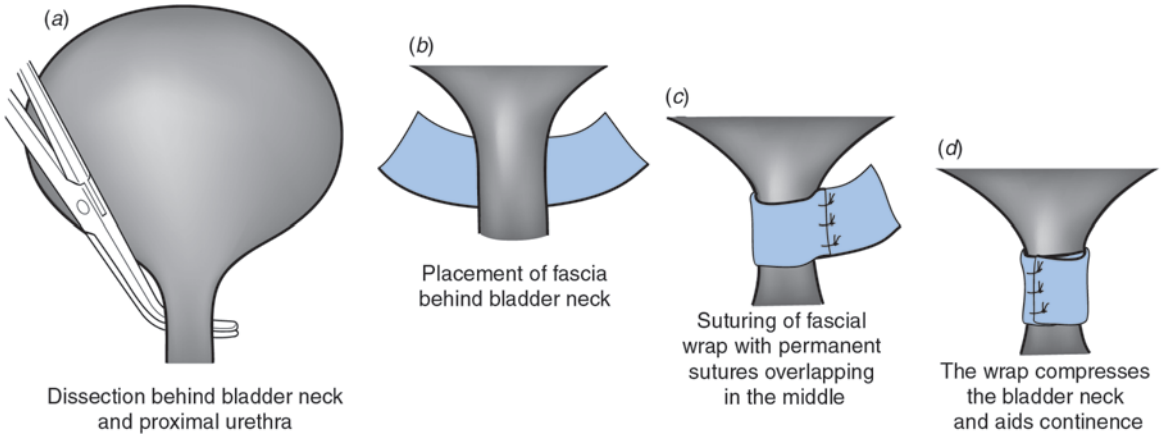

Figure 55.8 Walker described a fascial wrap of the bladder outlet in incontinent children. A strip of rectus fascia was harvested and wrapped around the bladder outlet and sewn together with permanent sutures. This provides consistent compression of the open bladder outlet and constant outlet resistance. Some patients with wide bladder outlets required bladder neck narrowing.

modify their technique until the erosion rated dropped to 7% in 35 patients. This improvement was attributed to using omentum to wrap the sheath and using a single-layer short silicone wrap. Satisfactory continence in this group was achieved in 72% of patients with this method[67] (Figure 55.8). Two other groups have reported synthetic constrictors or cuffs. de O Vilar et al reported a new device called a constrictor that compresses the bladder neck. It produced continence in all of the 42 patients in whom it was used; however, it had to be removed in 4 patients because of erosion or infection.[68] Kohn et al presented a series of children treated with a purse-string cuff around the bladder neck made of polytetrafluoroethylene (PTFE) tubing surrounding woven polyester tape:[69] 75% of patients were dry after surgery, but 30% of the devices had to be removed because of complications.

Walker et al described a procedure to wrap and compress the bladder neck circumferentially with rectus fascia with good results.[70] Some of their patients also needed bladder neck narrowing at the same time. Unlike silicone rubber, there were no erosions of the fascia, and post-surgery urodynamics showed that 70% of patients could not be made to leak at any pressure. Long-term follow-up of these patients indicates that the facial wrap and bladder dynamics are stable.[71] Bugg and Joseph presented a rectal fascia cinch that wraps around the bladder neck and is anchored to the pubis.[72] This procedure produced 60% continence. A myofascial flap made from rectus muscle can be used as a vascularized wrap and has been wrapped around the bladder neck and anchored to the pubic bone. This method has produced 75% continence in limited numbers.[73] Finally, a flap of bladder detrusor has been harvested and used to wrap around the bladder neck to compress the bladder neck.[74] Of course, any increase in fixed resistance at the bladder neck almost always precludes voiding and requires that the patient rely on CIC.

Injection therapy of the bladder outlet

Several substances have been injected under the mucosa of the bladder neck in order to increase intraluminal pressure generated by the weak bladder outlet and provide continence. The first substance used in significant numbers of patients was PTFE paste or Polytef.[75] Politanto et al popularized its use in adults and eventually applied the concept to children.[76,77] They reported 86% success rates in patients who were incontinent from bladder neck surgery and 50% in patients with neuropathic bladder. Injection therapy was relatively easy to perform and required no incision, so it could be done on an outpatient basis. Unfortunately, particles of Polytef were found to migrate to other organs in animal studies and particles were found in pulmonary granulomas in a human after periurethral injection.[78,79] Safety concerns have caused its abandonment in the United States. A newer form of silicone, polydimethylsiloxane or Macroplastique, has been used in Europe with continence achieved in 34% of patients.[80] It is not currently available in the United States. Other agents have been used, including autologous fat and collagen. Gonzalez de Garibay et al reported periurethral injection of fat

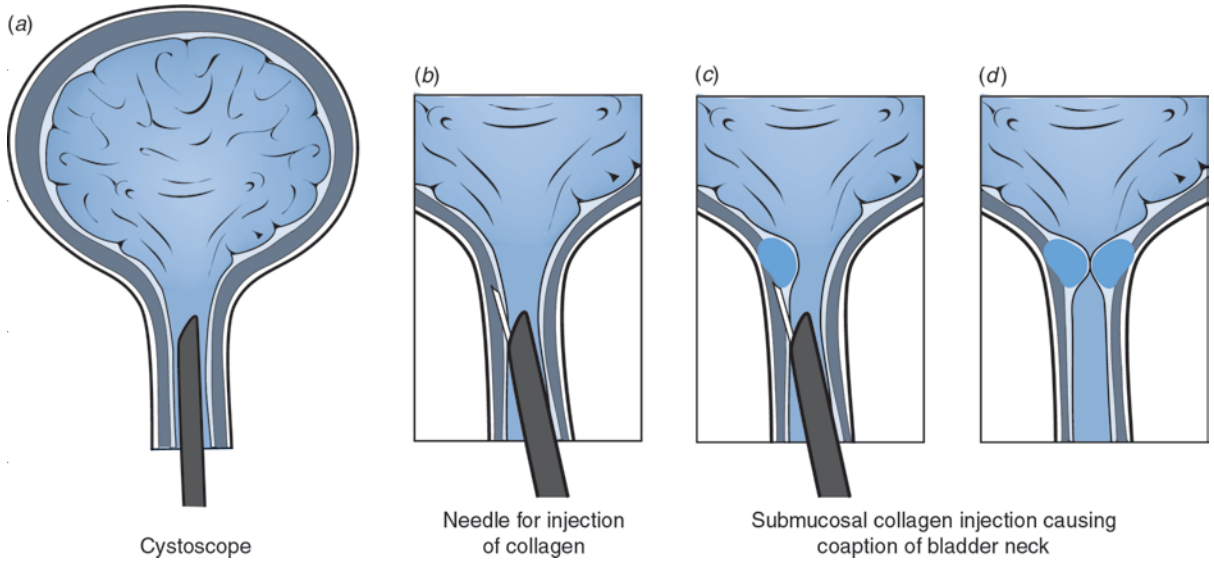

Figure 55.9 Injection of the bladder neck with various materials such as Polytef paste and collagen solutions has been used with more success in adults than in children. The needle is passed through a cystoscope and the material is injected submucosally either from the urethra or from a suprapubic approach. The material provides passive pressure to help to occlude the bladder outlet.

obtained from liposuction of the abdominal wall in 1989.[81] Initial success in treating incontinence was never as good as with Polytef, and the effects diminished with time because the fat did not survive due to poor neovascularity.[82] Eventually 80–90% of the injected fat was absorbed by the local tissue.

Gluteraldehyde cross-linked collagen has been one of the most common agents used to increase bladder outlet resistance. It has been used in the same manner as Polytef paste and is injected beneath the mucosa using a needle passed through a cystoscope (Figure 55.9). The success in treating children with incontinence has been inconsistent, with around 50–88% of patients considered to have a good result and 20–63% becoming dry.[83,84] Bomalaski et al reported a large series of collagen injections in children in 1996.[85] They reported a 22% cure rate of incontinence in 40 children, with improvement in another 54%. Of those patients with a mean follow-up of 4.5 years, the cure or improvement rate remained stable over time. Other clinicians have noted the biologic degradation of collagen and expressed concern about long-term durability.[86] Kassouf et al demonstrated poor results with collagen injections, in children with neuropathic bladder dysfunction. Only 20% of their patients improved after injection, and all of these eventually deteriorated within 2 months after treatment.[87]

The limited success and potential degradation should be explained to the patient and family. Also, 2.5% of patients are allergic to the collagen from dietary exposure and an additional 0.9% may develop late hypersensitivity.[88] Preoperative skin testing is necessary to establish that the patient does not have antibodies to the collagen and is less likely to react to the injection.

The newest agent to be used for injection of the bladder neck for incontinence is Deflux (dextranomer/hyaluronic acid copolymer). We have injected Deflux into the bladder neck of 16 children with bladder outlet incompetence. Of the 12 with neuropathic bladder, 25% were dry and an additional 33% improved after injection therapy, with a mean follow-up of only 9 months. None of the patients with other causes of incontinence achieved continence, whereas 33% showed improvement. No patients who performed intermittent catheterization through their urethra improved.[89]

With the widespread use of catheterizable urinary stomas in children with neuropathic incontinence, antegrade bladder neck injection of bulking agents through the catheterization channel has merit. The visualization of the bladder outlet from above is superior to the visualization from the urethra.

These mixed findings have limited injection therapy in most pediatric urologist's hands to incontinent patients who have had failed bladder neck reconstruction surgery. Up to 50% of these patients may become dry with injection therapy but some require

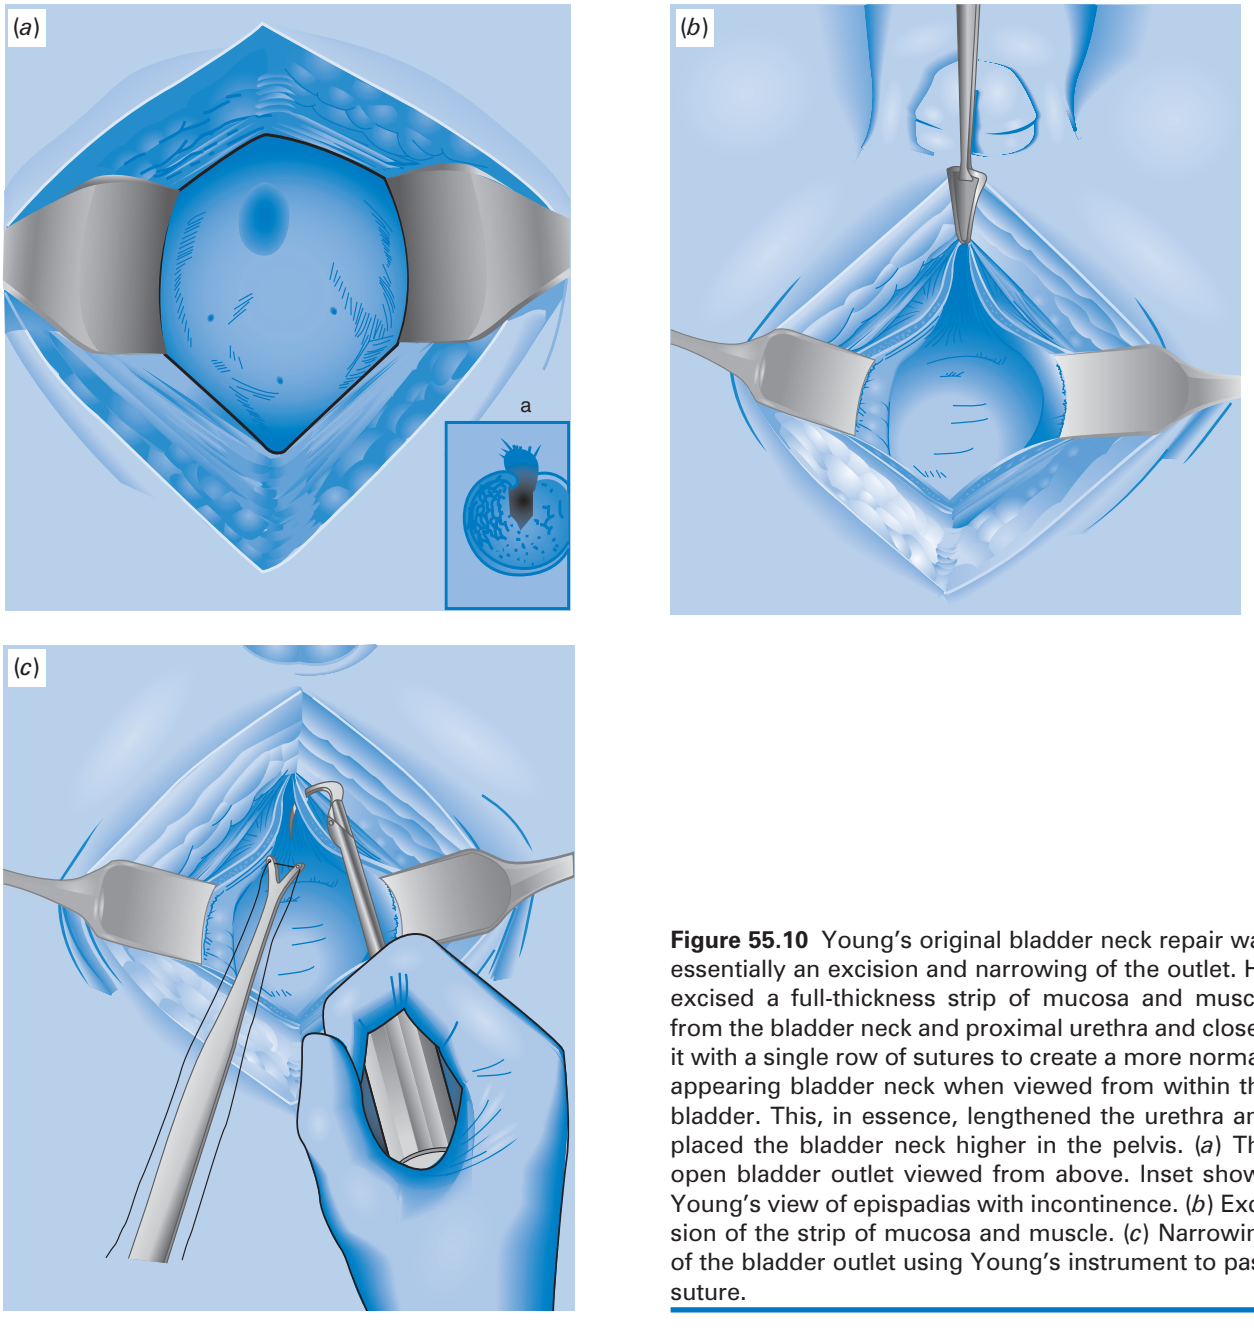

Figure 55.10 Young's original bladder neck repair was essentially an excision and narrowing of the outlet. He excised a full-thickness strip of mucosa and muscle from the bladder neck and proximal urethra and closed it with a single row of sutures to create a more normal-appearing bladder neck when viewed from within the bladder. This, in essence, lengthened the urethra and placed the bladder neck higher in the pelvis. (*a*) The open bladder outlet viewed from above. Inset shows Young's view of epispadias with incontinence. (*b*) Excision of the strip of mucosa and muscle. (*c*) Narrowing of the bladder outlet using Young's instrument to pass suture.

multiple injections.[90] This is a simple and safe outpatient procedure, but the results may degrade with time and its effects diminish.

Surgical reconfiguration of the bladder outlet

Young–Dees–Leadbetter procedure

In 1922 Hugh Young presented a refined procedure to reconfigure the inadequate bladder outlet in epispadiac patients who were incontinent due to bladder outlet incontinence.[91] Young had altered his approach from narrowing the posterior bladder outlet to narrowing the anterior urethral and bladder neck. He excised a full-thickness strip of tissue from the 'funnel-like neck' of the bladder and reapproximated the sides with a single row of chromic catgut sutures to create a more normal appearance (Figure 55.10). Ureterosigmoidostomy diversion was the accepted surgical treatment of incontinence due to epispadias and exstrophy prior to Young's procedure.[92] Young was obviously pleased with the results of his proce-

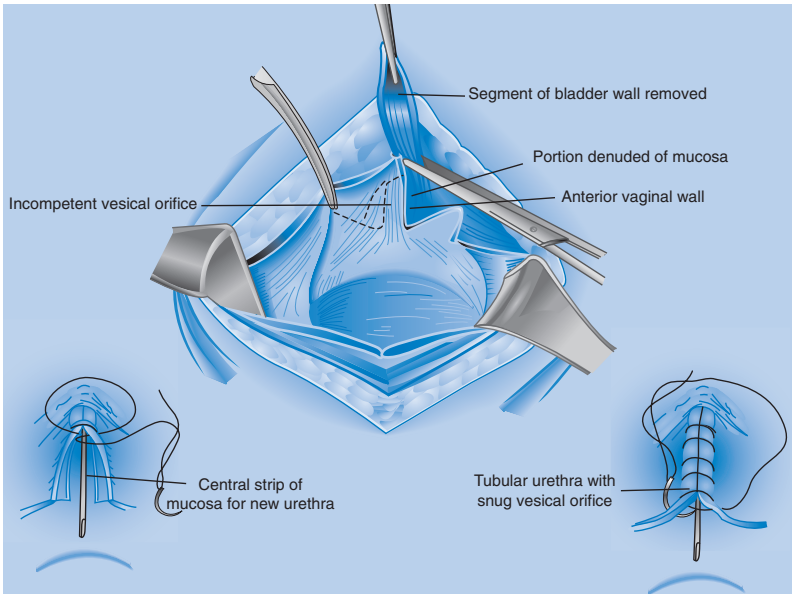

Figure 55.11 Dee's revision of Young's procedure extended the posterior urethral flap into the bladder and allowed a longer neourethra. He removed the mucosa from the muscle on the lateral aspect of this flap and, after closing the central flap of mucosa into a tube, he closed the muscle over the mucosa in a second layer. This provided additional muscle around the neourethra.

dure and reported, 'No fistula, no stricture, perfect urinary control, sexual powers normal'. For over 25 years after Young first presented his method to reconfigure the bladder neck for epispadias, his procedure remained the best surgical treatment for urinary incontinence due to a weak bladder outlet.

In 1949, John Dees improved upon Young's procedure by extending the posterior urethral flap into the bladder and removing the mucosa from the muscle on the lateral aspect of this flap. This posterior strip of urethra and bladder was then closed in two layers, mucosa and muscle, to form a neourethra[93] (Figure 55.11). Whereas Young had been content to narrow the proximal urethra and bladder neck, Dees changed the position of the bladder neck itself. He created a long neourethra from tissue that normally would have been the posterior bladder wall. The result was to move the bladder outlet higher into the pelvis and provide a longer, more muscular, urethra.

In 1964, Guy Leadbetter advanced this concept further by extending the posterior bladder flap even higher into the bladder.[94] This was made possible by moving the ureters from their normal location to a more cranial position further from the urethra and original bladder neck. The position of the ureters had been the limiting factor when Dees created his neourethra and moved the bladder neck above its natural location. Leadbetter moved the ureters out of the way by mobilizing them and reimplanting them transversely across the posterior bladder wall well above the trigone.

By extending the neourethra higher in the bladder, Leadbetter was also presented with a wider strip of bladder to use for his neourethra. A narrow strip of mucosa was left in the central portion of the neourethra. This was tubularized, the entire mucosa lateral to the strip was excised, and the two flaps of muscle lateral to the neourethra were then wrapped over the mucosa in an overlapping fashion, providing additional muscular support to the neourethra and bladder neck (Figure 55.12). With few changes today, the Young–Dees–Leadbetter bladder neck repair remains the gold standard of bladder neck reconstruction. Continence has been obtained in 78% of patients with neuropathic bladders and in 80% of exstrophy patients.[95–97] It must be noted that augmentation cystoplasty was necessary to obtain this degree of continence in 90% of the neuropathic bladder children in our series and in 50% of the exstrophy–epispadias patients in the Mayo Clinic series.

Disadvantages of the YDL bladder neck reconstruction include loss of significant bladder capacity that results from the reallocation of bladder wall tissue to the urethral continence mechanism. The neourethra may be tortuous and difficult to catheterize.

Variations of the Young–Dees–Leadbetter procedure

Of the many variations to the YDL, that of Mollard is closest to the original.[98] He creates a 7 cm long urethral strip that is wide enough to close over a 10 Fr catheter and removes the mucosa from the triangular muscle flaps lateral to the strip. He then incises one of the periurethral muscular flaps vertically parallel to the strip and rotates it horizontally across the midline

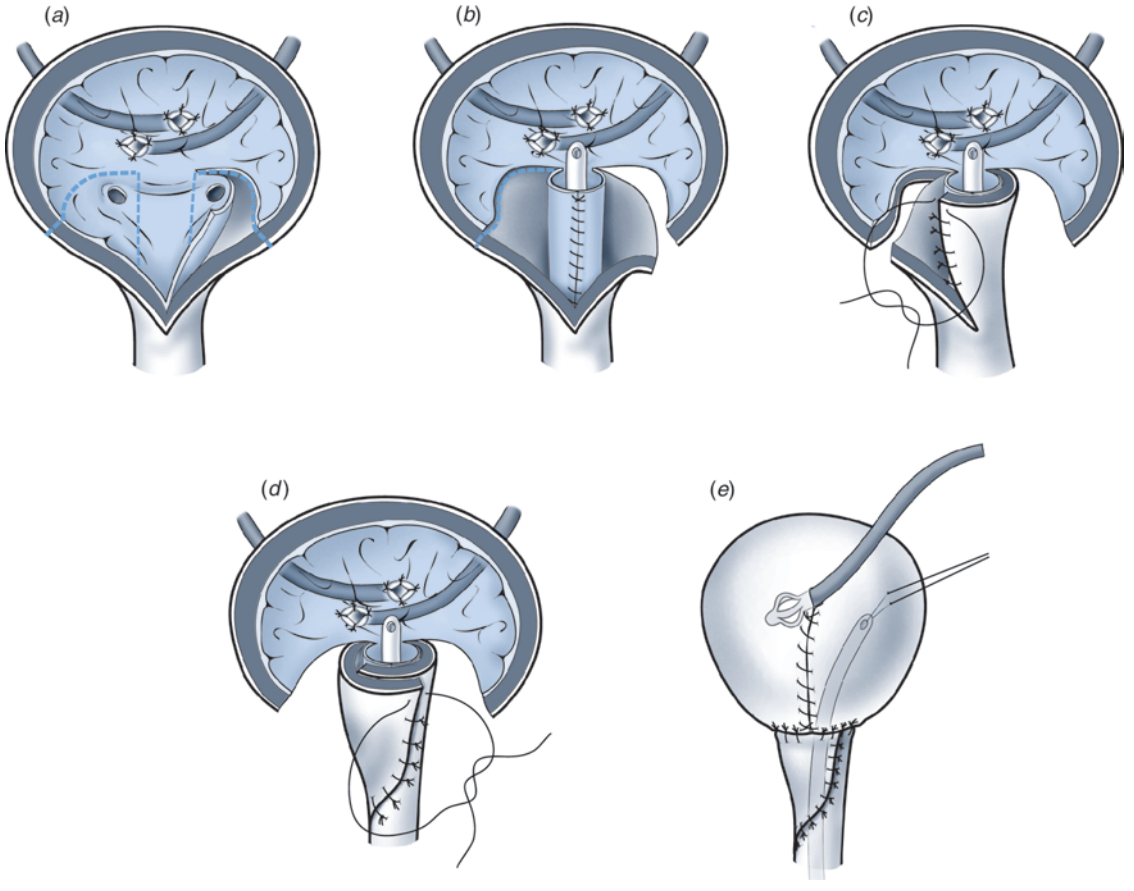

Figure 55.12 Leadbetter further improved upon the Young–Dees bladder neck repair by moving the ureters to a new location higher along the posterior bladder wall and away from the urethra. This maneuver allowed the posterior bladder strip to be even longer and produce a long neourethra and a much higher bladder neck. (*a* and *b*) Leadbetter removed the mucosa from the triangular flaps of bladder muscle on each side of the mucosal strip that was to be used for the neourethra. (*c*) After rolling the strip into a tube for the neourethra, he closed the lateral muscle flaps over the neourethra in layers to provide even more muscle at the bladder outlet. (*d*) Muscle is rotated over the neourethra in an overlapping fashion. (*e*) Dependable bladder drainage is necessary.

in order to develop an anterior bladder neck angle (Figure 55.13). Mollard's procedure has been applied mostly to exstrophy patients, and he has achieved a 70% continence rate.

Koff's variation on the YDL also differs from the original in its use of the periurethral muscle flaps.[99] Koff's initial incision is on the lateral aspect of the bladder neck, rather than the midline, and this produces a single long muscle flap on one side of the bladder. After he moves the ureters cephalad, Koff then strips the mucosa from the long muscle flap, leaving a midline strip of urethra and bladder to tubularize for the neourethra. The long muscle flap is then wrapped around the neourethra, producing what he has termed 'the cinch' (Figure 55.14). Koff has achieved 80% continence rates in mostly exstrophy patients. All of the patients have had significant difficulties voiding. Forty percent of the children required bladder augmentation and intermittent catheterization. Bladder capacity is lost to a similar degree as in the YDL procedure.

Mitchell returned to Young's original concept of a narrowed neourethra without added muscular support.[100] He noted that overlapping bladder muscle flaps used to create more outlet resistance made the bladder smaller by reducing the bladder itself. Mitchell's procedure is the only bladder neck repair that does not decrease bladder capacity as the anterior bladder and urethral flap is incorporated into the bladder (Figure 55.15). He mobilized a triangular full-thickness flap of anterior urethra and bladder neck and then narrowed the bladder outlet. The flap was then rotated cephalad and integrated into the bladder. Continence was achieved in 64% of patients who all voided, and were a mixed group of children including neuropathic bladders and exstrophy.

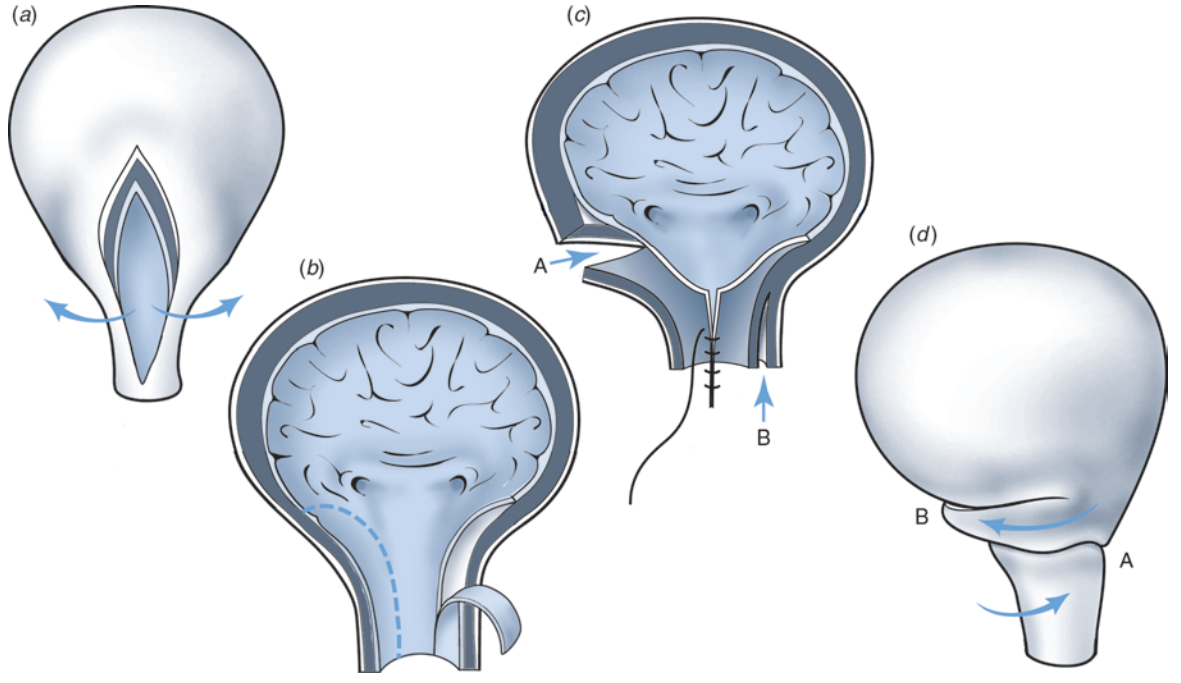

Figure 55.13 Mollard's variation of the Young–Dees–Leadbetter procedure is similar in the construction of the neourethra from a long posterior strip of urethra and bladder. It differs in that one of the two triangular flaps is incised vertically and parallel to the neourethra. This flap is then rotated horizontally across the midline to create an angle of the anterior bladder neck. (*a*) The bladder is opened in the midline. (*b*) The mucosa lateral to the central urethal strip is excised. (*c*) The two lateral muscle flaps are incised, one vertically and one horizontally. (*d*) Flap (A) is wrapped around the neourethra like the YDL operation, while flap (*b*) is rotated horizontally across the repair to create an anterior bladder neck.

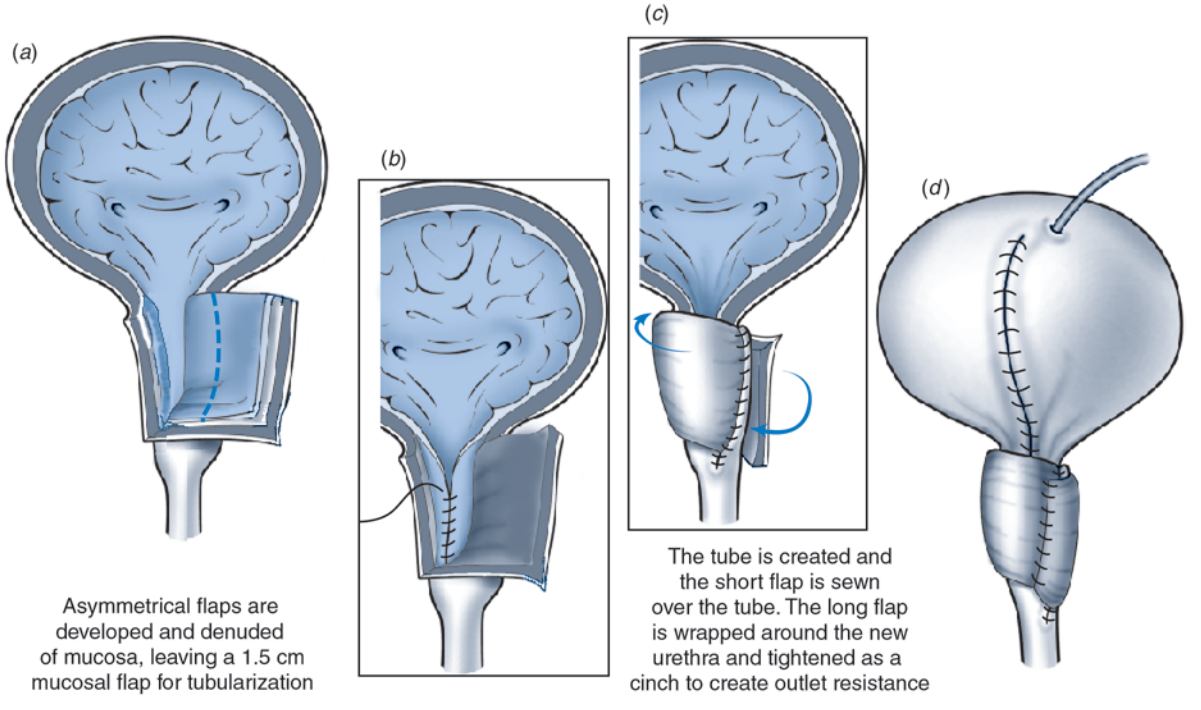

Figure 55.14 Koff's variation of the Young–Dees–Leadbetter procedure also creates the neourethra from a posterior flap of urethra and bladder and covers it with a flap of demucosalized muscle. The construction of this flap is different to other repairs that rely on two flaps. Koff makes a lateral incision of the bladder neck instead of opening the midline. This creates a single long flap on one side of the neourethra. The flap is then wrapped around the neourethra and sewn to itself with permanent sutures. It acts as a constant compression of the bladder outlet. (*a*) The bladder outlet is opened on one side. (*b*) A midline mucosal strip is tubularized and the mucosa is dissected from the remaining muscle flap. (*c* and *d*) The muscle flap is then rotated around the bladder outlet.

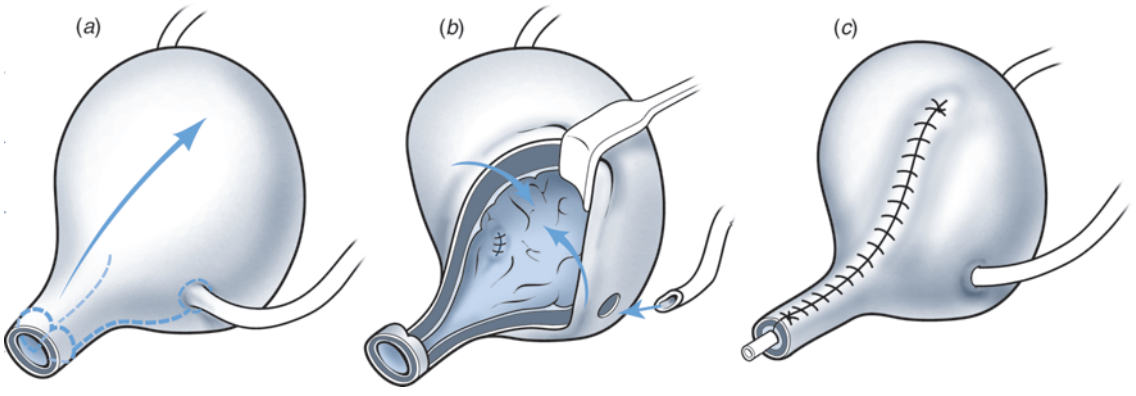

Figure 55.15 Mitchell returned to Young's original concept of a narrowed bladder neck that is not reinforced with additional muscle layers. His repair mobilizes a triangular flap of anterior bladder and urethra based on the bladder-side blood supply and then rotates the flap into the bladder. It is the only repair that does not decrease bladder volume. (*a*) An incision is made across the anterior urethra, extending up along the posterior lateral wall of the bladder outlet on each side. (*b*) The flap of bladder and urethra is rotated back into the bladder. (*c*) The incision is closed in the midline.

Some other variations of the YDL procedure have been developed, including Koyle's Thiersch–Duplay type-tubularization of the posterior bladder wall.[101] This procedure isolates and rolls a strip of mucosa into a tube in situ and then closes muscle and mucosa over the tube by rolling in the lateral tissue (Figure 55.16). He calls this the reverse Kropp or pPork repair, and has achieved 82% continence in neuropathic bladder patients. There may be problems with catheterization per urethra, and therefore all of his patients had an alternative access for bladder catheterization.

Arap et al presented the most radical variation of the YDL posterior-tube bladder neck repair for use in the most severe cases of exstrophy with tiny bladder plates.[102] Their procedure is performed in two stages: the first stage is creation of a colon conduit with antirefluxing ureterocolonic anastomosis; the second procedure creates a tube in the same manner as the YDL procedure but uses the entire bladder except for the dome, which is left open as a wide funnel (Figure 55.17).

The previously created colon conduit is then reconfigured as a reservoir and attached to the funneled

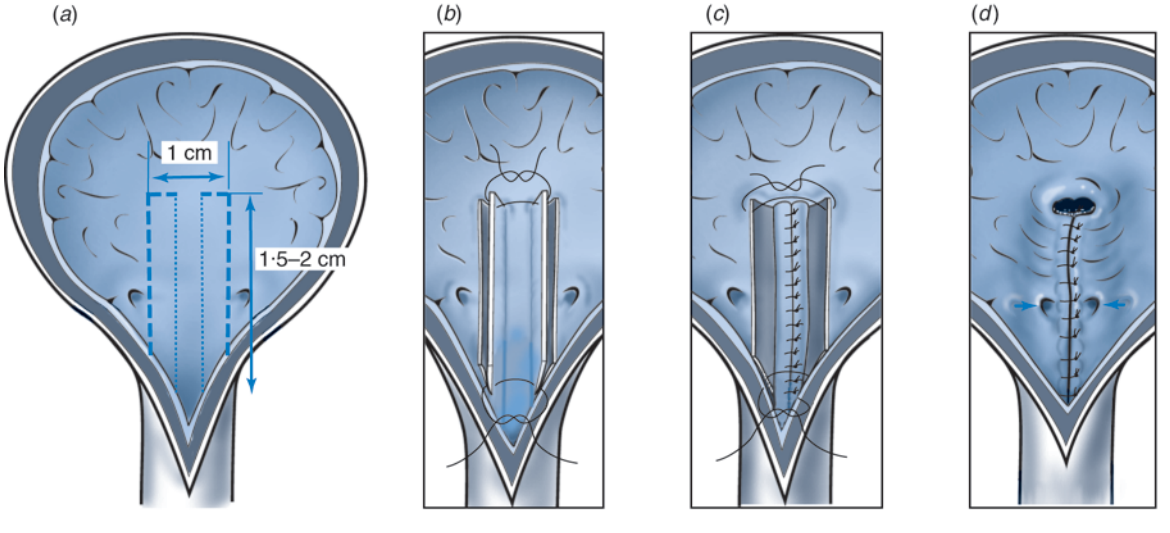

Figure 55.16 Koyle presented a bladder neck reconfiguration that isolates a strip of posterior mucosa in the posterior midline of the bladder. This strip is then rolled into a tube, creating a neourethra. Finally, the neourethra is covered with flaps of muscle and mucosa that have been mobilized lateral to the neourethra. (*a*) A mucosal flap is outlined. (*b*) The flap is then tubularized. (*c*) A second layer of muscle is closed. (*d*) Lateral mucosa is closed over the tube.

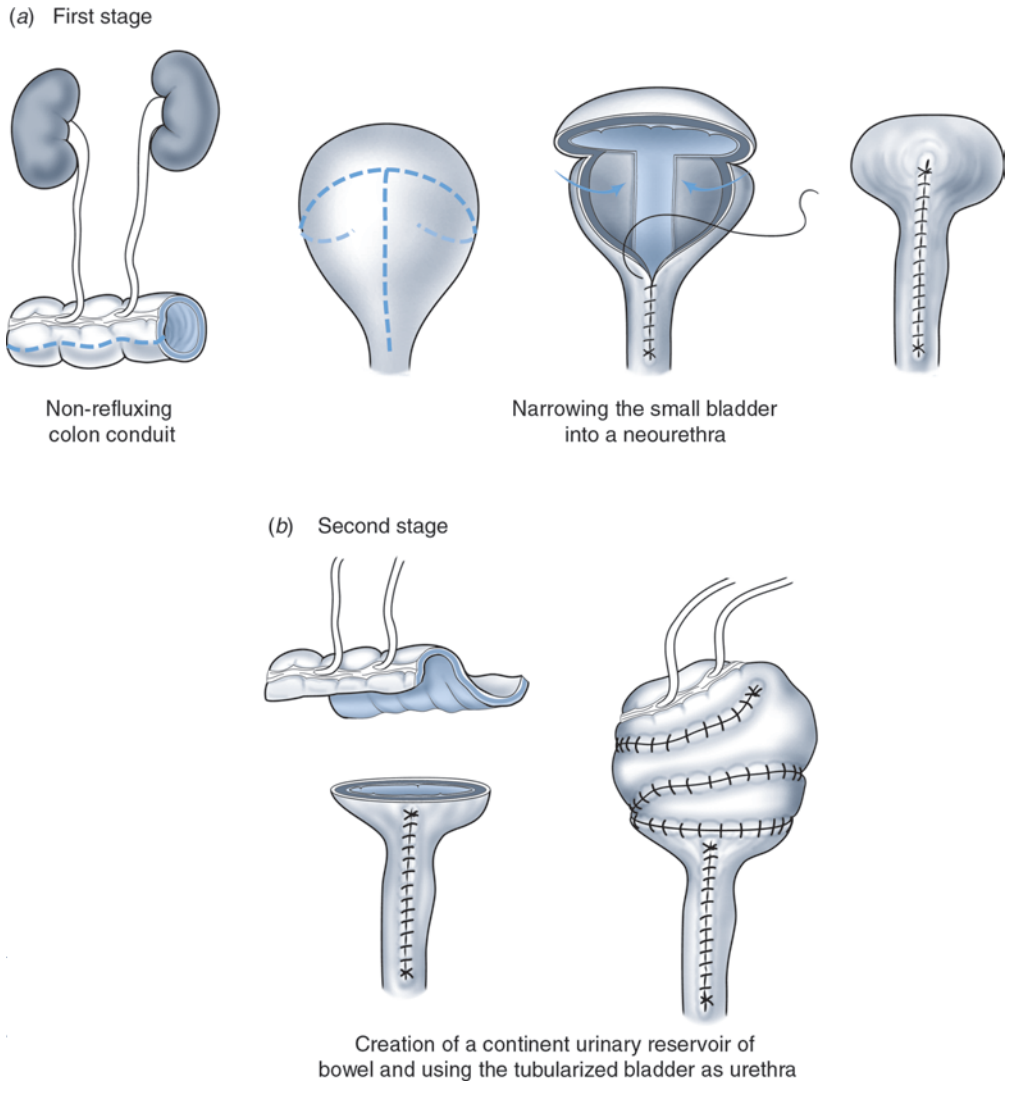

Figure 55.17 Arap's staged bladder reconstruction is the most radical reconfiguration of the bladder outlet. In the first stage the ureters are transplanted from the bladder plate to a non-refluxing anastomosis into a colon conduit. The second procedure creates a neourethra from the entire bladder except for the dome, which is left open as a wide funnel. The colon conduit is then reconfigured as a reservoir and sewn to the funneled bladder.

bladder plate. Arap reported a 75% continence rate with patients voiding frequently. Intermittent catheterization has provided continence and allowed a long dry interval in our limited experience with the Arap procedure.

Tanagho bladder neck repair

In 1968, Tanagho was studying function and anatomy of bladder muscle when he noticed 'a condensation of circle fibers above the internal meatus'.[103] He then designed the first anterior bladder tube repair for incontinence and perfected it in dogs.[104] Three years later he presented his experience in patients, including postprostatectomy adults.[105]

Tanagho intended to capture the muscle fibers of the anterior bladder and incorporate them into the bladder neck. He created a bladder-based flap from the anterior bladder just proximal to the urethra and rolled it into a tube for the neourethra (Figure 55.18). He then divided the urethra from the original bladder neck and anastomosed the neourethra to the native urethra end to end. The effect of this maneuver was to lengthen the urethra and to create a new, more cephalad bladder neck.

Tanagho achieved a 72% continence rate and patients voided well. He compared his long-term results in 50 patients to the YDL procedure performed in 25 patients and found a 70% success with the Tanagho anterior bladder tube compared with

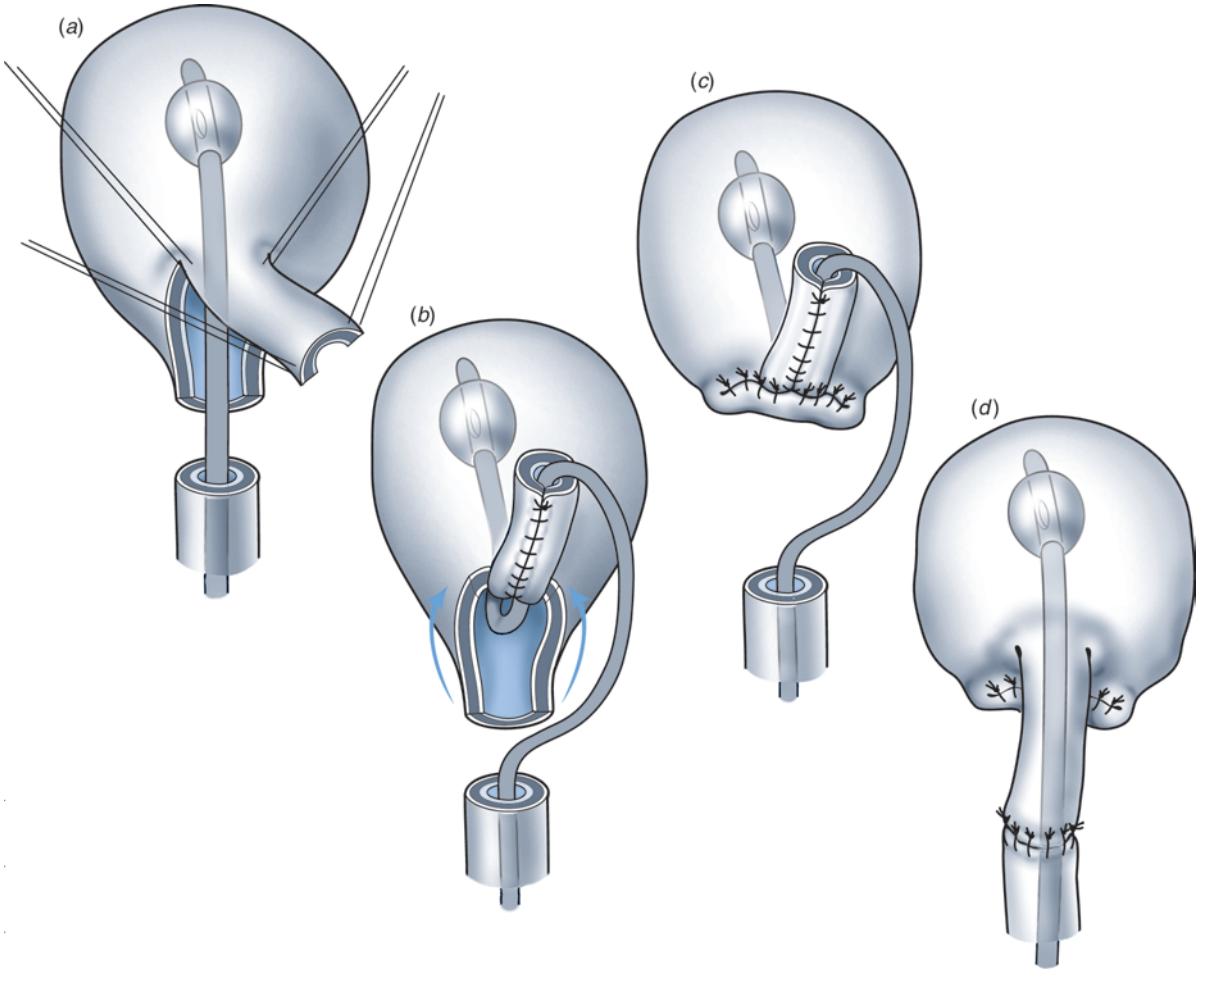

Figure 55.18 Tanagho's procedure created a neourethra from a strip of the anterior bladder neck and bladder. This allowed the creation of an angle at the posterior bladder neck. It required complete separation of the bladder from the urethra and a reanastomosis of the neourethra to the native urethra. (*a*) The bladder outlet is divided from the urethra and an anterior bladder-based tube is formed. (*b*) The flap is tubularized. (*c*) The posterior bladder is closed. (*d*) The tube is sewn to the urethra.

52% with the YDL posterior tube.[106] One advantage of Tanagho's bladder-based anterior flap was its applicability to short urethras, as demonstrated by Diamond and Ransley in urogenital sinus patients.[107] This application remains as the most likely use of the Tanagho repair in children today. Disadvantages include the necessity to divide the bladder from the urethra, possibly resulting in difficult catheterization, and loss of bladder volume.

Kropp bladder neck repair

In 1972, Jack Lapides made a contribution that changed forever our attitude and approach toward incontinence surgery.[108] His introduction of CIC controlled infection, decreased bladder pressure, and made many patients continent without further surgery.[109] CIC made voiding an option rather than a requirement, and changed the goals and results of incontinence surgery.

Kropp was the first surgeon to develop a new bladder neck reconstruction designed to take full advantage of CIC.[110] The goals of the surgery had changed. Dryness was foremost and voiding was no longer a consideration. CIC had been used in patients with other forms of bladder neck reconstruction before this, but they were all procedures that allowed the patient to void, at least in theory. The Kropp procedure was the first to preclude voiding.

The Kropp procedure uses a full-thickness flap of anterior bladder muscle. This flap is based on the urethra, unlike Tanagho's flap, which is based on the bladder. The full-thickness bladder flap is isolated from the bladder and rolled into a tube of the same

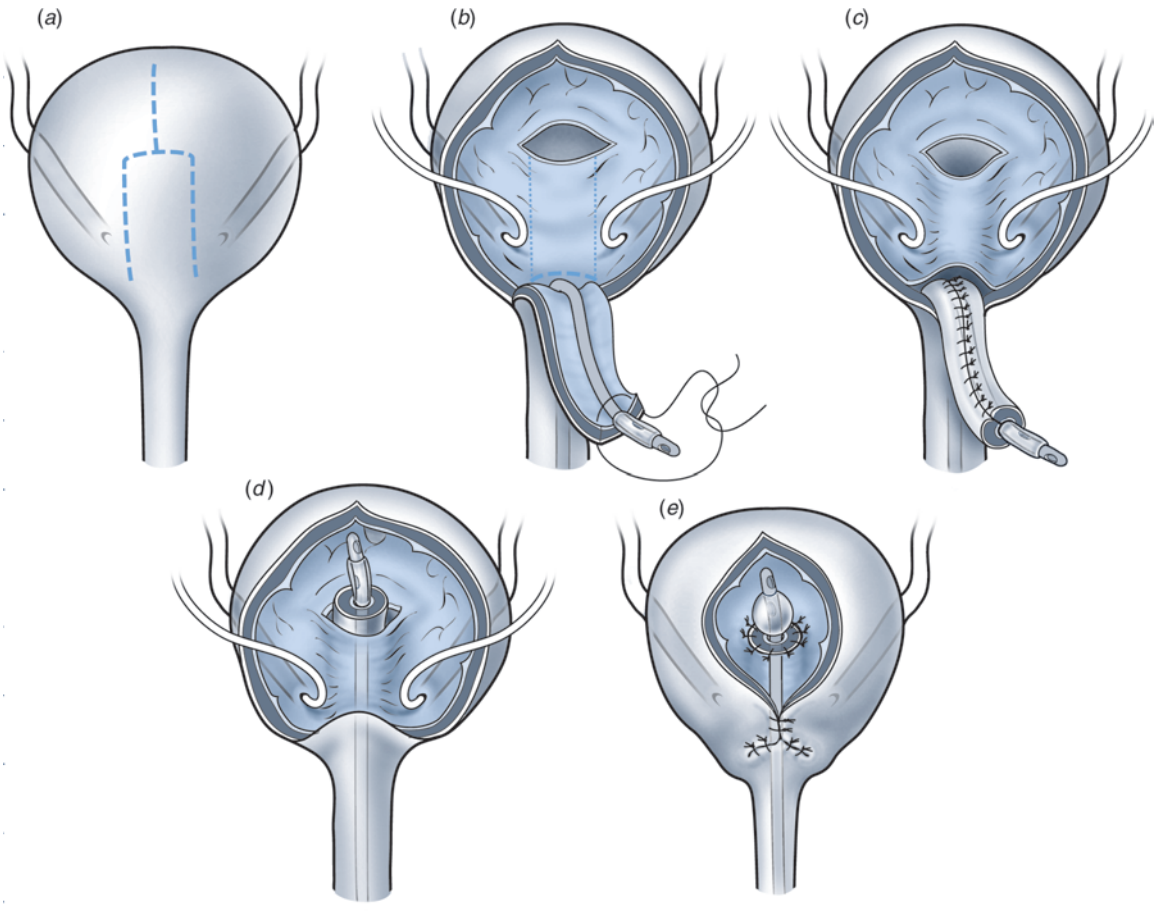

Figure 55.19 Kropp also creates a neourethra from a flap of anterior bladder neck and bladder but, unlike Tanagho, Kropp's flap is based on the urethra. The flap is tubularized and then placed in a submucosal tunnel created along the midline of the posterior bladder wall. (*a*) An anterior urethral-based flap is mobilized. (*b* and *c*) The flap is tubularized. A submucosal tunnel is made in the posterior bladder wall. (*d* and *e*) The tube is placed in the tunnel.

diameter as the urethra. The tube is then reimplanted in a submucosal tunnel in the midline of the posterior bladder wall between the ureters (Figure 55.19).

Advantages of Kropp's reconstruction included a very high continence rate of 80–94%.[111,112] Kropp's strict definition of continence has been complete dryness or rare leakage. The reoperation rate was high in the original series but most secondary procedures involved the storage function of the bladder and only 20% of patients required additional surgery to the bladder outlet. To facilitate storage and to compensate from bladder volume lost in construction of the tube, Kropp now suggests that all patients undergo a simultaneous bladder augmentation. There have been problems catheterizing through the repair but the improvement of leaving lateral attachments at the bladder neck intact and not completely separating the neourethra from the bladder has minimized this difficulty.

In 1997, Snodgrass reported a series of 22 children treated with the modified Kropp procedure described by Belman and Kaplan.[112,113] Snodgrass created a urethral-based flap of anterior bladder wall and rolled it into a tube. He did not divide the bladder neck from the remainder of the bladder. The posterior bladder mucosa is then incised in the midline to create a trough and the tube is laid in this trough with the mucosa closed over the tube (Figure 55.20) No attempt is made to tunnel the tube. He reported a 91% continence rate, defined as dry intervals of 3 hours. Snodgrass notes that these patients are socially continent and will have slight leakage when catheterization is delayed. Bladder augmentation was performed in 91% of his patients at the same time as bladder outlet surgery. Just as in the original Kropp procedure, voiding is impossible.

Pippi Salle bladder neck repair

Pippi Salle developed a bladder outlet repair for incontinence by creating a neourethra composed of both

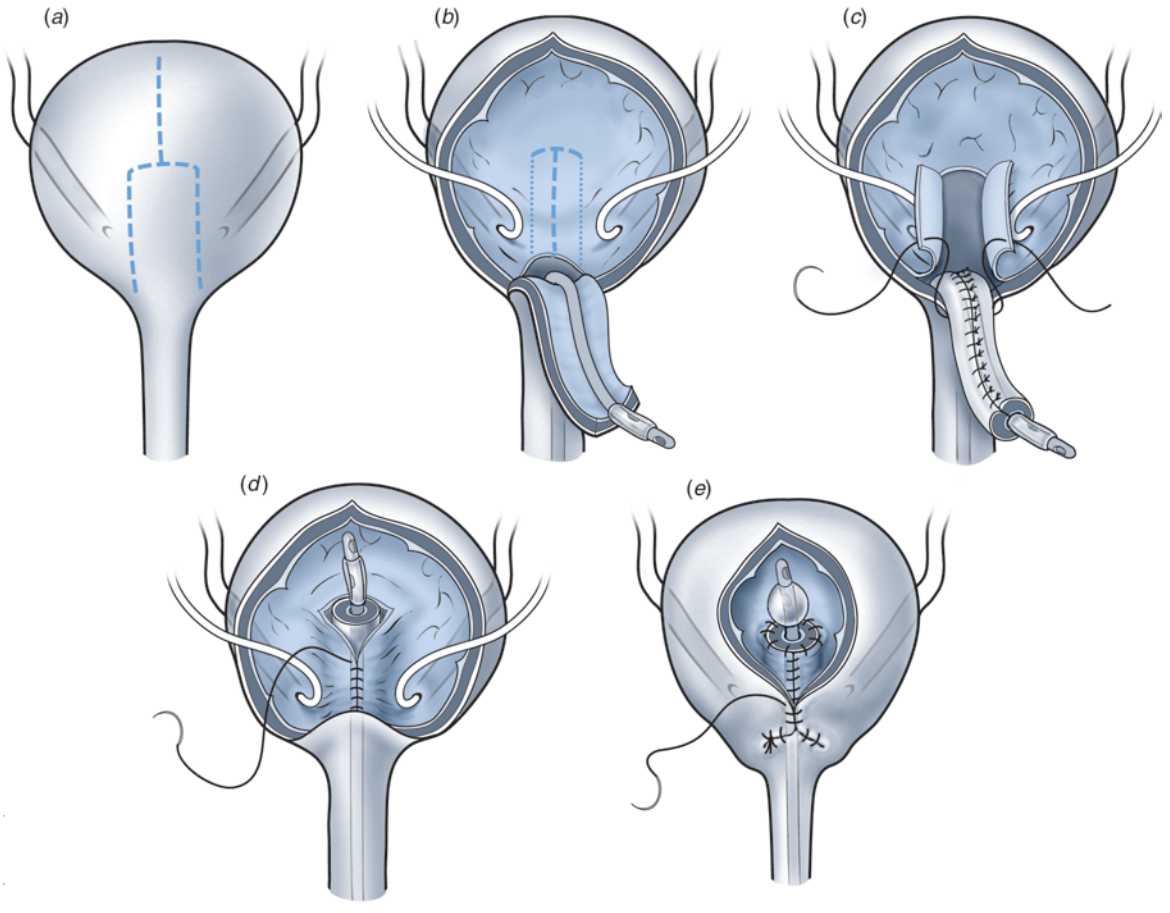

Figure 55.20 The Snodgrass variation of the Kropp procedure lays the Kropp tube in a trough instead of a tunnel. Construction of the tube is identical to Kropp. Creation of the trough shown in figures b, c and d is the only different maneuver.

anterior and posterior bladder flaps.[114] This flap valve continence mechanism produces the only neourethra made of two separate flaps. Both anterior and posterior strips of bladder are isolated and the anterior flap is completely mobilized as a flap based on the urethra. The posterior flap is outlined with two parallel mucosal incisions and the posterior bladder muscle is left intact. The anterior bladder flap is then flipped down to oppose the posterior flap at the level of the posterior bladder wall. The two flaps are sewn together, creating a neourethra, which extends above the level of the ureters (Figure 55.21). Mucosa on either side of the strip of posterior bladder wall is mobilized and the muscle from the anterior strip is sewn to the muscle of the posterior bladder. The complete-thickness bladder tube is then covered with the previously mobilized bladder mucosa just lateral to the tube.

The Pippi Salle repair produces continence rates of 80%, and this repair is easy to catheterize primarily because the posterior wall remains intact.[115] Bladder volume is decreased by the use of bladder wall to create the continence mechanism. This repair also requires the patient to catheterize, as voiding is impossible. McLorie and Khoury have warned about the potential danger of damaging the blood supply while isolating the long thin anterior bladder flap.[116]

Bladder neck closure

The ultimate bladder neck reconfiguration is complete closure of the bladder outlet. Today, after years of experience, we feel that most but not all bladder necks can be made continent. Those, that cannot be repaired can be closed. The concept of bladder neck closure was made a viable option in 1980 when Paul Mitrofanoff constructed the continent appendicovesicostomy and combined it with bladder neck closure in patients with neurogenic bladder[117] (Figure 55.22). Duckett and Snyder presented variations of bladder neck closure and continent stomas and Van Savage et al presented a series of 46 children with closure of bladder neck.[118,119]

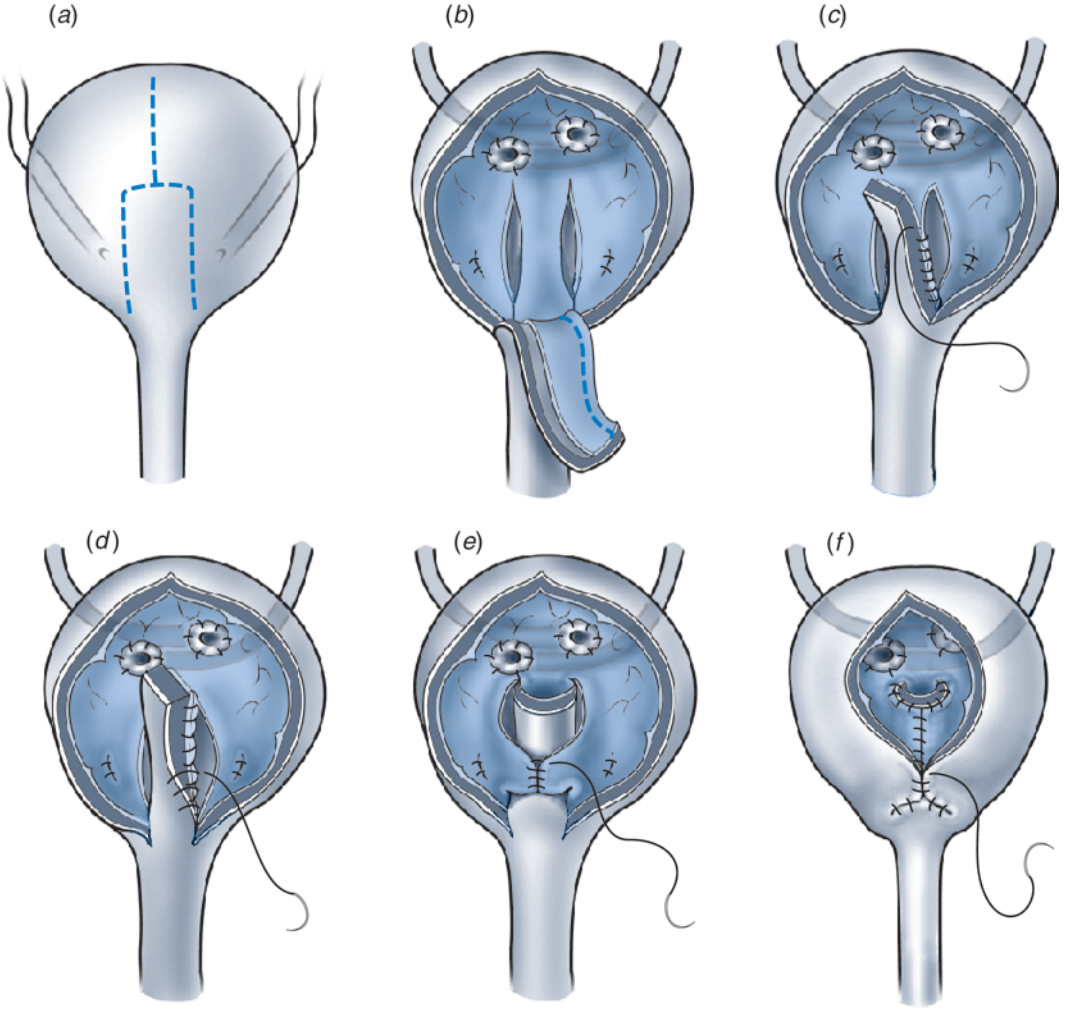

Figure 55.21 Pippi Salle creates a neourethra from an anterior and a posterior strip of bladder neck and bladder. The two are sewn together but only the anterior flap is mobilized completely. The posterior flap is isolated but not mobilized from the posterior bladder wall. The neourethra is then covered with mucosa and some muscle which is mobilized on each side. (*a*) An anterior bladder flap is mobilized. (*b*) A posterior bladder mucosal flap is mobilized. (*c*) The mucosa of the anterior and posterior flaps are sewn together. (*d*) The muscle of the flaps is sewn together. (*e* and *f*) The bladder mucosa in closed over the neourethra.

In general, bladder neck closure is a procedure of last resort and is utilized after other more flexible options in bladder neck reconstruction have been exhausted.[120,121] The indications for bladder neck closure are intractable urinary incontinence resistant to maximal medical management and reasonable surgical management. Patients usually have failed previous incontinence surgery or suffer from a primary condition that projects failure. The obvious advantage is complete urethral continence in as many as 96% of patients. Eighty-nine percent have stable upper urinary tracts and no bladder capacity is lost in the creation of a continence mechanism.[122] Disadvantages include a complete lifelong reliance on an extra-anatomic method of bladder emptying and no pressure pop-off valve. Bladder neck closure does have complications, with one series reporting initial results of 20% with stomal incontinence and 40% with urethral fistulas and persistent urethral leakage.[123] With surgical revision, 85% became completely continent. In reviewing multiple reports, 65% of patients with closed bladder necks require additional surgery for complications such as fistulas, stones, augmentation, ruptures, and other revisions.

The Mitrofanoff principle

Mitrofanoff's contribution, now termed the Mitrofanoff principle, has had a profound effect on incontinence surgery in children. His development of

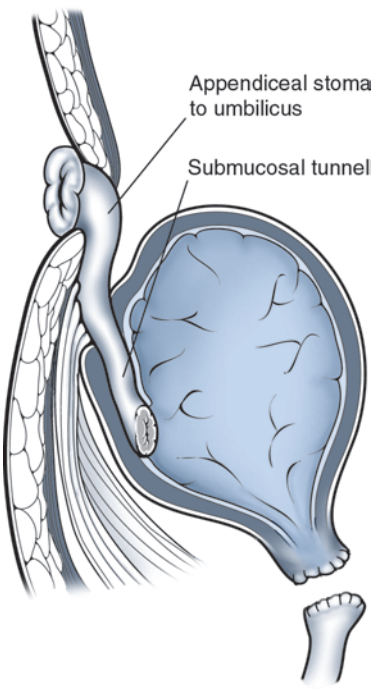

Figure 55.22 Mitrofanoff used a continent catheterizable stoma to empty the bladder. By implanting the appendix into the bladder in a continent manner, he allowed efficient bladder emptying without relying on the urethra. This allowed him to close the bladder neck surgically, leaving the appendix as the only access with which to empty the bladder.

alternative continent bladder access through a continent stoma has relieved the necessity for the patient to either void efficiently or to catheterize through the reconstructed bladder neck. There have been other alternatives to Mitrofanoff's original use of appendix for extra-anatomic access to the bladder. Other options for continent bladder access include ureter, fallopian tube, bladder tubes, and tubularized bowel.[124–126] With the recent interest in the Malone antegrade continence enema (MACE) for patients with neuropathic bowel and bladder, the appendix has been used more often as access to the colon.[127] Tubularized ileum and Yang/Monti tubes have been the most dependable and flexible method of bladder access for these patients[128] (Figure 55.23). We have developed a longer ileal tube for patients with a greater distance between the bladder and skin[129] (Figure 55.24). Today, an easily accessible, continent, catheterizable access for emptying the bladder is available for almost all patients.

We believe that catheterizable abdominal stomas promote continence by avoiding manipulation of the reconstructed bladder neck. In some cases they encourage patient compliance with intermittent catheterization because catheterizing through an abdominal stoma is easier and less time consuming than urethral catheterization for many patients. Regular catheterization keeps

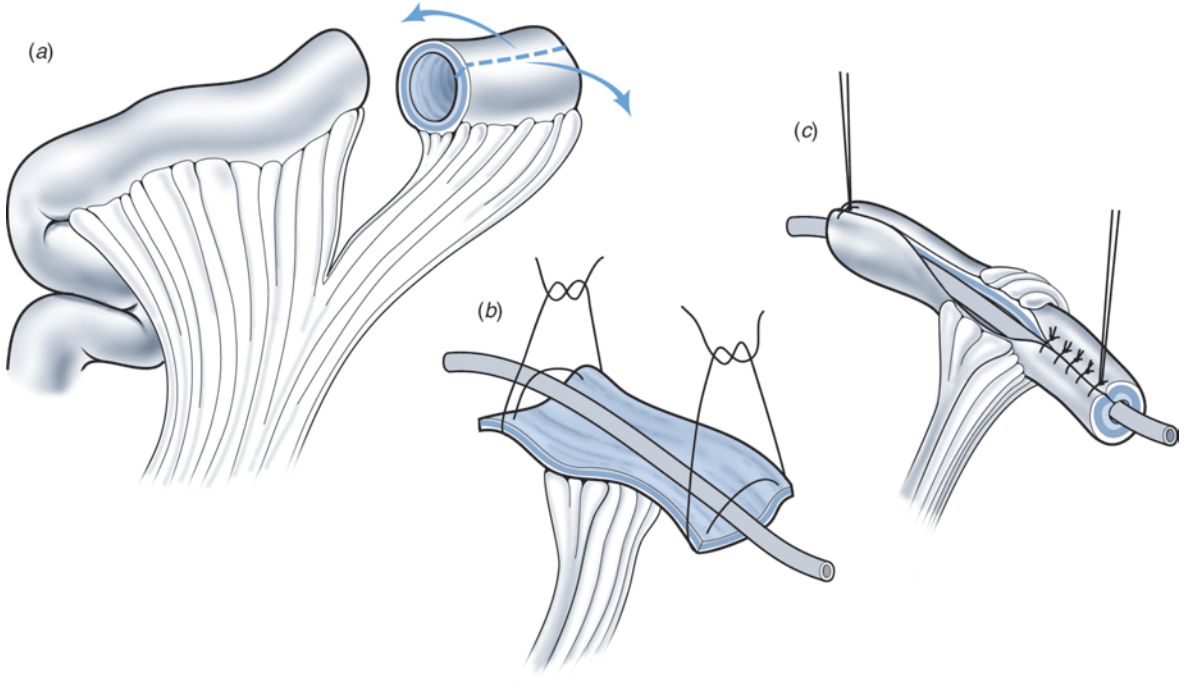

Figure 55.23 Monti popularized a concept originally described by Yang, who created a catheterizable tube from small bowel. (*a*) A 3–4 cm section of bowel is isolated on its mesentery and split on the antimesenteric border. (*b*) It is then closed along the transverse axis, 90° from the original. (*c*) This doubles the length of tube produced from a piece of bowel. The tube may then be implanted into the bladder for continent catheterizable access.

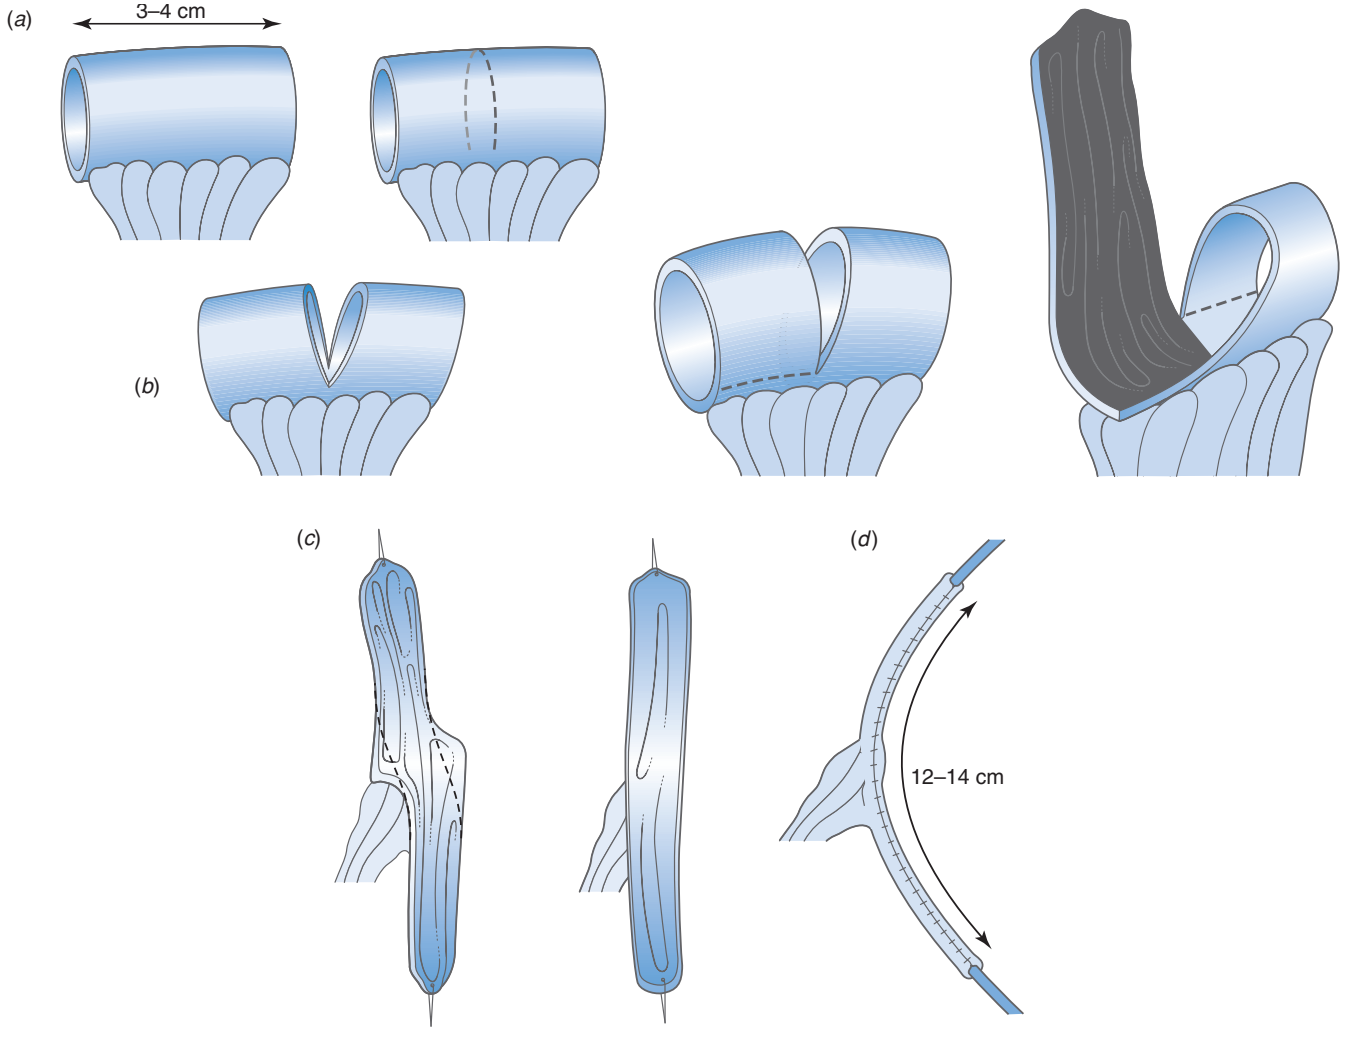

Figure 55.24 Casale presented a variation of the reconfigured ileal tube. (*a*) A 3–4 cm section of ileum is partially split into two rings, leaving the bowel over the mesentery intact. (*b*) The two rings are then split on opposite sides, allowing the bowel to be unfolded into a much longer flap. (*c*) Corners of bowel along the mesentery are trimmed off to make the strip uniform in width before it is tubularized. (*d*) The longer tube allows more flexibility in placement of the anastomosis, mesentery, and stoma.

bladder pressures low and minimizes stress on reconstruction done at the bladder neck. Stomas allow the surgeon to be more aggressive in creating resistance at the bladder outlet because the urethra will not be needed as the primary access for catheterization. The combination of continent stomas and augmentation has allowed patients who have suffered multiple failed continence surgeries to be salvaged with good results.[130]

Indicators for success

The definition of continence has changed over the years and is open to interpretation by each surgeon. 'Social continence' was felt to be adequate in the past and if a child used several continence pads per day but was free of diapers most pediatric urologists considered their treatment successful. Our tolerance of wetness has been modified over the years; perhaps in response to the change in public policy in the 1970s to mainstream the education of children with disabilities. In more modern reviews, surgeons have been more specific in defining successful continence. Dryness, without the odor of urine, has become the expected goal. This evolution of the definition of success makes comparing results from different eras and series difficult.

The effectiveness of procedures to treat the weak bladder outlet cannot be judged easily. Ultimate success is of course based on continence, but also

involves other criteria such as the ability to void and the need for other surgery to attain continence, such as bladder augmentation. It is unfair to compare procedures that allow voiding with those that prevent voiding by design.

Of the procedures that allow voiding, the YDL procedure, its variations, and the Tanagho have been the most successful, allowing 70–100% of patients to void initially. Voiding after this type of surgery is seldom normal, for these procedures usually produce a fixed resistance at the weak bladder neck. Voiding is often accomplished with abnormally high bladder pressures that are generated by a Valsalva's maneuver. These pressures are necessary to overcome the static increased bladder outlet resistance. Even if the patient is able to void for a period of several years, the detrusor may eventually fail and require intermittent catheterization. Many procedures produce 75% continence rates, but often these rates are dependent on intermittent catheterization and chronic detrusor relaxation achieved with medication or augmentation.

The artificial urinary sphincter would seem the best alternative for the patient who can void prior to surgery, as it provides a variable resistance at the bladder neck and should allow voiding at more physiologic pressures. Long-term studies of sphincters in children reveal that most patients eventually require intermittent catheterization because of inadequate emptying due to detrusor failure. The other complications of inevitable reoperation and potential secondary detrusor hyperreflexia are additional considerations with this device. If the patient does have the potential to void over a long period of time, the artificial sphincter is the best option. Around 80% of patients will be continent over a long period of time with the sphincter, although most require intermittent catheterization. Augmentation rates of 30–35% in long-term selective studies are less than with other bladder procedures.

Of the procedures that prevent voiding by design and rely on intermittent catheterization, the slings are the most simple and dependable in females and produce 80% continence rates with good durability. The Pippi Salle bladder neck reconstruction produces 80% continence, whereas the Kropp procedure produces the highest continence rates, approaching 100%. Bladder neck closure is also very dependable but leaves the patient reliant on only one bladder access, an extra-anatomic continent stoma, and no pop-off valve.

If one is choosing a bladder neck procedure, one must have specific goals in mind relating to the patient's potential to void. Patients with neuropathic bladders from sacral agenesis, myelomeningocele, and spinal cord trauma have poor potential to void regardless of bladder outlet resistance. Patients with epispadias and some with exstrophy have better detrusor function as a group and have the best potential to void.

If the goals of surgery are to have the patient dry and voiding, the artificial sphincter would seem the best choice, followed by the YDL procedure or variations. If the surgical goals are to have the patient dry and to catheterize through the bladder neck and urethra, the Pippi Salle repair or the artificial sphincter allows continence with easy catheterization in most cases. If the goals are to have the patient dry and the bladder neck and urethra are not important for voiding or catheterization because a continent stoma is available, the Kropp repair and a bladder neck closure are good options.

Another measure of success that has been used to judge bladder neck surgery is the need for bladder augmentation to achieve continence. On the surface, it would seem that the YDL procedure and its variations and the Tanagho procedures are superior because series of these procedures report augmentation rates of 0–40%. This compares with Kropp's reported augmentation rate of 78%, bladder neck closure of 61–80%, and rates of 80% with the Pippi Salle repair. Closer inspections of the series reveal that the patient groups are not comparable. Studies with the lowest augmentation rates (15–20%) are consistently made up of mostly epispadias, exstrophy, and urogenital sinus patients, whereas the series with high augmentation rates (70–90%) usually include a significant number of neuropathic bladders. The need for augmentation is much more a function of the underlying condition and the pathophysiology of the detrusor rather than a result of bladder outlet incompetence or corrective surgery.

Conclusions and recommendations

Patients found to have incontinence due to bladder outlet incompetence as demonstrated by leak point pressures, cystograms, or cystoscopic examinations should always be treated with all available medical options needed to improve continence. CIC, anticholinergic medication, α-adrenergic medications, control of constipation, and control of infection should be utilized. If these methods fail and the patient and family have the sufficient motivation and

understanding of what continence procedures require, then the urologist may explore the surgical options.

The patient and family should have a vital role in the decision-making process and they must understand the consequences of having surgery to increase leak point pressure. The surgeon makes a profound change in the physiology of the urinary tract and in doing so depends on the patient and family to perform the management required by this change. Whether it is performing intermittent catheterization, emptying the bladder on schedule with an artificial sphincter, or taking medication, the success of the surgery and the health of the child depend on their willingness and ability to comply.

Once the child, family, and surgeon agree to perform a procedure to increase resistance at the bladder neck, there are many good options. The choice of procedure depends on the goals of surgery and the particular surgeon's preferences. It is important to approach each patient individually. Children with incontinence that requires surgical management are often complex cases, with other health and social concerns. In general, however, we can look at the underlying pathology and goals of surgery and recommend procedures that are good management options.

If the child can void to completion prior to surgery and has a condition that may allow long-term voiding, then the artificial sphincter or the YDL procedure is a good option. The conditions that leave children with relatively isolated bladder outlet incompetence and adequate detrusor function include epispadias, bilateral ectopic ureters, some surgical injuries to the bladder neck, and urogenital sinus anomalies. As a rule, artificial sphincters should not be used if there has been prior bladder neck reconstruction, such as in exstrophy closure, because of the risk of erosion. The rare child with pure stress incontinence may be treated with suspension of the bladder outlet using any of the procedures used in adult stress incontinence such as the McGuire or Raz. Slings may be used in children who void, but they should be applied loosely.

Patients with exstrophy are still treated with the YDL procedure or one of the variations. New urodynamic data suggest that the procedures such as the YDL procedure, which surgically alter the trigone, may lead to worsening of detrusor function. Kaefer et al[131] studied epispadias patients and Diamond et al[132] reviewed exstrophy patients before and after bladder neck surgery, and both studies showed that most patients suffer a deterioration of filling and voiding dynamics. Most bladders developed high pressures, increased contractility, and diminished capacity, whereas some bladders increased in size and developed poor contractility. Only 25% of 30 exstrophy patients maintained normal detrusor function after their bladder outlet resistance was surgically increased. We have yet to determine whether the detrusor functional changes observed are the result of surgical trauma to the bladder, increased demands on the bladder to retain urine and cycle, or are predetermined by different levels of dysfunction inherent in each exstrophy bladder.

The newest development in exstrophy surgery is to perform the entire repair, including closure, bladder neck reconfiguration, and urethroplasty, as a single procedure in the newborn period.[133] We continue to perform staged repairs with the bladder outlet repair done at age 3 years. For the past 2 years we have been adding a continent umbilical urinary stoma at the time of bladder outlet repair. This allows the child to void per urethra and also offers easy access to check residual urine or to perform intermittent catheterization without violating the repaired bladder outlet if the child cannot void adequately. We believe that the surgeon should elevate and suspend the bladder neck and urethra at the same time as a bladder outlet reconfiguration such as the YDL procedure is performed.

In patients who cannot void adequately prior to surgery and who have poor potential for good detrusor function there are more options. These children, for the most part, have neuropathic bladders from myelodysplasia or other neurologic conditions. They will be dependent on CIC to empty the bladder. In girls, the fascial sling has become the treatment of choice because of its simplicity and reliability. In boys, there are many options but we currently use the YDL, Pippi Salle, or Kropp procedures. If the plan calls for intermittent catheterization through the repaired bladder neck in a boy the Pippi Salle procedure is preferred because it is easy to catheterize. At this time, almost all patients have the simultaneous creation of a continent catheterizable abdominal stoma. This allows easy access to the bladder and there is no need to worry about routine catheterization or catheter trauma to the repaired bladder outlet.

The majority of children with neuropathic incontinence at the bladder outlet also have bladders with limited detrusor function and storage capacity. Most children today undergo a simultaneous augmentation cystoplasty to create a large, low-pressure, storage reservoir. There is no question that augmentation

alone will improve continence in this patient population even if the bladder outlet is weak.[134] In our experience, augmentation alone has not provided reliable continence even in patients with reasonable bladder outlet resistance. For this reason, we believe that in most cases of reconstruction for incontinence, the surgeon should maximize both bladder outlet resistance and the storage capacity of the bladder.

In preparing the revised edition of this chapter, I was struck by the change in emphasis in surgical treatment of severe anatomic or neuropathic incontinence. New work in this field is directed toward less-aggressive surgical intervention such as slings, wraps, and injection therapy. There have been few advances in the area of major bladder outlet reconstruction in the past 8 years and, if anything, this surgery has become less radical as in the modifications of the YDL procedure.

Procedures to improve resistance at the incompetent bladder outlet have been advanced greatly by the development of associated procedures such as bladder augmentation over the past 25 years. Two singular contributions in this field came from Lapides, with his concept of CIC, and Mitrofanoff, whose novel idea to create a continent catheterizable stoma allowed a non-urethral method of bladder emptying. Finally, the predictors of success in bladder outlet reconstruction remain unchanged despite any new advances. They are sufficient resistance at the bladder outlet, a low-pressure reservoir of adequate size, and a reliable means to empty the bladder efficiently.

Bladder augmentation: current and future techniques

56

Bradley P Kropp and Earl Y Cheng

Introduction

The surgical management of the child with a neuropathic bladder can be a formidable task, but major advances in surgical technique have been made in recent decades. The ability to augment the capacity of the bladder with a piece of reconfigured bowel in conjunction with clean intermittent catheterization (CIC) has dramatically altered our ability to form a compliant urinary reservoir that protects the integrity of the upper urinary tract and promotes urinary continence. Conventional enterocystoplasty uses detubularized segments of small or large bowel. Despite the functional success of intestinocystoplasty, clinical experience has demonstrated that numerous complications can result from the incorporation of small and large bowel and their associated heterotopic epithelium into the urinary tract. To avoid some of these deleterious side effects of the use of bowel for bladder augmentation, several procedures have now been developed to augment the bladder without the use of bowel, including gastrocystoplasty, autoaugmentation, seromuscular enterocystoplasty, and ureterocystoplasty. In addition, recent advances in tissue engineering techniques have increased the possibility of regenerating new bladder tissue that is clinically useful for augmentation purposes. This chapter reviews the relevant surgical anatomy and physiology, advantages and disadvantages, surgical technique, and clinical results of conventional enterocystoplasty and each of the alternative procedures that avoid the use of bowel. These are summarized in Table 56.1. Since the care of the child with a neuropathic bladder can be complex and requires individualization that is dependent on the desires of the patient and family, familiarity with each of these procedures is extremely important for the pediatric urologist when considering augmentation cystoplasty.

Indications and preoperative assessment

Enterocystoplasty is performed when there is a need to enlarge and/or decrease the storage pressure in the native bladder. This can result from a host of conditions, including spina bifida, spinal cord trauma, posterior urethral valves (PUV), dysfunctional voiding, radiation, and infectious or other chronic inflammatory processes. Enterocystoplasty is intended to relieve high-pressure and low-capacity characteristics. There are two major indications for enterocystoplasty. The first is the presence or risk of upper tract deterioration secondary to a poorly compliant bladder. The second indication is when the bladder is a causative factor in urinary incontinence. All patients who are being considered for enterocystoplasty should be thoroughly studied with preoperative urodynamics and initially treated by medical alternatives such as anticholinergic medications and/or intermittent catheterization. It is extremely important that patients understand that, in most instances, enterocystoplasty will not result in normal voiding and a lifelong commitment to intermittent catheterization will be required.[1]

Lapides' landmark studies in the early 1970s, demonstrating that intermittent catheterization can be performed safely and effectively in children,[2,3] have had the single greatest impact on the ability to perform enterocystoplasties in children. If a patient is not dedicated to performing lifelong intermittent catheterization, then a non-continent form of urinary diversion should be chosen instead of enterocystoplasty.

The goals of enterocystoplasty are to change the native bladder environment by reducing storage pressure and increasing volume. A thorough preoperative evaluation will help to determine which type of augmentation is most appropriate and beneficial for each

Table 56.1 Advantages and disadvantages of procedures for bladder augmentation

Procedure	Advantages	Disadvantages
Intestinocystoplasty	Extremely compliant tissue Availability of tissue Proven long-term clinical efficacy	Heterotopic epithelium Mucus Infections Stones Hyperchloremic metabolic acidosis Malignant transformation Spontaneous rupture
Gastrocystoplasty	Moderately compliant tissue Easily definable submucosal plane for reimplantation Minimal mucus and stone formation Acid buffering in renal insufficiency patients	Hematuria dysuria Hypochloremic hypokalemic metabolic alkalosis
Autoaugmentation	Preservation of native urothelium Avoids bowel Technically less demanding procedure Extraperitoneal procedure Does not preclude future conventional enterocystoplasty	Inability to predict success preoperatively
Seromuscular enterocystoplasty	Preservation of native urothelium Muscle-backed mucosa not well defined	Technically more demanding procedure Factors that predict success preoperatively
Ureterocystoplasty	Preservation of native urothelium Muscle-backed mucosa Compliant tissue Avoids bowel	Limited patient population Large surgical incision(s)

child. Major factors that must be addressed before proceeding with enterocystoplasty include (1) assessment of renal function; (2) absence or presence of reflux and/or ureteral dilatation; (3) determination of outlet resistance; (4) history of bowel dysfunction; (5) need for a continent catheterizable stoma; (6) physical and mental capacity to perform intermittent catheterization; and (7) previous urinary diversion. Since there is currently no perfect bladder augmentation applicable to all children, all of the above factors must be considered in order to make the most suitable and best choice for the patient and family.

Renal function

Renal function can be assessed by measurement of serum creatinine, using one of several methods to calculate estimated creatinine clearance, 24-hour urine collection, or estimation of glomerular filtration rate via a radioisotope renal scan. The authors prefer to obtain a serum creatinine and nuclear renal scan before any type of bladder augmentation. In patients with abnormal renal function, a 24-hour urine collection for volume and creatinine clearance is also performed. The information obtained from this assessment may make one segment of bowel or an alternative procedure more attractive or appropriate than others. For example, in a patient with chronic renal insufficiency, a gastrocystoplasty is often a better choice than intestinocystoplasty because fewer urinary wastes are absorbed and electrolyte disturbances such as metabolic acidosis are reduced.

Reflux and ureteral dilatation

The presence of reflux and/or massive ureteral dilatation is an important preoperative determinant. When massive ureteral reflux is present, the exact bladder capacity and compliance may be difficult to assess. Occlusion of the ureteral orifices with balloon catheters can theoretically be helpful in assessing these parameters. An anesthetic is usually required to place these catheters. Although this technique has been reported, the authors have not found this procedure to be very helpful.

Although reflux has been reported to resolve spontaneously after enterocystoplasty,[4–7] antireflux surgery

should be considered at the time of reconstruction, especially if reflux occurs at low intravesical pressures. In patients who have low to moderate grade reflux in association with high intravesical pressures and poor bladder compliance, enterocystoplasty alone without ureteral reimplantation can be considered, as low-grade reflux tends to resolve with reduction of intravesical pressure. Recently, endoscopic subureteric injection with dextranomer/hyaluronic acid copolymer has been shown to correct reflux with a reasonable degree of success. Thus, in cases of mild to moderate reflux that occur at elevated pressures, the authors are more likely to proceed with augmentation without concomitant open reimplant surgery. If the reflux does not resolve after augmentation, endoscopic correction can be performed. Alternatively, endoscopic correction can be considered at the time of augmentation, especially in cases where concomitant bladder neck procedures that may limit endoscopic access are being performed.

In patients where there is ureteral dilatation in the absence of reflux, a very low-pressure reservoir must be constructed so that adynamic ureters can propel the urine into the bladder. Although not well documented in the literature, clinical experience strongly suggests that dilated ureters with walls that do not coapt are not capable of generating a peristaltic wave of greater than 40 cmH_2O. Thus, dilated ureters are likely to require very low intravesical pressures, well below 40 cmH_2O, for proper efflux of urine into the bladder.

Preoperative assessment of native bladder wall dynamics can be extremely difficult in patients who have a neuropathic bladder with an open bladder neck and low outlet resistance. In these patients who leak from an empty bladder, cyclical filling and distention of the bladder do not occur. The bladder has not been stretched under physiologic conditions. When performing preoperative urodynamics in these patients, a balloon catheter can be snugged down into the bladder neck to prevent leakage, allowing bladder capacity and compliance to be evaluated. This technique has been reported to be a good predictor of the need for future augmentation.[8] However, Kronner et al[9] demonstrated that preoperative urodynamics in such patients do not necessarily correlate well with eventual bladder outcome. They concluded that preoperative assessment of bladder capacity and compliance could not reliably predict which patients would eventually require enterocystoplasty after outlet resistance had been increased. Since preoperative urodynamics do not appear to be accurate in patients with an open bladder neck, the decision to perform an enterocystoplasty in conjunction with a bladder neck procedure should be based on preoperative discussions regarding the risks and benefits of immediate versus delayed enterocystoplasty.

Previous urinary diversion

As with patients with low outlet resistance, those with a defunctionalized bladder secondary to previous urinary diversion who are being considered for undiversion or transplantation are also difficult to assess preoperatively with regard to the need for bladder augmentation. In patients with a vesicostomy, urodynamics can be performed by occluding the vesicostomy with the balloon from the urodynamic catheter. For the same reasons previously described for patients with a poor outlet, interpretation of these urodynamic findings and assessment of their significance may be difficult. In PUV patients who have previously had urinary diversion and subsequently undergo renal transplantation, there are good data showing that the native bladders re-expand and regain function irrespective of preoperative urodynamic findings.[10–12] Currently, there are few data on outcomes in patients with neuropathic bladders associated with spina bifida after primary closure or undiversion without enterocystoplasty; however, if the original diversion was done for poor compliance or volume, augmentation is likely to be required.

In the defunctionalized bladder not associated with spina bifida, some authors feel that bladder cycling may help to determine whether a bladder is adequate for closure without augmentation.[11,12] A gastrostomy button placed in the vesicostomy to facilitate bladder cycling can be used in these patients.[13] The authors' experience has been that preoperative bladder cycling can be helpful in some patients, at least in increasing bladder capacity. However, urodynamic results remain difficult to interpret in many patients. In general, we favor undiversion without augmentation when there is doubt as to whether augmentation will be required. Secondary enterocystoplasty can always be performed in patients in whom the bladder does not eventually attain adequate bladder compliance and capacity following undiversion or transplantation. It should be emphasized that this approach is only recommended for patients with a defunctionalized bladder not associated with spina bifida, since such patients usually do poorly following vesicostomy closure. Reliable follow-up also needs to be assured in all patients following undiversion.

Bowel function

A thorough evaluation of bowel function, including a history of constipation or diarrhea, must be carried out prior to enterocystoplasty. Postoperative bowel dysfunction can occur in up to 50% of patients who have undergone enterocystoplasty.[14] In addition, King[15] found that removal of the ileocecal segment in children with spina bifida causes severe diarrhea in approximately 10% of patients. However, in a more recent series of 63 patients who underwent ileal cecal cystoplasty, bowel complication was found to be only 3%.[16] Nevertheless, before undertaking any type of urinary reconstruction that involves the use of a bowel segment, discussion with the patient and family should include potential gastrointestinal complications. The type of augmentation should be chosen with these potential complications in mind.

Ability to catheterize

Since most patients who undergo enterocystoplasty will not be able to void completely without lifelong intermittent catheterization, one should consider the formation of a catheterizable stoma at the time of the augmentation. This is especially important in patients who are sensate or are in wheelchairs. Clinical experience has shown that when both the native urethra and a catheterizable stoma are present, the majority of patients will choose to use the catheterizable stoma. In addition, assessment of the physical and mental capacities of the patient and family must be undertaken to make sure that they will be able to perform intermittent catheterization on a regular schedule.

Families want to believe that their child will become continent after enterocystoplasty and that the kidneys will be protected. However, the amount of time and effort that will be required is often not appreciated preoperatively. Therefore, all must understand the risks and benefits of enterocystoplasty prior to surgery and the lifelong commitment to a rigorous schedule of intermittent catheterization. Since there are many potential problems associated with failure to catheterize, including spontaneous bladder rupture and death, urinary reconstruction should be deferred until the patient has the physical and mental maturity needed to care for him or herself.

Intestinocystoplasty

Small bowel

Currently, ileum is the most commonly used bowel segment for enterocystoplasty. The abundant supply of small bowel, easy workability, mobility, reliable blood supply, and compliance of the reconfigured ileum have led most reconstructive surgeons to choose ileum over other bowel segments. Although the jejunum can be used for urinary reconstruction, the high incidence of metabolic complications (hyponatremic, hypochloremic, and hyperkalemic acidosis) associated with use of this segment make it less desirable and thus it is rarely used. The major contraindications to the use of ileum are a history of short gut syndrome, inflammatory bowel disease, pelvic and/or abdominal radiation, and significant renal insufficiency. Under these conditions, alternative segments such as stomach are more appropriate.

Anatomy and physiology

The proximal two-fifths of the small bowel proper is jejunum and the distal three-fifths is ileum. The coils of mid-ileum usually lie in the pelvis, whereas the terminal 30 cm of ileum, the most commonly used portion for enterocystoplasty, usually rises out of the pelvis to lie in close relationship to the cecum and the ascending colon.

The mesentery of the small bowel attaches to the posterior abdominal wall. The ‘root’ of the small bowel mesentery runs obliquely across the abdomen. As the root of the mesentery runs obliquely from left to right, it crosses, in order, the abdominal aorta, the vertebral column, and the third portion of the duodenum. The mid-portion of the small bowel has the longest mesentery, whereas the segments of the small bowel closest to the cecum and the duodenojejunal flexure have the shortest. Therefore, in patients in whom the mesentery is short, a segment of ileum 30 cm or more above the ileocecal valve will be the most mobile and will reach the furthest into the pelvis.

The arterial supply to the entire small bowel is derived from the superior mesenteric artery (Figure 56.1). There are usually 12–16 branches of the superior mesenteric artery running to the jejunum and ileum and entering the small bowel at its mesenteric border. The ileocolic artery is the most distal segment of this vessel. It is found in the right lower abdominal quadrant, where it gives off branches that supply the terminal ileum, the cecum and appendix, and the proximal ascending colon. Venous drainage of the small bowel occurs through multiple mesenteric channels that coalesce to form the superior mesenteric vein. It is this abundant and redundant blood supply that makes the use of different segments of ileum viable for urinary reconstruction.

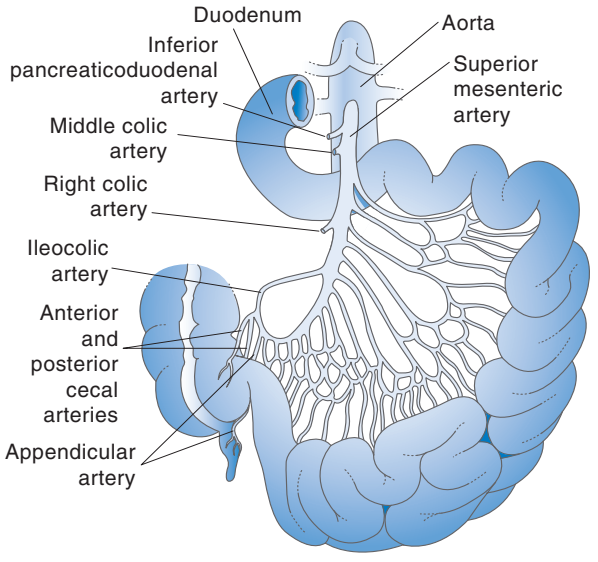

Figure 56.1 Arterial blood supply to the small intestine. The portion of the ileum with the longest mesentery that is commonly used for intestinocystoplasty is around 20–30 cm proximal to the ileocecal valve. (Adapted from Lindner,[17] with permission.)

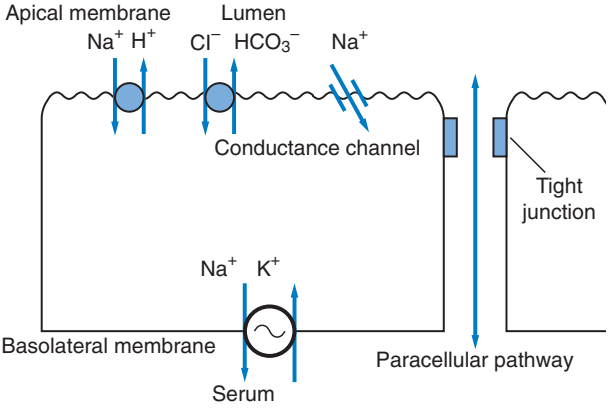

Figure 56.2 Intestinal transport mechanisms. Sodium absorption in both the small and large bowel is transcellular and occurs via a Na^+–H^+ exchanger on the apical membrane and a Na^+–K^+ pump on the basolateral membrane. The colon has an additional pathway of entry for Na^+ via conductance channels, which allows for non-coupled sodium absorption. Chloride and bicarbonate transport is coupled, which is pertinent in the development of metabolic acidosis following intestinocystoplasty. Water and electrolyte movement also occurs via paracellular pathways associated with tight junctions between the cells. Paracellular movement occurs more in the ileum than in the colon owing to leakier tight junctions. (Adapted from Lindner,[17] with permission.)

The small intestine is innervated from the autonomic plexuses grouped around the 'take-off' of the superior mesenteric artery from the aorta. These plexuses include preganglionic parasympathetic nerves from the vagus as well as postganglionic sympathetic fibers from the celiac plexus. The submucosa of the small intestine contains the nerve plexus of Meissner. Between the longitudinal and circular muscle of the small bowel is the intramuscular myenteric (Auerbach's) plexus, consisting of non-myelinated nerve fiber plus numerous ganglion cells.

The bowel wall is made up of an outer serosal coat, two layers of muscle (outer longitudinal smooth muscle and inner circular smooth muscle), a submucosal layer, and a mucous membrane composed of a single layer of columnar epithelial cells. Since the muscle and epithelial layers are relatively thin, the plane between these layers is difficult to establish surgically; therefore, tunneling procedures for ureters and catheterizable stomas may be quite difficult in small bowel.

The physiology of the small and large intestine involves an intricate balance of water and electrolyte shifts. The major mechanisms of intestinal transport of water and electrolytes are illustrated in Figure 56.2. Water and electrolyte movement varies throughout the length of the bowel. These changes can be accounted for by both structural and functional differences between the small and large bowel. The major structural difference between the small and large bowel involves the 'tight' junctions that join the epithelial cells (see Figure 56.2). These tight junctions have characteristic permeabilities and ionic conductance that form the basis for paracellular ion and water movement.[18] Because such junctions are tightest in the colon and more permeable or leaky in the proximal small bowel, paracellular movement may account for a significant portion of water and electrolyte transport in the small bowel, and not play as an important role in the colon.

Although paracellular movement accounts for some of the bidirectional water and electrolyte transport, most of these shifts are thought to occur via transcellular mechanisms that occur through the intestinal absorptive cell. A characteristic example of the intestinal absorptive mechanism is the Na^+/K^+-ATPase enzyme, which is located on the basolateral membrane. This pump maintains low intracellular sodium concentrations and thus creates an electrochemical gradient for sodium absorption as well as passive transport of other electrolytes and water.

Sodium entry in the small bowel is accomplished by way of a Na^+–H^+ countertransport system in the apical membrane. In addition, a significant portion of

the sodium entry into the colon also occurs via electrogenic Na^+ conductance channels that allow for non-coupled sodium absorption. The presence of this channel in the colon probably accounts for its ability to transport Na^+ and water against large gradients.

Chloride is absorbed throughout the entire small and large bowel. Bicarbonate is absorbed in large quantities in the jejunum but secreted in the ileum and colon. Chloride absorption in exchange for HCO_3^- secretion plays a large role in the transport of these electrolytes in the ileum and colon. Na^+–H^+ exchange and Cl^-–HCO_3^- exchange occur together. The net result is the electroneutral absorption of Na^+ and Cl^-.

Metabolic acidosis may develop whenever urine is in contact with ileal or colonic mucosa. The mechanism by which this hyperchloremic metabolic acidosis occurs is thought to be directly related to ammonium (NH_4^+) reabsorption that can occur along the entire small and large bowel. It is likely that the inhibitory effect of ammonium on Na^+–H^+ exchange allows ionized ammonium transport where it substitutes for sodium in the Na^+–H^+ exchanger.[19] The result of this ammonium absorption is increased Cl^- absorption in order to maintain electrical neutrality. This leads to hyperchloremia and eventual metabolic acidosis. Although the exact physiologic mechanisms of electrolyte transport continue to be defined, it must be remembered that the major function of the intestine, regarding this transport, does not change when intestine is used for urinary reconstruction. Continued fluid and electrolyte fluxes account for the majority of the physiologic problems associated with the use of intestine in the urinary tract.

Advantages and disadvantages

Ileum is the most commonly used bowel segment for bladder augmentation. The advantages realized with use of ileum are (1) large quantity available; (2) ease in handling and reconfiguration; (3) predictable and abundant blood supply; (4) most compliant segment of bowel; (5) moderate mucus production compared with colon; (6) less severe metabolic complications than colon or stomach; and (7) fewer gastrointestinal complications than cecum.

The disadvantages in using ileum include (1) occasional short mesentery that cannot reach the pelvis; (2) possible development of diarrhea and vitamin B_{12} deficiency when the most distal ileum is used; (3) difficulty with creation of submucosal tunnels; and (4) metabolic acidosis; as well as (5) bowel obstruction; (6) stone formation; (7) mucus production; (8) urinary tract infections (UTIs); and (9) tumor formation, all of which are risks with large bowel segments as well.

Large bowel

Through the early 1980s, the cecum and sigmoid colon were more commonly used than ileum for enterocystoplasty. However, because of the shorter mesenteries, increased mucus production, and difficulty with configuration associated with large bowel, ileum has come to be the preferred segment of bowel for enterocystoplasty for most surgeons. Nevertheless, detubularized large bowel is still used for simple bladder augmentation in select patients, and in the hands of some surgeons, sigmoid colon may be the preferred segment.

Anatomy and physiology

Anatomically, the large bowel can be divided into five sections: (1) the cecum and vermiform appendix; (2) the ascending colon and the hepatic flexure; (3) the transverse colon and mesocolon; (4) the splenic flexure and descending colon; and (5) the sigmoid colon.

The colon is 1.4–1.7 m in length. Its diameter is greatest on the right side and gradually decreases as it approaches the sigmoid colon. The diameter of the sigmoid colon is often no wider than a loop of terminal ileum. The large bowel is made up of five distinct layers: serosa, muscularis externa, submucosa, muscularis mucosa, and mucosa. The outer serosal coat is a component of the peritoneum and normally completely covers the cecum, the appendix, and the transverse and sigmoid colon segments. The muscularis externa of the large bowel is composed of a complete inner circular and incomplete outer longitudinal layer of smooth muscle. The submucosa is composed of areolar tissue and lies between the muscularis externa and the muscularis mucosa. This layer contains the blood and lymphatic vessels supplying the bowel and is also the most important layer when developing an anastomotic site. The thin muscularis mucosa is made up of circular and longitudinal smooth muscle. The mucosa is composed of a layer of simple columnar epithelium containing goblet cells and is smooth and devoid of villi.

The muscle layers of the colon are notably different from those of the stomach, small intestine, and rectum. Longitudinal smooth muscle covers the large bowel incompletely. The longitudinal fibers are arranged in three narrow but distinct bands called

teniae coli. The teniae of the cecum and ascending colon have a constant position relative to the bowel circumference. One band lies on the ventral surface of the colon, whereas the other two lie medial and lateral to the ventral band. The teniae of the transverse colon are less constant in position. Near the rectosigmoid junction the teniae become quite indistinct. The unique anatomy of the teniae facilitates reimplantation of ureters, appendix, and catheterizable stomas to create a reliable flap-valve continence mechanism. The deep circular muscular coat of the colon wall is visible between the longitudinal muscle fibers of the teniae. Contractions of the colon produce a pouching or sacculations of the bowel between the teniae. These pouchings, or haustra, are randomly distributed and are easily noted on gross examination and visible on X-ray studies.

Cecum and vermiform appendix

The cecum measures approximately 6 cm in length and lies caudal to the entrance of the ileum into the colon. It is the thinnest portion of the colon. The cecum is normally mobile. In over 90% of individuals it is completely covered with peritoneum and possesses no mesentery. In some patients, such as children with spina bifida and ventroperitoneal shunts, the cecum can become fused with the posterior abdominal wall. This in turn causes foreshortening of the peritoneal attachments, resulting in the cecum becoming more superiorly located in the right colic gutter.[20]

The terminal 14 cm of ileum, the cecum, appendix, and the ascending colon are supplied by the ileocolic artery, which is the terminal segment of the superior mesenteric artery. The ileocolic artery ends just proximal to the ileocecal junction and then divides into four major branches. The most superior branch, the colic artery, passes to the ascending colon, anastomosing with the descending branches of the right colic artery initiating the right colic portion of the marginal artery of Drummond or mesenteric arcade (Figure 56.3.).

The three bands of teniae coli originate at the base of the appendix. The appendix varies in length from

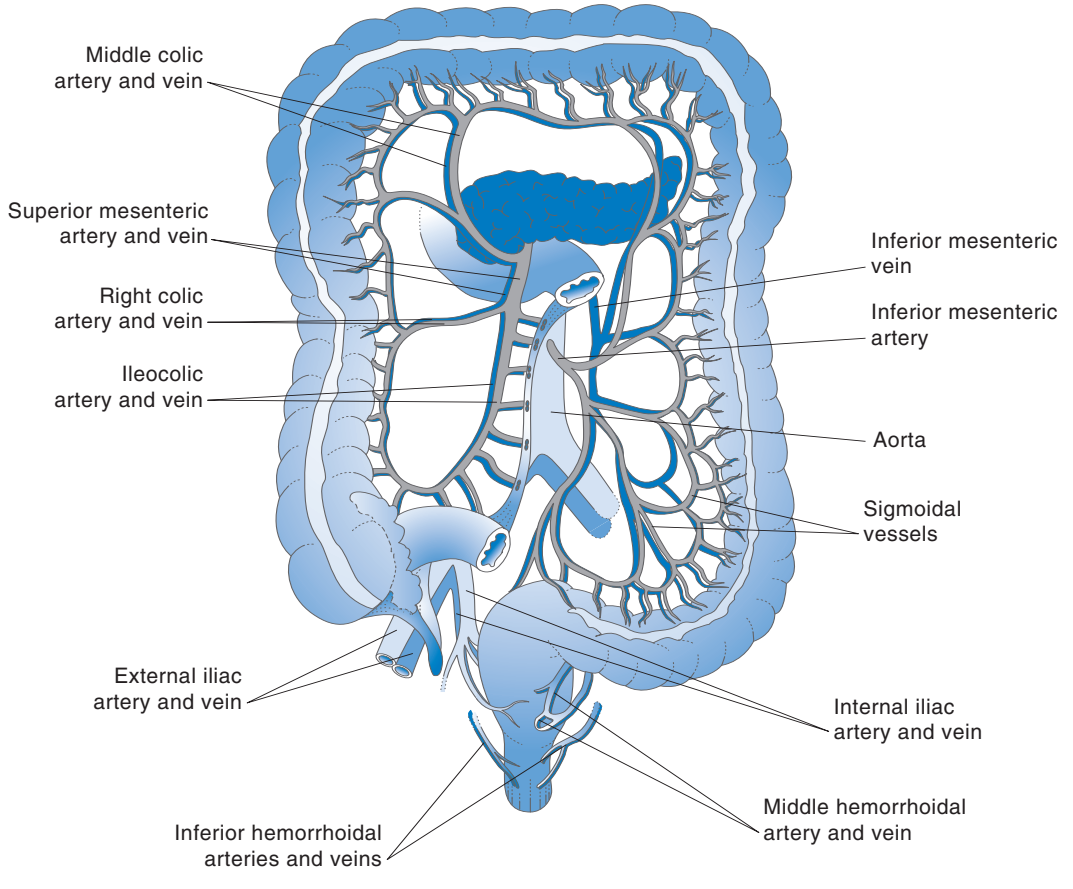

Figure 56.3 Arterial blood supply to the large bowel. Preservation of the marginal artery is extremely important when isolating portions of colon for intestinocystoplasty. (Adapted from Lindner,[17] with permission.)

2 to 20 cm, with an average of 9 cm. In the majority of patients, the appendix is held in position by the posterior inferior ileocecal fold. In about 5% of patients, the mesentery of the appendix runs directly from the posterior peritoneum in the region of the ileocecal junction onto the midportion of the appendix, at which point it is usually joined by the appendicular artery, a branch of the ileocolic artery. The appendicular artery arises either as a branch of the posterior cecal artery or directly from the main ileocolic trunk. It may also arise from the ileal branch of the ileocolic artery. Regardless of its site of origin, the appendicular artery will usually pass dorsal to the most distal segment of the terminal ileum before it enters the mesoappendix.

Ascending colon and transverse colon

The ascending colon occupies most of the right side of the abdominal cavity and extends from the cecum to the hepatic flexure. The blood supply to the ascending colon comes from the colic branches of the ileocolic artery, the right colic artery, and the right branches of the middle colic artery. The right colic artery is the most variable vessel in the colon and is absent in 5–7% of people. The transverse colon receives blood from the left colic artery; however, the major supplier is the middle colic artery, which is a more direct branch of the superior mesenteric artery.

Sigmoid colon

The sigmoid colon frequently has an S-shape, and is divided into a fixed superior and a mobile inferior portion. The fixed portion of the sigmoid colon begins at the level of the iliac crest. The mobile portion of the sigmoid colon begins at the medial border of the left psoas major muscle and ends where it joins the rectum. The length, location of loops, degree of redundancy, relationship to other structures, and mobility of the sigmoid colon are markedly variable. It is very common in the spina bifida population to encounter sigmoid colon so enlarged and redundant that the mobile portion crosses the midline and lies anterior to the cecum.

The inferior mesenteric artery is the major vessel to the left transverse colon, the splenic flexure, the left colon, the sigmoid colon, and the rectum. The left colic artery is the first branch of the inferior mesenteric artery and runs in the direction of the superior half of the descending colon. The ascending branch of the left colic artery runs superiorly and parallel with the left colon, contributing to the marginal artery of Drummond. The descending branch of the left colic artery supplies the fixed segment of the sigmoid. The sigmoid arteries, which are second branches of the inferior mesenteric, supply the lower portion of the descending colon, the sigmoid colon, and a small segment of the upper rectum.

Advantages and disadvantages

The ileocecal segment and cecum have been used extensively in reconstructive urology. One major advantage of these segments is utilization of the portion of bowel that has the largest diameter, which results in a capacious and compliant reservoir that often fits the bladder base neatly. It has a well-defined blood supply that is reliable. The modified ileocecal valve can also be used as an antireflux or continence mechanism.

The major disadvantage in using the ileocecal segment is related to the loss of the ileocecal valve in the intestine. Patients with neurologic disorders or short gut may have an increased incidence of diarrhea and difficulty with fecal continence following removal of this segment from the intestinal tract. In addition, it is not available in the cloacal exstrophy population who have little or no hindgut. The ileocecal segment also reabsorbs urinary wastes, which may result in hyperchloremic acidosis. Finally, cecum usually produces more mucus than the ileum, which can lead to increased infections and stone formation.

The major advantage in using sigmoid colon is the redundancy that is present, especially in the spina bifida population. The mobile portion of the sigmoid is so redundant in such children that it often lies in the right lower quadrant. It can be easily opened and reconfigured into a U-shape to increase compliance. The thicker muscle can be used to create an antireflux ureteral anastomosis as well as for placement of a tunneled continent catheterizable stoma such as the appendix.

The major disadvantage in using the sigmoid colon is the reduced ability to create a large-capacity, compliant reservoir. The diameter of the sigmoid may be only as large as the ileum. In this circumstance, a segment of colon at least 20–28 cm is required to create an adequately sized reservoir. This amount of sigmoid colon can occasionally be difficult to obtain in the non-spina bifida population. Mucus production from the sigmoid is increased compared with small bowel. This may increase the potential for the development of UTI and bladder stones. In the Indiana series the highest spontaneous perforation rate occurred among

those with sigmoid cystoplasties.[21] However, this has not been observed in other large series. Finally, hyperchloremic acidosis is more common when the sigmoid colon is used, compared with other bowel segments. Frequently, patients will need lifelong alkalizing agents, but this is also true after cecocystoplasty or ileocystoplasty.[22]

Surgical technique

The goals of bladder augmentation are to provide a large-capacity, low-pressure urinary reservoir. Hinman[23] and Koff,[24] in particular, have documented the importance of detubularization and reconfiguration of the small and large bowel to facilitate maximum gains in capacity and compliance. Detubularization of bowel segments prevents synchronous contractions of the circular muscle of the gut. Since the radius of the reservoir is directly related to the volume, a greater radius in the augmented bladder translates into a larger low-pressure reservoir. The diameter of the reconfigured bowel segment increases with the number of folds that are incorporated during the reconfiguration (Figure 56.4).

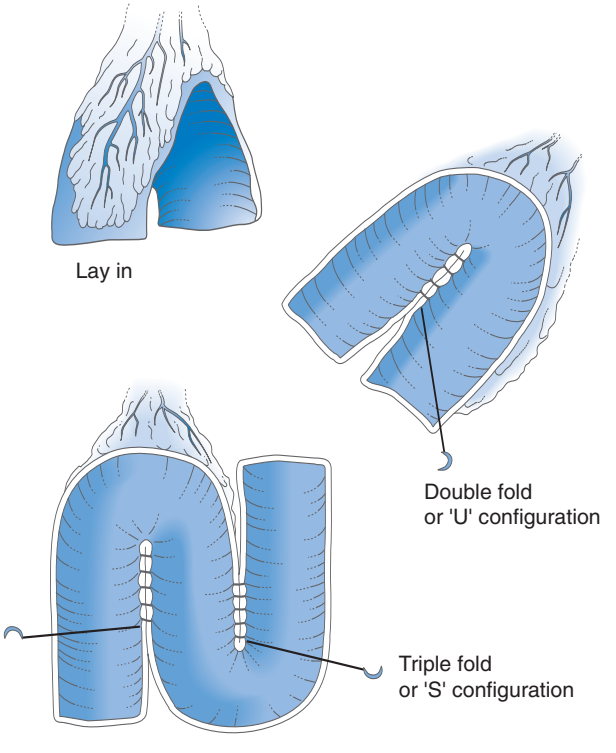

Figure 56.4 The detubularized ileum can be reconfigured in numerous ways. Each additional fold increases the potential radius of the augmented bladder. (Adapted from Rink and Adams,[25] with permission of WB Saunders.)

Regardless of the bowel segment used for augmentation, detubularization and reconfiguration should always be employed.

Ileocystoplasty

Enterocystoplasty is very reliable in lowering storage pressures and expanding the capacity of the non-compliant bladder. Ureteral reimplantations and procedures to increase outlet resistance can safely be undertaken at the same time. However, not every augmentation is completely successful. This may be related to the bladder having a great tendency to reform itself, turning the augmentation into a diverticulum with a relatively small opening. To prevent this, the bladder should be bivalved ('clamshelled') from the bladder neck ventrally to the trigone posteriorly. Alternatively, when the bladder is small and thick walled, the 'star' modification can be performed[26] (Figure 56.5). The star procedure involves opening the bladder in the sagittal plane. A second incision is then made in the coronal plane. If ureteral reimplantation or bladder neck reconstruction is being performed, the second incision is not made until after these procedures are completed. The authors will also occasionally employ an upside-down U-shaped or a Boari flap modification for the initial bladder opening when a catheterizable stoma is being positioned at the umbilicus. In severely diseased bladders from tuberculosis, schistosomiasis, interstitial cystitis, and rarely bladder exstrophy, supratrigonal bladder excision is

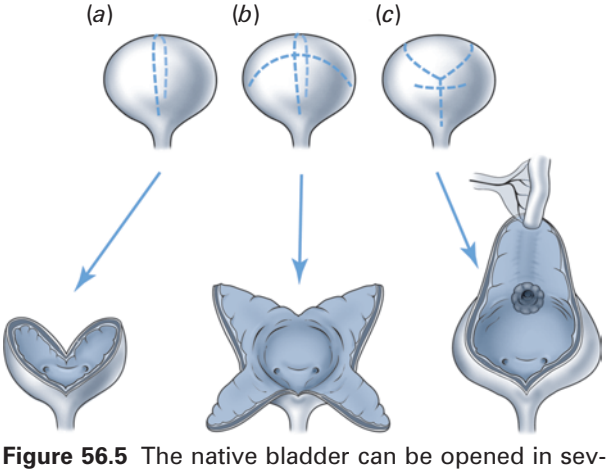

Figure 56.5 The native bladder can be opened in several ways: (*a*) bivalved in a 'clam'-like fashion with full extension of the incision into the bladder neck to prevent an hourglass deformation of the augmented bladder; (*b*) the 'star' modification; (*c*) a 'U' incision to create a flap of bladder that can be used for tunneling when creating a continent catheterizable stoma to the umbilicus.

sometimes necessary, as in neuropathic bladders when the walls are very thick. Whatever type of bladder opening is used, the goal is the same: to provide a wide bladder plate to which the bowel segment can be sewn, thus preventing a narrow anastomosis or hourglass deformity that might result in the augmentation becoming a diverticulum.

When using ileum for enterocystoplasty, the segment chosen should be at least 15 cm proximal to the ileocecal valve to prevent vitamin B_{12} malabsorption, diarrhea due to malabsorption of bile salts, and potential injury to the blood supply to the cecum. Guidelines on the length of ileum required to obtain the appropriate size and shape of the augmentation vary.[24,27] Most commonly, an ileal segment between 20 and 35 cm in length is used. However, a slightly longer segment may be required in an older child or an individual with a severely diseased and contracted bladder.

Prior to harvesting the ileal segment, it is important to ensure the mesentery reaches well down into the pelvis. Extensive mobilization of the mesentery is sometimes required if it is foreshortened. This is most common in the spina bifida population, often secondary to spinal abnormalities and the intraperitoneal adhesions that occur from the ventriculoperitoneal shunt. Once the appropriate bowel segment has been selected, the bowel is divided between straight clamps. The authors prefer to perform a single-layer hand-sewn ileoileostomy. A two-layer hand-sewn or a stapled anastomosis can also be used. Closure of the mesenteric window with interrupted permanent

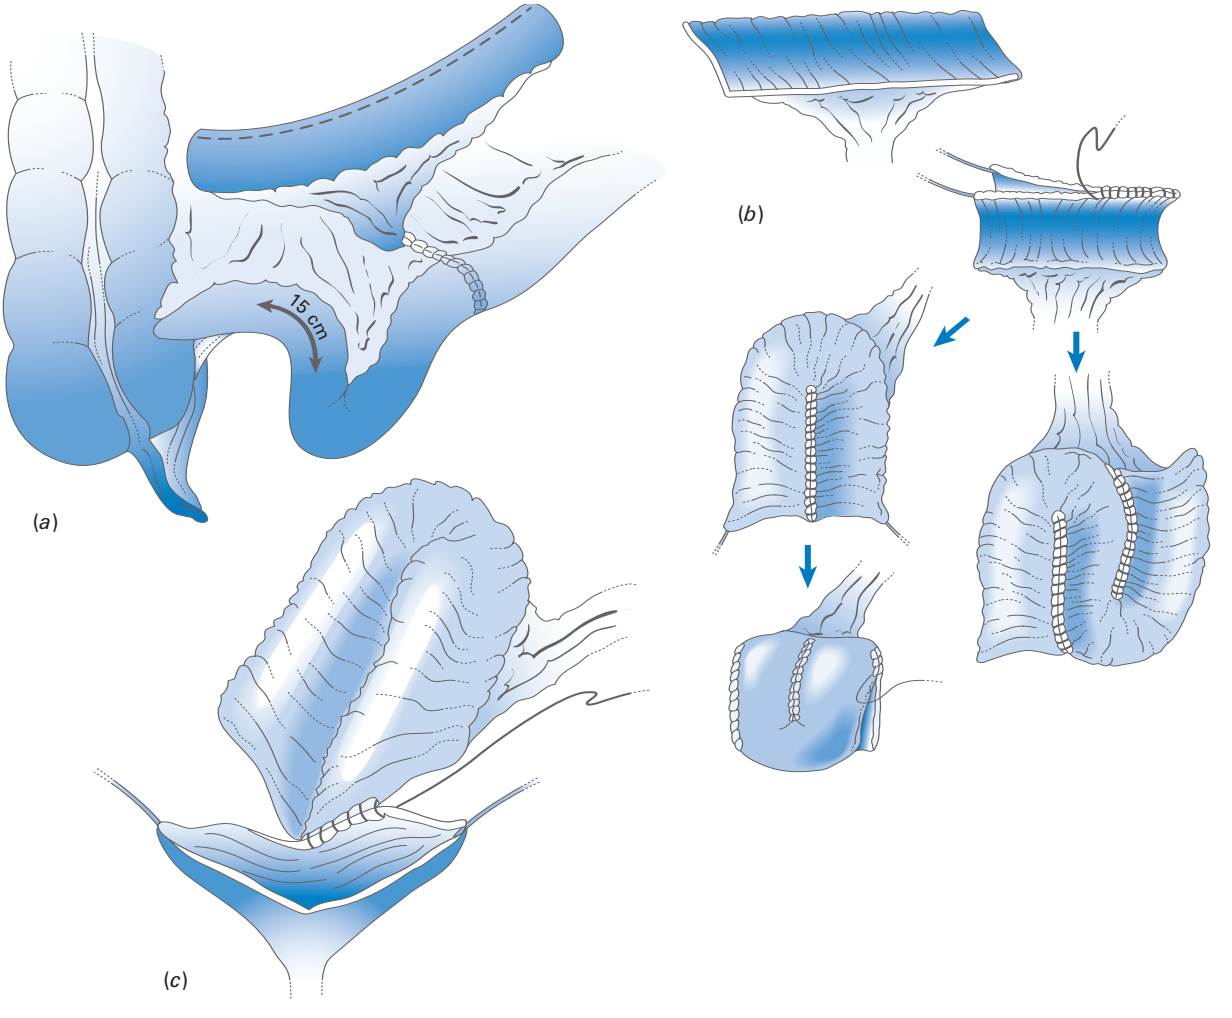

Figure 56.6 Ileocystoplasty. (*a*) A dependent portion of the ileum that is 20–30 cm long and a minimum of 15 cm proximal to the ileocecal valve is isolated and detubularized. Bowel continuity is reestablished with an end-to-end ileoileostomy. (*b*) Depending on the size of the ileal segment, it can be reconfigured and folded in several ways, including the U, S, and W (not illustrated) configurations. In addition, the edges of the reconfigured bowel can be sewn together to create a cup patch. (*c*) The anastomosis of the reconfigured bowel to the native bladder begins in the posterior apex of the opened bladder. (Adapted from Rink and Adams,[25] with permission of WB Saunders.)

sutures then completes the anastomosis. The isolated ileal segment is detubularized along its antimesenteric border after thorough intraluminal irrigation with normal saline. The ileal segment is then reconfigured into a U, S, or W (Figure 56.6).

After opening the native bladder as described above, the reconfigured bowel segment is anastomosed to the bladder with a full-thickness absorbable suture beginning at the posterior apex of the opened native bladder. Once the posterior aspect of the running, locking anastomosis has been completed, a second running, locking suture beginning at the bladder neck apex is begun and carried along the lateral aspect to meet the previous suture. Before final closure of the anastomosis, a suprapubic tube is brought out through the native bladder wall. After completion of the augmentation, the bladder is inflated and a watertight anastomosis confirmed by irrigation. A Penrose or closed suction drain is usually left in place along the posterior and anterior aspects of the bladder. The bowel is then examined to confirm its integrity and the abdomen is closed in an anatomic fashion using heavy, running, absorbable sutures.

Ileocecocystoplasty and cecocystoplasty

The ileocecal segment and cecum have frequently been used for augmentation cystoplasty. The cecum alone is rarely used. Simple detubularization and reconfiguration can be performed. The terminal ileum can be detubularized and incorporated into the cecal segment to increase total volume (Figure 56.7). Continuity of the bowel is re-established with an end-to-side ileocolostomy. The reconfigured ileocecal segment is then anastomosed to the bivalved bladder

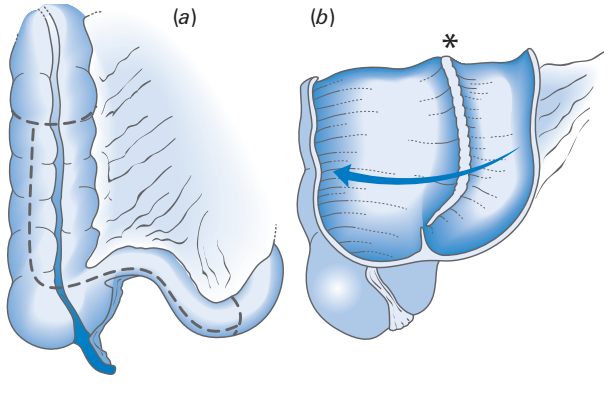

Figure 56.7 Ileocecocystoplasty: the ileum and cecum are isolated as a single unit (*a*) and reconfigured to form a 'cup' for augmentation (*b*). * = suture line between ileum and cecum. (Adapted from Rink and Adams,[25] with permission of WB Saunders.)

with a single or double layer of running, locking, absorbable suture. Alternatively, the terminal ileum can be used for ureteral replacement when the ureters are short or the ileum can be tapered and used as a continent catheterizable stoma.

Sigmoid cystoplasty

The sigmoid colon easily reaches the bladder and can be used for augmentation cystoplasty. It is especially valuable when reimplantation of ureters or a catheterizable stoma is not possible in the native bladder because the sigmoid musculature can easily be separated from the muscosa, facilitating tunneling. Twenty cm of sigmoid is usually sufficient to achieve an adequate capacity after the segment is reconfigured. It is important to detubularize the sigmoid in order to prevent high-pressure coordinated contractions. Several techniques of sigmoid reconfiguration have been described (Figure 56.8). The authors prefer the U or S configuration because of simplicity and the possibility of significant contractile activity that may result from the method described by Mitchell[28] (see Figure 56.8c). When the sigmoid segment has been isolated, colon continuity is re-established with a single-layer, hand-sewn, end-to-end colocolostomy. The reconfigured sigmoid segment is then anastomosed to the native bladder in a similar fashion as described for ileum.

Postoperative care

Following enterocystoplasty, parenteral antibiotics are continued for 48 hours unless the intraoperative urine culture is positive. Then, a full 7 days of culture-sensitive coverage is used. A nasogastric tube is left in place until bowel function returns. Urinary drainage is maintained through the suprapubic tube and a secondary catheter through either the native urethra or the appendicovesicostomy (when performed). Diligent observation is needed during the immediate postoperative period to ensure that obstruction of the catheters does not occur secondary to blood clots or mucus. Daily bladder irrigations are important to decrease mucus build-up in the bladder, which can lead to infection, stone formation, and inefficient emptying. Bladder irrigations can begin immediately after surgery with 30 ml three times a day. This is increased to 60 ml twice a day after discharge. Both the suprapubic tube and secondary catheter are left to gravity drainage for 2–3 weeks. The suprapubic tube is then plugged and the patient begins intermittent catheterization. Before this, a cystogram can be performed to

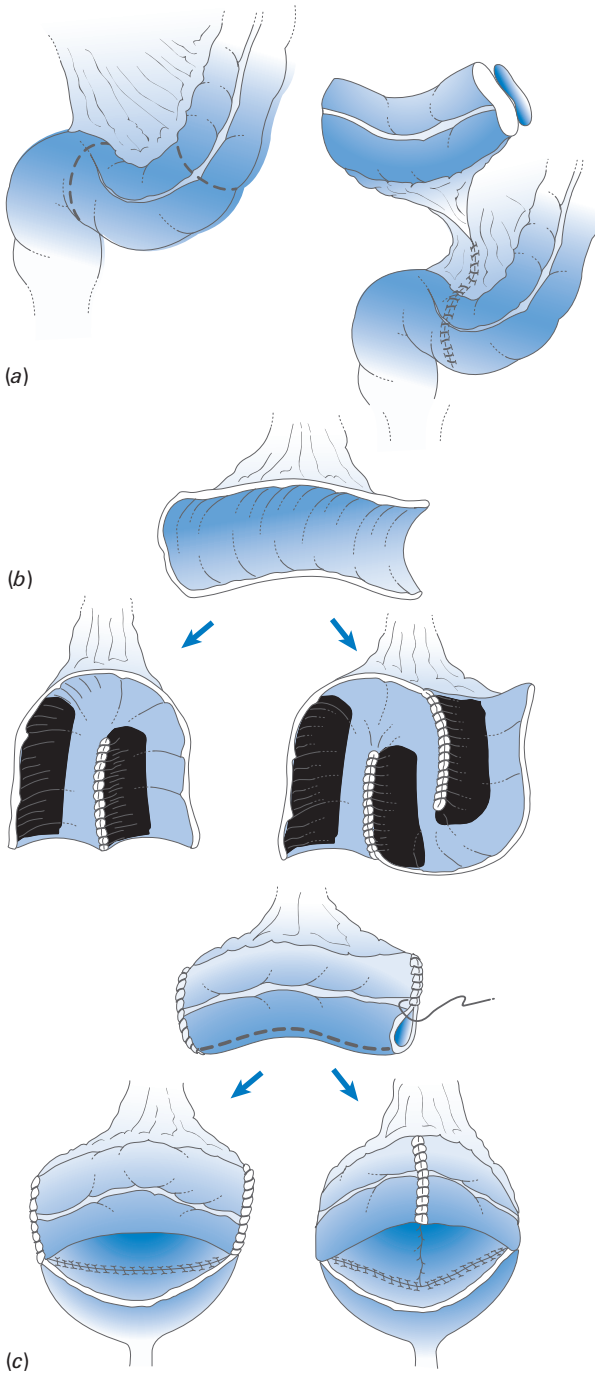

Figure 56.8 Sigmoid cystoplasty. (*a*) A portion of sigmoid colon is isolated. (*b*) The sigmoid can then be reconfigured in a similar fashion as is performed for ileocystoplasty with detubularization and folding back on itself. (*c*) Alternatively, the colonic segment can be closed at both ends, opened along the antimesenteric border, and then anastomosed to the bladder. This latter method is less optimal, owing to the persistence of high intraluminal pressures following augmentation. (Adapted from Rink and Adams,[25] with permission of WB Saunders.)

ensure adequate healing and the absence of extravasation; however, it is not absolutely necessary. Adequate emptying of the bladder with catheterization can be confirmed by checking residual urine via the indwelling suprapubic tube. Once the patient demonstrates proficiency at performing intermittent catheterization, the suprapubic tube is removed. Daily irrigations to clear the bladder of mucus are then recommended. Patients are told to catheterize every 2–3 hours during the daytime and once at night for the next few weeks. The time interval between catheterizations is gradually lengthened, depending on the compliance of the augmented bladder and the gradually increasing storage volumes. In general, adequate stretching of the augmented bladder occurs within 6 months so that most patients need only catheterize approximately four to six times during the day to stay dry and maintain safe filling pressures. If a patient is going to attempt spontaneous voiding, one should wait until at least 3 months after surgery and then follow postvoid residuals to ensure adequate emptying. Radiographic imaging of the augmented bladder and the upper urinary tract is performed approximately 3 months postoperatively.

Results of ileocystoplasty and colocystoplasty

Bladder capacity and compliance

The most common preoperative urodynamic finding in the pediatric patient with a neuropathic bladder in need of bladder augmentation is a small-capacity, poorly compliant bladder with or without evidence of hyperreflexia and bladder instability. Both small and large bowel segments, when detubularized and reconfigured, have been found to provide adequately compliant tissue for enterocystoplasty that ameliorates or eliminates these adverse characteristics.[29] Flood et al[30] reported on 22 augmentation cystoplasties performed over a period of 8 years. Mean age at surgery was 37 years, with a range of 2–82 years. The major indication for augmentation cystoplasty was reduced bladder compliance. A detubularized ileal augmentation was performed in 67% of the patients, 30% had a detubularized ileocecocystoplasty, and the remainder had detubularized sigmoid augmentation. Mean follow-up was 37 months. Bladder capacities increased from a preoperative mean of 108 ml to 438 ml postoperatively. Excellent or improved results by all parameters were achieved in 95% of these patients.[30] Kilic et al[31] reported on 30 children who underwent intestinocystoplasty. Sigmoid was used in 11 cases,

ileum in six, and ileocecum in two. Postoperative evaluations revealed a mean postoperative capacity of 237 ml in the colonic group, 240 ml in the ileal group, and 250 ml in the ileocecal group. Mean compliance was 20.6 ml/cmH_2O in the colonic group, 21.6 ml/cmH_2O in the ileal group, and 25.5 ml/cmH_2O in the ileocecal group. They concluded that ileal, ileocecal, and colonic augmentations all provided high-volume reservoirs of similar compliance. More recently, Quek and Ginsberg reported long-term results on 26 patients with neurogenic voiding dysfunction who underwent enterocystoplasty. Mean follow-up in these patients was 8.0 years. Ninety-six percent of the patients had near or complete resolution of urinary incontinence. Mean total bladder capacity increased from 201 ml to 615 ml. They concluded that bladder augmentation provides durable clinical and urodynamic improvement for patients with neurogenic bladder dysfunction.[32]

It is apparent that all segments of intestine, when appropriately reconfigured, can adequately increase the capacity of the native bladder. However, enterocystoplasty does not guarantee that the bladder will be free of hyperreflexia. Robertson et al[33] reported the persistence of hyperreflexia in 23% of patients after enterocystoplasty and documented regular phasic contractions in 77% of the augmented bladders despite bowel detubularization. It should be mentioned that in a majority of the patients in this series an ileocecal segment was used. Recently, Pope et al[34] reported on 19 of 323 patients who had undergone primary enterocystoplasty but required a secondary augmentation owing to the persistence of high pressures. Twelve of the 19 patients had had colocystoplasties (14% of the total colocystoplasties), four had gastrocystoplasties (10% of the total gastrocystoplasties), and two had undergone ileocystoplasty. Cecum was used in one (1%). It is apparent in this large series that colocystoplasties are more likely to allow high storage pressures to persist. However, it must be noted that not all of the colocystoplasties were completely detubularized but instead reconfigured after the ends were closed with the colon opened along the antimesenteric border. Given this, it is difficult in this series to compare colon to ileum that was reconfigured into an S or W shape. Nevertheless, these studies emphasize the importance of careful functional and urodynamic follow-up in patients after enterocystoplasty, since some will require anticholinergics or secondary augmentation due to failure of the original procedure to improve bladder capacity and compliance adequately.

In summary, it appears that both small and large bowel, when detubularized, can be used for cystoplasty to provide a compliant and large-capacity reservoir. However, the large bowel may retain increased contractile activity despite detubularization.[21,29] It appears that detubularized ileum has less energetic phasic contractions than colon and therefore has potentially less risk for persistent high storage pressures.[34] Given these advantages of ileum over colon, it is the authors' preference to use ileum whenever possible when performing simple enterocystoplasty.

Metabolic issues

Electrolytes

The major function of intact small and large bowel is to absorb food, fluid, and electrolytes. When urine is stored in the bowel for prolonged periods, there is increased absorption of urinary solutes, which increases the risk of metabolic derangement. Koch and McDougal[35] hypothesized that ammonium reabsorption plays a key role in the development of hyperchloremic metabolic acidosis in patients following intestinocystoplasty. In support of this hypothesis, Stampfer and McDougal[19] demonstrated in a rat model that ammonium inhibits the sodium/hydrogen exchanger, resulting in ionized ammonium transport where it substitutes for sodium in the exchanger. This then leads to the increased absorption of chloride to maintain electrolyte neutrality, resulting in the development of hyperchloremic metabolic acidosis. In patients with normal renal function, serum electrolytes are usually unaffected by enterocystoplasty.[36–38] However, in patients with impaired renal function, metabolic acidosis can be profound. Careful preoperative evaluation and judicious use of bowel is recommended in patients with chronic renal insufficiency.[39] A gastric segment or cutaneous diversion may be safer. Owing to the electrolyte problems that can often develop in patients with significant renal insufficiency, the authors recommend gastrocystoplasty rather than conventional enterocystoplasty in this patient population.

Bone growth

Impaired bone growth and demineralization are major concerns related to prolonged acidosis. Demineralization occurs secondary to the increased excretion of titratable acid (bony buffers). These concerns have received a large amount of attention in the last decade. Hochstetler et al[40] demonstrated in a rat model that

animals with ileocystoplasty, when given an acid challenge, developed bone demineralization and decreased bone growth that can be corrected with bicarbonate therapy. Current basic science literature demonstrated that enterocystoplasty in rats neither impairs skeletal growth nor bone quantity, but leads to significant loss of bone mass when combined with resection of the ileocaecal segment.[41] This same group has also reported histomorphometrically that bone loss occurs after enterocystoplasty in the rat model.[42]

The more recent clinical literature has not clarified the true incidence or effect on bone growth. Mundy and Nurse[43] reported an average of 20% reduction in growth potential in three of six children who had colocystoplasties. However, no decrease in growth potential was noted in 10 children who had ileocystoplasties. They concluded that bone growth impairment after colocystoplasty was more likely than after ileocystoplasty. Two other reports demonstrated no impairment of bone growth or demineralization in children and adults after urinary reconstruction with various bowel segments.[38,44] However, two series have demonstrated variable degrees of reduction in bone mineral density in children with enterocystoplasties.[45,46] Finally, four other series have not demonstrated any effects on bone growth.[47–50] Interestingly, two of these reports are in bladder exstrophy patients; both of them report growth retardation in this population with or without augmentation.[47,48] In a large study that compared linear growth in bladder exstrophy patients with and without augmentation, using pre- and postaugmentation growth velocities, a statistically significant decrease in linear growth after intestinal bladder augmentation was demonstrated.[51] Further longitudinal studies will be required to clarify this issue. Therefore, until such studies are available, close observation for the development of acidosis and the treatment of any electrolyte abnormalities following intestinocystoplasty with bicarbonate therapy is recommended.

Bowel dysfunction

Bowel dysfunction is known to occur occasionally after enterocystoplasty. Diarrhea can develop after resection of large segments of ileum, removal of the ileocecal valve, and extensive colonic resections. The incidence of bowel dysfunction following enterocystoplasty in all patients, including adults, has been reported to be between 10 and 54%.[14,52,53] In the spina bifida population, the incidence is approximately 20%. Since the overall incidence of bowel problems in children with spina bifida is further increased when the ileocecal valve is removed, one should try to avoid the use of ileocecal segments for augmentation in this patient population. Osmotic diarrhea has been theorized to occur after removal of the ileocecal valve, which results in a decreased transit time within the intestine.[54] It should be noted that these original data were not supported in a recent report by Husmann and Cain[16] in which only 3% of their 63 ileal cecal cystoplasty patients had worsening of their bowel function. Despite this encouraging recent report, the authors feel that careful preoperative screening of patients with spina bifida with regard to their bowel habits is extremely important.

The diarrhea that develops postoperatively can be osmotic or secretory in nature. Secretory diarrhea is thought to occur because of decreased resorption of bile salts and subsequent fat malabsorption, resulting in steatorrhea. Barrington et al[55] reported on 14 patients who developed bowel difficulties after enterocystoplasty. They showed a direct correlation in many of these patients between their diarrhea and interruption of the enterohepatic circulation of bile acids. They also found that these patients can be identified by using bowel frequency charts and can be treated with anion-exchange resins.

Vitamin B_{12} deficiency

Concerns regarding the development of vitamin B_{12} deficiency following small bowel resection or the use of small bowel for urinary reconstruction are well documented. The distal ileum is the major site of vitamin B_{12} absorption. It has previously been reported that up to 35% of patients will develop vitamin B_{12} deficiency following the construction of a Kock pouch, which uses about 80 cm of small bowel.[56] Despite theoretical and legitimate concerns about the development of vitamin B_{12} deficiency in children following ileocystoplasty, it has yet to be reported in the literature. Stein et al[44] reported on 51 children who had undergone such reconstructions, but no significant drop in vitamin B_{12} levels was noted following surgery. From the available published data, it appears that the use of shorter segments of ileum, about 35 cm, as used for the Camey type 1 enterocystoplasty and conventional ileocystoplasty in children, does not place the patient at significant risk for vitamin B_{12} deficiency, even in the long term.[37]

Despite the lack of evidence of any vitamin B_{12} deficiencies developing in children undergoing enterocystoplasty, the authors recommend harvesting

small bowel segments that are at least 15 cm away from the ileocecal valve. The vitamin B_{12} receptor sites are clustered in the most terminal portion of the ileum. If large amounts of small bowel are required for reconstruction of the bladder, periodic vitamin B_{12} levels should be obtained postoperatively. Alternatively, a vitamin B_{12} injection can be given prophylactically 3 years after enterocystoplasty. There is no evidence that the use of sigmoid colon for augmentation places patients at risk for vitamin B_{12} deficiency.

Mucus production and stone formation

Mucus production and bladder stone formation are both complications related to the use of the gastrointestinal tract for urinary reconstruction. All segments of bowel produce mucus. However, mucus production from the ileum is less than from the colon.[25] This has been confirmed clinically by several authors.[21,57] Mucus in the urinary tract is associated with an increased risk of infection.[58] Mucus production also increases during an acute infection, resulting in poor bladder emptying, especially when small catheters are used to drain the bladder.[27] Clinically, mucus production appears to decrease over time following ileocystoplasty. This is probably because of villus atrophy that occurs in the ileum. Colonic epithelium does not appear to undergo this type of change. Significant mucus production in colonic augmentations continues throughout the life of the patient.

The risk of stone formation after enterocystoplasty ranges between 7 and 52%.[59–64] The usual stone composition reported is magnesium ammonium phosphate (struvite), although several other stone compositions have been reported. Since the majority of stones are struvite in origin, it appears that chronic bacteriuria with urease-producing organisms may have a contributory role. However, it is also clear that the presence of mucus has an important role in the development of bladder stones following intestinocystoplasty. Mucus may serve as a biofilm that can harbor bacteria and promote further growth in a protected environment. Khoury et al[65] have also demonstrated that the mucus from stone formers has increased levels of calcium, phosphate, and magnesium, and an increase in the calcium to phosphate ratio, compared with non-stone formers. This increased calcium to phosphate ratio may be clinically important in predicting which patients are at risk for stone formation. Given these findings, it appears that mucus has strong lithogenic properties and is a nidus for stone formation. Daily irrigation of the augmented bladder to prevent excess mucus build-up can be an effective measure to reduce the risk of stone formation in the augmented bladder. Hensle et al[66] recently reported that an irrigation protocol consisting of saline twice a week (240 ml) and gentamicin sulfate solution once a week (240–480 mg of gentamicin/L of saline, at 120–240 ml per irrigation, depending on patient age and reservoir size) significantly reduced the number of reservoir calculi from 43% to 7%. However, Brough et al[61] did not observe a decreased incidence of stone formation when they instituted a regular bladder washout program in children following intestinocystoplasty.

Palmer et al[60] identified an additional risk factor for the development of bladder stones in the augmented bladder. They noted the presence of hypocitraturia in some of their stone-forming patients. Treatment with oral potassium citrate returned urinary citrate levels to within normal values and no recurrent calculi were then seen. Woodhouse and Robertson[67] have also reported that a metabolic screen in their augmented patients demonstrated that 80% of patients have risk factors for at least three different types of stones. All of the patients were found to have an increase in urinary pH and hypocitraturia.

Bladder calculi in the augmented bladder are amenable to both open surgery and endoscopic management.[59,60,63,68,69] Neither procedure appears to have a clear advantage at this time. An open procedure is usually simpler when the stones are large, although new energy sources for the endoscopic treatment of stones, such as the holmium laser, may enhance the ability to manage bladder stones non-invasively. Miller and Park[70] have also described a method of using a laparoscopic entrapment sac percutaneously to control the loss of multiple fragments. This method has been used by the authors and has been highly successful. Treatment of bladder calculi needs to be individualized. Factors that should influence the surgical approach include number and size of calculi, previous bladder outlet procedure, availability of endoscopic equipment, availability of energy sources, and the surgeon's experience with endoscopic techniques.

Infections

Bacteriuria following enterocystoplasty is the rule, since these patients are being intermittently catheterized. If the bladder is not emptied completely, symptomatic UTI may result. It is not known whether one type of bowel segment is at greater risk for the development of UTIs than another. Hirst[71] reported the

presence of bacteriuria in 50% of sigmoid augmentations, whereas only 25% of ileocystoplasties had bacteriuria at any one time. In a series of 231 augmentation patients, Rink et al[21] reported a symptomatic UTI rate of 22.7% following ileocystoplasty, 17.3% following sigmoid cystoplasty, 12% following cecocystoplasty, and 8% following gastrocystoplasty. They reported an overall 14% incidence of febrile UTIs with no statistical difference in the incidence between the various bowel segments. It appears that all augmented bladders are at risk for infection.

Tumors

Many fear that there may be an increased risk of malignancy in bladders after enterocystoplasty, as is the case after conventional ureterosigmoidostomy. Adenocarcinoma is the predominant tumor that develops after ureterosigmoidostomy, found most frequently at the site of the ureteral orifice. The latency period for tumor formation in the ureterosigmoidostomy patients ranges between 3 and 53 years, with a mean of 26 years. It is estimated that there is a 7000-fold increased risk of developing adenocarcinoma following ureterosigmoidostomy. It is with great trepidation that we enter the new millennium with hundreds of children having received enterocystoplasties without knowing whether there is an increased risk for the development of cancer. Filmer and Spencer[72] reported on 14 patients with tumor formation in the augmented bladder: nine of these patients had ileocystoplasty and colon was used in five. The exact etiology and pathogenesis of these tumors are unknown but they seem analogous to cancers occurring after uterosigmoidostomy. Nurse and Mundy[73] studied 34 patients who had undergone augmentation cystoplasty or colonic substitution cystoplasty. A high incidence of histologic abnormalities in the intestinal segment was reported to occur along the anastomotic suture line and in the remaining bladder. Such abnormalities were directly correlated with heavy mixed bacterial growth in the urine and high levels of urinary *N*-nitrosamines. Woodhams et al[74] have reported that there are no diurnal or long-term variations in urinary *N*-nitrosamine levels. They also found that levels were consistently higher in patients with inflamed or infected cystoplasties, those using intermittent self-catheterization, and those not taking antibiotic prophylaxis. Shokeir et al[75] and Ali-El-Dein et al[76] demonstrated that all bowel segments exposed to urine, regardless of their position (bladder or ureteral substitution), are at risk for malignant changes, and that urine cytologies may be a useful diagnostic tool in this setting. Barrington et al[77] reported on four patients who developed tumors in augmented bladders. All of the tumors were adenocarcinomas and were located on the bladder side of the anastomosis. It was concluded that these tumors were derived from the native urothelium. It was also demonstrated that transitional epithelium could undergo intestinal mucosal-like changes throughout the exposed native urothelium, including the renal pelvis, which was observed in one patient who had vesicoureteral reflux (VUR). Soergel et al[78] reported from the Indiana Augmentation database of 483 cases, three new cases of transitional cell carcinoma (TCC). Mean time from augmentation to TCC was 19 years. None of these patients had any additional risk factors. Thus, it is felt that development of bladder cancer is a real issue and that all patients should undergo endoscopic surveillance beginning 10 years after initial surgery.

Barrington et al[79] showed that there are elevated levels of transforming growth factor-β (TGF-β) in the enterocystoplasty population. It is believed that TGF-β increases cellular proliferation and/or phagocytic activity, producing nitrosamines and oxygen free radicals. It has been demonstrated that urinary TGF-β levels can be decreased with the administration of pentosan polysulfate sodium.[80] Therefore, if further research demonstrates elevated TGF-β as a risk factor, potential treatment options would be available. Barrington et al[81] have also demonstrated a decreased serum level of selenium, a free oxygen radical scavenger, in the neuropathic bladder population. These may be possible reasons for augmented bladders being at increased risk for tumor formation.

The issue of potential malignancy in augmented bladders cannot be overlooked or ignored. This is a potentially disastrous complication for children in whom one hopes to provide a surgically reconstructed bladder that will last for life. Future research is needed to determine the true risk of tumor formation, which children are at greatest risk, and whether premalignant changes can be detected endoscopically or with urine markers or cytology. Although the incidence of tumor formation following enterocystoplasty is unknown, lifelong follow-up and yearly cystoscopic evaluation and urine cytologies from the augmented bladder should be considered beginning no later than 6–10 years after the augmentation.[82] All malignant tumors reported have occurred after this time lapse.[72]

Perforation

Many complications can occur following enterocystoplasty. However, no complication is more potentially devastating or life threatening than unsuspected spontaneous bladder perforation. Although the exact incidence of perforation is not known, nearly every large series of enterocystoplasties includes at least one patient.[25,83–89] Amongst these reports, seven deaths have been directly attributed to such perforation.[90] Most of these deaths were due, at least in part, to delay in diagnosis. Therefore, a high index of suspicion is needed in any patient with a history of enterocystoplasty who presents with abdominal and/or shoulder pain.

It is not known whether one type of bowel is particularly prone to perforation after cystoplasty. Rink[28] reported a higher incidence of spontaneous perforations in sigmoid cystoplasties. They initially felt that the sigmoid colon was inherently at greater risk for perforation, but they now feel that this higher incidence may be more directly related to their initial technique of sigmoid detubularization. Others have reported that the highest incidence of perforation occurred when ileum was used.[89] DeFoor et al believe that gastrocystoplasty may be at a lower risk for perforation.[91] However, it appears that no segment of bowel, tubularized or detubularized, is immune from this complication.

The etiology of bladder perforation is unknown. Initially, perforations were thought either to be linked to traumatic catheterization or as a consequence of failure to catheterize on a timely basis.[83,87] However, perforation has been reported in patients who do not perform intermittent catheterization.[85] Another contributing factor in bladder perforation may be vascular compromise in the bowel wall. Crane et al[92] reported that specimens from perforated bladders demonstrated histologic evidence of bowel wall ischemia. Also supporting the theory of bowel wall ischemia is an arterial perfusion study in a canine augmentation model, where a decrease in blood flow to the bowel wall was seen when the reservoir was overdistended and intravesical pressures were increased.[93] The perfusion change was most striking at the antimesenteric border in the detubularized bowel. In addition to overdistention, high pressures due to bladder hyperreflexia may lead to an increased risk of perforation. Bauer et al[89] noted the presence of postoperative hyperreflexia in 40% of their patients who suffered a spontaneous perforation.

Some authors have suggested that a low urethral resistance is protective against both the high pressures associated with bladder hyperreflexia and failure to empty the reservoir on a timely basis.[88] However, Jayanthi et al[94] reported on 28 patients who underwent complete bladder neck ligation in conjunction with enterocystoplasty with a catheterizable stoma. In this series the one bladder perforation that occurred was associated with blunt trauma and was not spontaneous in origin. Therefore, achieving total urinary continence surgically without a pop-off valve mechanism does not in itself increase the risk for spontaneous rupture.

There does not appear to be one single etiology or risk factor that makes some individuals more prone to bladder perforation than others. Multiple factors are probably involved. Repetitive overdistention secondary to poor compliance, bladder hyperreflexia, and chronic infection all appear to place the augmented bladder at increased risk for spontaneous perforation.

The diagnosis of bladder perforation can be difficult at times, and a high index of suspicion is required to make the diagnosis quickly. Most pediatric patients who undergo enterocystoplasty are neurologically impaired. Lower abdominal sensation is diminished. Therefore, the clinical presentation may be non-specific. Nausea, vomiting, fever, oliguria, and possibly referred pain to the shoulder secondary to diaphragmatic irritation may be presenting complaints.[95]

On physical examination the abdomen is distended, with pain and irritation above the level of anesthesia. It may be difficult to distinguish pyelonephritis from a spontaneous bladder perforation. Thus, a standard or computed tomographic (CT) cystogram is recommended in any patient with an augmented bladder who presents with the above symptoms. Although the diagnostic role of a cystogram has been questioned in the past,[86,87] it is the most specific diagnostic radiographic test.[85,89] Braverman and Lebowitz[96] have recommended fluoroscopy during the filling phase to make sure that the bladder is completely distended in order to diagnosis the perforation accurately. Residual contrast in the abdomen after the bladder has been drained establishes the diagnosis. Alternatively, an abdominal CT scan can be diagnostic and is helpful in demonstrating the extent of the extravasation.

When spontaneous perforation of the augmented bladder is suspected clinically and/or confirmed radiographically, immediate treatment is required. Catheter drainage, fluid resuscitation, and broad-spectrum antibiotics should be started immediately. In a stable patient, non-operative management with

catheter drainage, antibiotics, and serial physical evaluations may be all that is needed.[97] This non-operative approach should be used only in selected patients in whom a small rupture is suspected. In the majority of patients, immediate exploration and closure of the bladder leak is safer. Intra-abdominal lavage, and irrigation and placement of intra-abdominal drains should then be done. Finally, all patients with an augmented bladder must be educated on the potentially lethal complications associated with delay in diagnosis of a spontaneous perforation. They should be instructed to inform a treating physician that they have an augmented bladder, and are at some risk for bladder perforation.

Surgical alternatives to intestinocystoplasty

As discussed above, bladder augmentation with small and large bowel segments may result in electrolyte abnormalities, UTIs, mucus production, stones, and tumor formation. Most long-term complications are attributable to the presence of intestinal mucosa in a urinary tract reservoir for urine storage. In an effort to avoid the unwanted effects of enterocystoplasty, several other surgical procedures have been developed: these include gastrocystoplasty, ureterocystoplasty, autoaugmentation, and seromuscular enterocystoplasty.

Gastrocystoplasty

Gastric tissue was first reported to be applied to the urinary tract in 1956 when Sinaiko described the use of a stomach segment for urinary diversion.[98] Leong and Ong[99,100] subsequently reported the successful use of stomach for augmentation of the bladder in both dogs and humans. More recently, Mitchell and colleagues have modified Leong's original techniques for gastrocystoplasty and popularized its use in pediatric patients.[101,102] Since then, experience from multiple institutions over the past two decades indicates that the use of stomach is feasible and effective in augmenting the neuropathic bladder. However, widespread use of stomach tissue as an alternative to intestine has been limited by the findings that the hematuria–dysuria syndrome (HDS) can be problematic in many patients (especially those that are sensate) and that, in the long term, gastrocystoplasty does not appear to result in a reservoir that is as capacious and compliant as that which is achieved with conventional intestinocystoplasty. Nevertheless, the use of stomach tissue can be very advantageous and appropriate in some patients. For example, in patients with renal insufficiency and metabolic acidosis, gastrocystoplasty helps to buffer the adverse effects of the acidosis because of its ability to secrete acid into the urine. Thus, in select patients, the use of stomach for augmentation is a viable and appropriate alternative to the use of intestine.

Anatomy and physiology

Anatomically, the stomach can be divided into five parts: the lesser curvature, greater curvature, fundus, body, and antrum. The layers of the gastric wall include the outer serosal coat, a muscular coat, the submucosal layer, and the epithelium. The muscular coat consists of smooth muscle fibers oriented in a longitudinal, circular, and an oblique fashion. The epithelium of the gastric mucosa consists of a single layer of tall columnar epithelial cells and smaller acid-secreting cells. Loose areolar tissue in the submucosa lies between the mucosal and muscular layers. This loosely arranged layer allows technically simple separation of the mucosa from underlying muscle, permitting implantation of ureters in an antireflux fashion and tunneling of continent catheterizable stomas.

The entire arterial supply of the stomach is based on branches of the celiac artery, including the gastric, splenic, and hepatic arteries (Figure 56.9). The right and left gastroepiploic arteries supply the greater curvature and are pertinent for use in gastrocystoplasty. The gastroepiploic arteries arise from the right gastric and splenic arteries, respectively. They usually do not anastomose directly but are connected through small arterial branches.

The main physiologic function of the stomach is to digest food mechanically and chemically. Given this, the muscle of the stomach functionally contracts in a manner that is different from the rest of the intestinal tract in that it acts to churn its contents as opposed to moving the bolus of food along a peristaltic wave. This unique pattern of contractility may be the cause of the phasic contractions that are seen in the augmented bladder following gastrocystoplasty.

The stomach chemically digests food through the secretion of acid. The exact mechanisms responsible for the control of acid secretion from the stomach are still not completely understood. Current evidence suggests that parietal cells, which are mainly located in the body of the stomach, secrete acid in response to

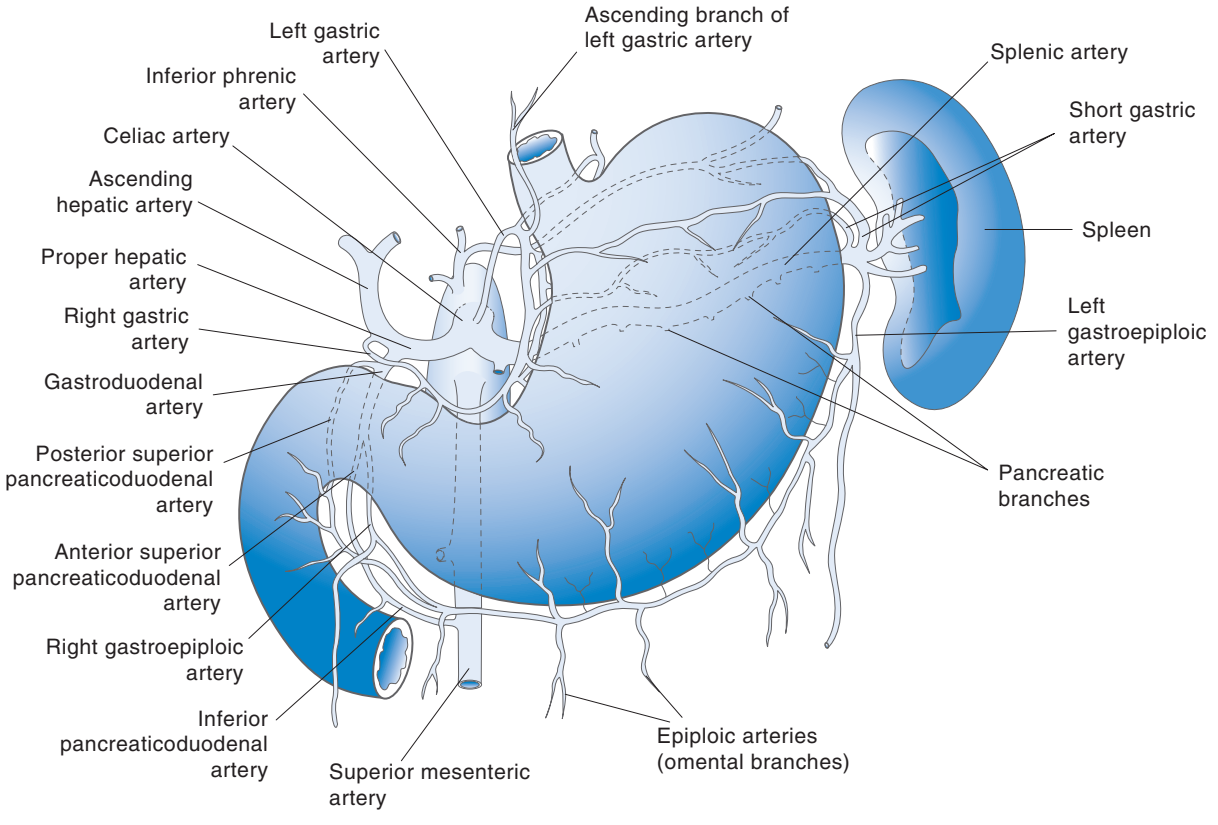

Figure 56.9 Arterial blood supply to the stomach. (Adapted from Lindner,[17] with permission.)

gastrin that is released from G cells located in the antral mucosa. G cells, in turn, are stimulated to release gastrin by direct contact of the mucosa with food, antral distention, and vagal stimulation. Acid secretion can also be stimulated by acetycholine and histamine. The latter is important in that acid secretion from gastric segments following gastrocystoplasty can be inhibited with H_2 receptor blockers.

In addition to the stomach's ability to secrete chloride, other metabolic properties of importance include its barrier function to ammonium and chloride reabsorption. The combination of hydrogen ion and chloride secretion predisposes patients to the development of hypochloremic, hypokalemic, and metabolic alkalosis following gastrocystoplasty. However, this secretion of acid is beneficial in patients who have chronic acidosis associated with renal insufficiency.

Advantages and disadvantages

Surgically, the stomach is relatively thick and easy to work with. Use of stomach for bladder augmentation has clear advantages in patients with renal insufficiency owing to its ability to secrete acid. This allows for buffering of systemic acidosis and reduces the need for bicarbonate supplementation. The resultant acid urine also appears to decrease the incidence of bacteriuria. In comparison to other intestinal segments, there is decreased mucus production and stone formation. The inherent musculature of the gastric segment may offer an additional advantage over small and large bowel by increasing the possibility for spontaneous voiding. This may result in more efficient emptying, less residual urine, and decreased need for intermittent catheterization.[103,104] Lastly, gastrocystoplasty can potentially be accomplished laparoscopically, which offers significant advantages in more rapid patient recovery following surgery.[105]

The main disadvantage of gastrocystoplasty that currently limits its widespread use in children with neuropathic bladders is the high incidence of HDS. This is most troublesome in patients who have a sensate urethra and perineum. Given this, caution should be exercised in selecting patients who are sensate and are at risk for incontinence (i.e. bladder exstrophy) when other enteric segments are available. This also applies when considering gastrocystoplasty in a patient with end-stage renal disease in need of transplantation, since ulcer formation and perforation of defunctionalized bladders have been reported.[106]

Postoperative studies suggest that gastrocystoplasty results in a less compliant and capacious reservoir than that usually achieved with conventional enterocystoplasty. Gastrocystoplasty may therefore be less useful in patients with a very small, non-compliant bladder plate.[31,107]

Surgical technique

The original gastrocystoplasty, as described by Leong and Ong,[99,100] used the antrum of the stomach. Since incorporation of antral tissue may increase cyclical secretion of acid because of antral distention during bladder filling, more recent forms of gastrocystoplasty[102,108] favor utilization of a wedge taken from the greater curvature of the stomach that incorporates more body and less antrum (Figure 56.10). Depending on the individual vascular supply, this wedge of tissue may be based on either the right or left gastroepiploic artery. There is usually a vascular window between these arteries that defines which artery is dominant. Since the right gastroepiploic artery is longer and dominant in the majority of cases, this is more commonly used. A 10–15 cm length of stomach along the greater curvature is chosen, with special care being taken to minimize inclusion of antral tissue. Branches of the gastroepiploic artery that are not directly supplying the wedge to be harvested are ligated. The wedge of stomach is isolated with the use of bowel clamps or an automatic stapler. The authors prefer the latter. The apex of the gastric wedge should be at least 1 cm below the lesser curvature to prevent injury to the vagus nerve and the right gastric vessels. Before isolation of the gastric wedge, it is advisable to ligate branches of the right gastric artery near the apex of the wedge, since failure to do this can result in significant blood loss.[109] A flap of greater omentum must also be mobilized along with the gastric wedge. The stomach is then closed in two layers. Alternatively, Raz et al[110] have described a technique using an automatic stapler to harvest a gastric segment along the greater curvature of the stomach without opening the stomach.

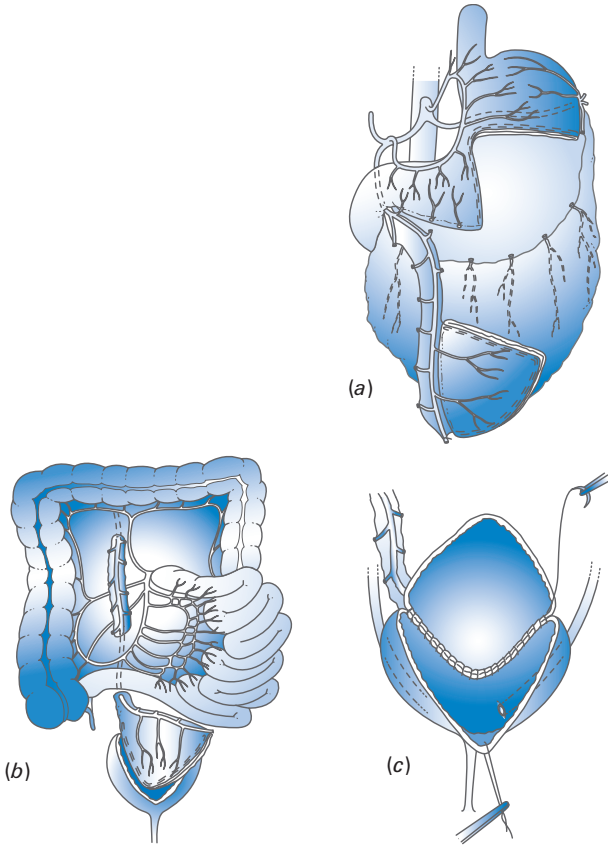

Figure 56.10 Gastrocystoplasty. (*a*) A wedge of stomach is isolated along the greater curvature of the stomach with its blood supply based on either the right or left gastroepiploic artery. (*b*) The flap is brought through the mesenteries of the small and large bowel or retroperitonealized following complete mobilization of the small and large bowel. (*c*) The flap is then anastomosed to the bivalved bladder.

Once the gastric segment is isolated, it is retroperitonealized by bringing it through the mesenteries of the transverse colon and small bowel. Special care should be taken to close these defects in the mesentery to prevent internal intestinal herniation. Alternatively, the right colon and duodenum can be mobilized up to the root of the small bowel mesentery, which allows placement of the gastric segment and its trailing vascular supply entirely in the retroperitoneal space. After the segment has been relocated inferiorly into the pelvis, it is rotated 90° to straighten the mesentery and vessels. The staples are then removed and the posterior tip of the stomach is sutured to the posterior aspect of the bivalved bladder using a running, interlocking 3–0 polyglactin suture.

Postoperatively, the augmented bladder should be adequately drained with a suprapubic tube and urethral catheter. A nasogastric suction tube is maintained for 3–5 days postoperatively. Following removal of the nasogastric tube and resumption of oral intake, the patient should be encouraged to eat small, frequent meals for the first few weeks to months.

Results

The urodynamic results of gastrocystoplasty are somewhat variable. Some authors report that it is

useful in increasing capacity and compliance, similar to large and small bowel.[111] In studies that have analyzed both preoperative and postoperative urodynamics, gastrocystoplasty has been shown to increase bladder capacity by approximately 150–200%.[112–114] However, it should be noted that there is a wide range of results reported with regard to increased bladder capacity following gastrocystoplasty.[31,108,111,113–115] In a recent series comparing the urodynamic findings and clinical outcomes following augmentation with stomach versus intestine, it was shown that both stomach and intestine are efficacious in improving compliance, but that the use of ileum and colon results in a higher volume reservoir. Intestinal segments appear to expand more readily following augmentation than does stomach.[31] Some of the differences in the literature regarding improvements in capacity and compliance following gastrocystoplasty may be in part explained by the variable amounts of stomach that have been harvested in individual patients. However, less volume expansion seems inherent to gastric segments when compared with ileum and colon.

A unique postoperative urodynamic finding after gastrocystoplasty is the presence of low-amplitude, rhythmic contractions during bladder filling. These contractions are usually <30 cmH_2O.[102,115] However, contractions >30 cmH_2O have been noted to be present in 10% of patients.[113–115]

Taken together, experience with gastrocystoplasty demonstrates that it is clearly an effective procedure in providing improvements in bladder compliance and capacity. However, in comparison to ileum and colon, stomach often results in a reservoir that is less capacious and perhaps less compliant.

HDS is unique to gastrocystoplasty. It is defined as the presence of pain in the bladder, suprapubic, or genital area, coffee-brown or bright-red hematuria in the absence of infection, skin irritation or excoriation, and painful urination or pain with catheterization. HDS occurs in up to one-third of patients and is the major factor that has limited the more widespread use of gastrocystoplasty in children requiring enterocystoplasty. In the largest series to date with long-term follow-up, Plaire et al[116] reported that 24% of patients following gastrocystoplasty had some element of this syndrome. Other retrospective series have reported the incidence of HDS to be as low as 2% and as high as 50%.[22,111,117] The disparity in these numbers probably relates to the variable make-up of the patient populations in each study. Also, longer-term follow-up may result in an increased incidence of complications.[118] In all studies evaluating HDS following gastrocystoplasty, a uniform finding is that HDS is much more prevalent in patients who have a sensate urethra and perineum, whereas it is less common in patients who are insensate, as in patients with a neuropathic bladder secondary to spina bifida or spinal cord injury. Despite the relatively high incidence of HDS following gastrocystoplasty, most patients respond well to either H_2 receptor blockers or hydrogen ion pump blockers such as omeprazole.[119] In some patients, alkaline irrigation of the bladder can also be used effectively.[120] A small percentage of patients may be refractory to all forms of conservative medical management, necessitating conversion to a different form of augmentation or diversion.[121]

The etiology of HDS is not entirely clear. Bogaert et al[122] demonstrated that the gastric mucosa in the augmented bladder is stimulated in the same way as the native stomach. With this in mind, some authors have proposed that hypergastrinemia may be a causative or major contributing factor in patients with HDS. The association of hypergastrinemia and HDS has been demonstrated in several patients.[114,119,123–125] Despite this association, there has never been a direct correlation between this syndrome and aciduria and/or hypergastrinemia.[111,117]

Another potential complication associated with the use of stomach is peptic ulcer disease of the gastric patch with subsequent perforation.[106] It has been postulated that *Helicobacter pylori* infection may be an important etiologic factor in patients who develop ulcerative changes in the gastric portion of the augmented bladder.[126] Although patients are at significant risk for the development of HDS following gastrocystoplasty and other related complications associated with acid secretion by the stomach segment, it is rarely necessary to remove the gastric patch. Medical management of these problems is usually successful.

The beneficial effects of gastrocystoplasty in patients with reduced renal function and systemic acidosis are well documented.[102,103] However, the metabolic losses of acids and chloride may be overabundant, resulting in significant hypochloremic, hypokalemic, and metabolic alkalosis in some. This metabolic imbalance has been severe enough to warrant hospitalization in up to 7% of patients with gastrocystoplasty.[111,112] The mechanisms responsible for the development of a severe form of hypochloremic, hypokalemic alkalosis have not been precisely or sequentially elucidated. Significant risk factors appear

to be recent viral illness associated with vomiting and other gastrointestinal losses, urinary concentrating defect,[102] renal insufficiency,[127] and the absence of acidosis prior to gastrocystoplasty.

As is the case with HDS, the development of hypergastrinemia following gastrocystoplasty has been postulated, although not definitively proven, to play a significant etiologic role in the development of metabolic alkalosis.[119,123,125] Clinical management of patients with hypochloremic, hypokalemic alkalosis includes aggressive intravenous rehydration with normal saline, replenishment of sodium and chloride, and use of H_2 receptor blockers. Once again, it is unusual to have an electrolyte abnormality that is so severe and unresponsive to medical therapy that removal of the gastric segment becomes necessary.

In comparison to conventional enterocystoplasty with small and large bowel, the incidence of bacteriuria, mucus production, and the development of bladder stones are significantly less following gastrocystoplasty.[62,102,115,128,129] The combination of decreased mucus, acidic urine, and the potential for spontaneous voiding (thus eliminating the need for intermittent catheterization) may be responsible for this decreased incidence.

Composite gastrocystoplasty and intestinocystoplasty (gastrointestinal composite)

As seen in the previous discussion regarding intestinocystoplasty and gastrocystoplasty, use of single enteric segments for augmentation has unique individual advantages and disadvantages. Since some of the metabolic effects of gastrocystoplasty are directly opposite to those of intestinocystoplasty, it has been proposed that some of these metabolic effects could buffer each other if both enteric segments are placed in combination. This concept was first introduced by Lockhart et al.[130] Ideally, the advantages of each segment could be retained and maximized with concomitant reduction of many of the undesired side effects: i.e. the stomach could still be retained for reimplantation of catheterizable tubes and ureters, whereas incorporation of a piece of ileum could reduce the side effects of increased acid secretion in the bladder (HDS) and enhance the urodynamic effects that are achieved with the use of stomach alone. Over the last decade, several reports have now demonstrated that gastrointestinal composite augmentation is feasible and advantageous in select patients.[131–134] The composite augment can either be constructed primarily or as a secondary procedure following a previous augmentation with a single piece of stomach or bowel. The size of each individual gastrointestinal segment can be varied depending on the individual metabolic and urodynamic needs of each patient. Austin et al[133,134] have demonstrated that the beneficial reduction in acid load in patients with renal insufficiency can still be maintained with the gastrointestinal composite augmentation, while the buffering effects of the incorporated intestine helps to reduce the incidence of HDS. In addition, the incidence of bacteriuria and stone formation is lower in composite reservoirs than intestinocystoplasty alone, presumably in part due to the lessened mucus production from the gastric segment. Although technically demanding, gastrointestinal composite augmentation appears to be a viable and improved form of augmentation in select patients with short bowel syndrome, metabolic acidosis, and renal insufficiency.

Autoaugmentation

Autoaugmentation, also known as vesicomyotomy and vesicomyectomy, was introduced by Cartwright and Snow.[135,136] This is a novel approach to bladder augmentation that aims to enlarge bladder capacity and improve bladder compliance without using a patch graft or opening the bladder. In essence, this procedure creates a large bladder diverticulum by removal of the bladder muscle from the dome. The most important advantage of this procedure is the avoidance of intestinal epithelium with its associated complications. The native urothelium is preserved. The major drawback of autoaugmentation is that experience has failed to identify the most appropriate patients for this procedure. Mixed results have been obtained clinically with regard to postoperative symptomatic and urodynamic improvement in the autoaugmented bladder. Evaluation of the available data indicates that there is no direct correlation between preoperative urodynamic findings and success. It works well in some patients while it fails in others. Nevertheless, it appears that this procedure is best suited for patients with reduced compliance in combination with a near-normal preoperative bladder capacity.[137–139]

Despite the problems in predicting surgical success preoperatively, it seems reasonable to consider autoaugmentation as an option in some patients in whom bladder augmentation is needed and there is a desire to avoid the use of bowel. However, patients

need to be aware of the relatively high failure rate of autoaugmentation in comparison to conventional enterocystoplasty. Patients that should be excluded from consideration for autoaugmentation include those with failed bladder exstrophy repair, those who have had multiple previous bladder operations, and patients with very small bladder capacities. Autoaugmentation in these children is more difficult technically and results in general have been poor.[137,139]

Anatomy and physiology

Autoaugmentation preserves the native bladder urothelium. The metabolic and physiologic properties of this urothelium following autoaugmentation are not well studied, although available data suggest that no significant changes occur. Following autoaugmentation, the mucosal herniation has been shown in both experimental animals and humans to have evidence of collagen deposition, neovascularity, variable inflammatory changes, and occasional muscle fibers.[139–141] No significant metaplastic or dysplastic changes in the native urothelium have been reported.

Advantages and disadvantages

The primary advantage of autoaugmentation over conventional enterocystoplasty is preservation of the patient's native urothelium in the augmented segment. This avoids the complications associated with enterocystoplasty related to the presence of heterotopic epithelium in contact with the urine noted previously. Technically, autoaugmentation can be an extraperitoneal procedure performed through a Pfannenstiel incision, avoiding the complications of transperitoneal bowel surgery. Although autoaugmentation is usually performed without a formal cystotomy, other bladder procedures such as ureteral reimplantation and appendicovesicostomy can be carried out (intravesically or extravesically) at the same time. Lastly, it is important to note that autoaugmentation does not preclude further augmentation procedures if unsuccessful.

The main disadvantage of autoaugmentation is the inability to predict which patients will do well with this technique. An additional concern is the theoretical risk of bladder rupture that has been demonstrated in animal studies.[142,143] Although perforation of the autoaugmented bladder has been reported in only one patient to date,[144] the overall increased risk of bladder rupture compared with other types of bladder augmentation has yet to be defined.

Surgical technique

Patients should receive a full bowel preparation preoperatively and be counseled on the possible need to perform an alternative type of augmentation if intraoperative findings dictate that autoaugmentation is not technically feasible. Specifics regarding the technique of autoaugmentation have been well described by Snow and Cartwright.[139] The procedure is usually performed through a Pfannenstiel incision and is done extraperitoneally. Once the bladder is mobilized, the peritoneal covering is entirely detached. Snow and Cartwright advocate the performance of intraoperative urodynamics, both before and after the autoaugmentation. Although not definitive, intraoperative urodynamics can be useful in making an assessment of potential success. It also assists in establishing the maximum volume following autoaugmentation to which the bladder can be safely distended during the immediate postoperative period.

Once the initial intraoperative urodynamic study is completed, the bladder is filled and a needle-tipped electrocautery device is used to divide the detrusor

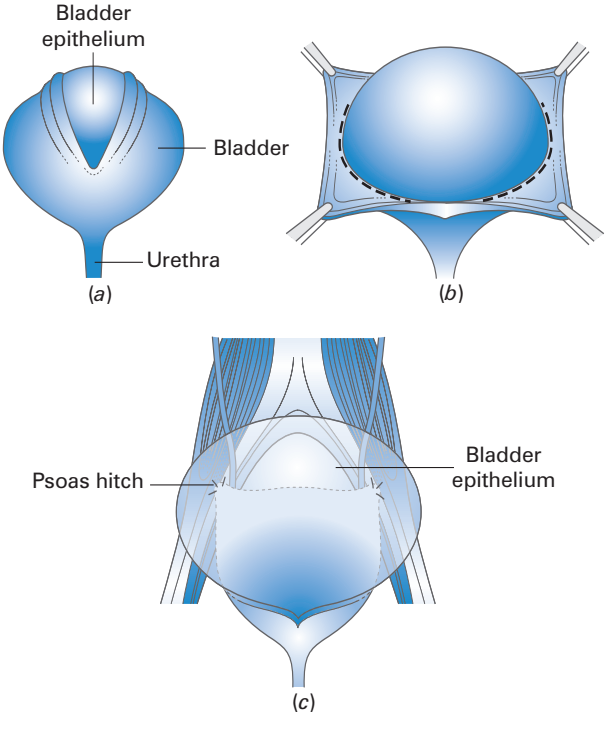

Figure 56.11 Autoaugmentation. (*a*) The detrusor muscle is incised in the midline and a plane is established between the muscle and the underlying mucosa. (*b*) This plane is further developed and a large mouth diverticulum is created. (*c*) The remaining detrusor muscle is fixed posteriorly to prevent its coaptation. (Adapted from Cartwright and Snow,[135] with permission.)

musculature from the underlying epithelium (Figure 56.11). This is usually started ventrally in a vertical fashion. The plane between the underlying epithelium and the overlying muscle is then identified and further developed using both blunt and sharp dissection. Special care is taken to avoid tears in the urothelium, since this can be difficult to repair in some cases and urinary extravasation postoperatively is associated with inflammation. Inability to distend the bladder postoperatively may result in contraction. When perforation does occur, it should be repaired with fine, absorbable suture. Removal of overlying muscle fibers continues until the detrusor musculature is removed from at least one-half of the bladder. Optimally, as much musculature is removed as possible. At this juncture, intraoperative urodynamics is repeated once again. If there is minimal to no improvement in bladder capacity and/or compliance, autoaugmentation should be abandoned and conventional enterocystoplasty undertaken following excision of the redundant bladder epithelium.

After autoaugmentation is completed, either one can excise the detached detrusor musculature or the remaining lateral bladder muscle can be attached to the psoas muscles. However, neither of these steps has been found to be essential for success.[139,145] Postoperatively, a urethral catheter and Penrose drain are left in place. Suprapubic tubes are avoided, as the bladder should be watertight. Experience has shown that bladder distention during initial healing is important for surgical success. This can be accomplished either by intermittent distention of the bladder to the capacity that was determined appropriate intraoperatively or by maintaining catheter drainage with constant bladder distention at an intravesical pressure of 20–40 cmH_2O. The catheter can generally be removed in 1–2 weeks. It is recommended that a cystogram be performed before catheter removal to exclude urinary extravasation.

Recently, several authors have demonstrated that technically successful bladder autoaugmentation can be accomplished laparoscopically.[146–149] Although a laparoscopic approach is feasible, further experience is necessary to determine whether this approach is clinically successful and cost-effective.

Results

The efficacy of autoaugmentation in improving bladder capacity and compliance has been varied. Cartwright and Snow[137] have reported follow-up of greater than 1 year in 30 patients, 19 of whom had a neuropathic bladder secondary to spina bifida. All patients had preoperative urodynamic evidence of reduced bladder compliance and detrusor hyperreflexia. Whereas clinical success has been dramatic in some patients, the overall results have been less impressive. One-third of the patients had a significant increase in bladder capacity, an additional one-third were unchanged, while one-third had loss of capacity. Evaluation of bladder compliance revealed that 60% had an improvement in compliance by >50% compared with preoperative measurements, 20% had a 20–50% improvement, and the remainder did not change significantly. Following autoaugmentation, the majority of patients remained on intermittent catheterization, although 20% demonstrated the ability to void spontaneously. Seven of these 30 patients have required secondary enterocystoplasty.

Snow and Cartwright have re-evaluated preoperative parameters in these patients in an effort to identify specific factors that would help to prognosticate eventual outcome following autoaugmentation. Unfortunately, they were unable to identify any such factors. However, certain generalizations can be made from this analysis. Autoaugmentation appears to be poorly suited to patients with a history of bladder exstrophy or multiple prior bladder operations, since in these patients it is difficult to develop a plane between the bladder muscle and mucosa. Results have also been relatively poor in these groups. The ideal candidate is the patient with a near-normal bladder capacity but reduced compliance.

Since the original publications describing the autoaugmentation technique, several other centers have reported their experiences with autoaugmentation in children. Stothers et al[150] performed autoaugmentations in 12 pediatric patients. They observed a mean increase in bladder capacity of 40% and a mean decrease in leak point pressure of 33%. Skobejko-Wlodarska et al[151] have reported on the use of autoaugmentation in 21 children with spina bifida and found a modest increase in bladder capacity in two-thirds of patients and significant improvements in bladder compliance in another two-thirds. Two recent series with long-term follow-up in children with myelomeningocele have demonstrated less favorable results.[152,153] Both studies demonstrated that a majority of patients were considered surgical failures due to a lack of clinical and/or urodynamic improvement and a high incidence of patients requiring subsequent enterocystoplasty.

The experience with autoaugmentation in the adult population appears to be more predictable and con-

sistently favorable than the results described thus far in children. Stohrer et al[154,155] reported on 50 adult patients from their spinal cord injury center. In patients with neuropathic hyperreflexive bladders that were refractory to medical therapy, bladder autoaugmentation was found to increase mean bladder capacity from 121 to 406 ml with concomitant improvements in bladder compliance. McGuire and colleagues[156] recently compared the efficacy of enterocystoplasty to autoaugmentation in adults. They reported on over 60 patients undergoing either autoaugmentation or conventional enterocystoplasty. There were no significant differences in postoperative urodynamic parameters between enterocystoplasty and autoaugmentation in patients with refractory detrusor instability, interstitial cystitis, radiation cystitis, and other forms of neuropathic bladder. An important finding was that enterocystoplasty was uniformly superior to autoaugmentation in patients with a history of myelodysplasia. The overall improvement in the results of autoaugmentation in adults may be related to differences in the bladder disease processes and patient population. Autoaugmentation is mostly performed in children with a neuropathic bladder from congenital causes, whereas in adults the neuropathic bladder is usually an acquired condition. It may be that autoaugmentation is more successful in adults because surgery is undertaken earlier in the disease process prior to irreversible histologic and functional changes in the bladder wall.

Seromuscular enterocystoplasty

Seromuscular enterocystoplasty involves the use of a demucosalized flap of colon, stomach, or ileum. The removal of the gastrointestinal mucosa results in a denuded seromuscular flap that can either (1) be used alone as an augmentation flap that is subsequently re-epithelialized with native urothelium from the native bladder or (2) used in conjunction with autoaugmentation in which the seromuscular flap is placed over the exposed bladder mucosa of an autoaugmented bladder. The use of a demucosalized segment of bowel for bladder augmentation was first described by Shoemaker in 1955.[157,158] He was able to show that seromuscular bowel flaps, when placed into the bladder wall with the denuded side either inward or reversed, such that the serosa faced the lumen of the bladder, were re-epithelialized by urothelium. Unfortunately, subsequent long-term studies in small and large animals have consistently demonstrated that seromuscular bowel segments alone scar and contract.[159–162] Histologic evaluation suggests that the scarring is due to the trauma associated with the demucosalization process and/or a prolonged inflammatory response in the denuded bowel before the re-epithelialization of the seromuscular flap from the native bladder urothelium occurs.

The intention of seromuscular enterocystoplasty is to combine the advantages of conventional enterocystoplasty while preserving the native urothelium of the bladder. This procedure ideally results in a muscle-backed augmentation flap that is lined with urothelium. Contraction of the seromuscular flap is hopefully avoided by either rapid regrowth of native urothelium over the demucosalized surface or adherence of the native urothelium to the demucosalized gastrointestinal segment (when combined with autoaugmentation). Numerous animal studies have demonstrated that seromuscular enterocystoplasty with or without autoaugmentation can successfully augment the bladder, with elimination of the complications related to retained intestinal epithelium.[163–167] However, clinical experience thus far has been mixed and varied. Early experience with this procedure suggested that the success may be limited by the same factors that give rise to inconsistent results with autoaugmentation. More recent modifications of the technique, including improved methods for demucosalization and constant distention of the seromuscular flap during the initial postoperative period, have demonstrated that more reliable results are possible. Further experience with long-term follow-up is needed to better determine the factors that are important in predicting success and whether this type of augmentation remains stable without future fibrosis, loss of compliance, and/or metaplastic changes. Nevertheless, seromuscular enterocystoplasty represents an intriguing advancement in bladder augmentation techniques whose appropriateness for routine use in children is currently being defined.

Anatomy and physiology

Seromuscular enterocystoplasty has been accomplished with stomach, ileum, and colon. The metabolic consequences of seromuscular enterocystoplasty are presumed to be minimal, since the native urothelium is kept intact. This assumption is supported in part by animal studies.[166] Histology from these studies reveals that the urothelium covering the seromuscular flap appears normal.[167,168] Whether or not late metaplastic changes will occur in the bladder urothelium when it is placed in direct contact with a seromuscular segment of

bowel is not known. It has been well documented that stromal–epithelial interactions in other individual organs are important for normal cell growth and function.[169,170] The stroma of the bowel segment may adversely affect the overlying growth and function of the bladder urothelium in the long term.

Advantages and disadvantages

The advantages of this procedure are similar to those of autoaugmentation, with the most important being preservation of the native urothelium. This avoids the aforementioned complications associated with the interposition of heterotopic intestinal epithelium in the urinary tract. Since it has been shown that partial re-epithelialization of the seromuscular segment with enteric epithelium can occur, it is not clear that these problems will be totally avoided. This is especially important when considering the long-term risk of tumor formation, since the presence of any intestinal mucosa is clearly worrisome. An advantage of seromuscular enterocystoplasty over autoaugmentation alone is the provision of adequate muscle backing of the augmented segment. This may potentially reduce the risk of scarring and fibrosis and may lessen the risk of spontaneous perforation.

There are currently two major disadvantages to this procedure. It is a technically demanding procedure and much more labor intensive than conventional augmentation cystoplasty or autoaugmentation alone. In addition, clinical experience is limited and the available published results are mixed with regard to postoperative urodynamic improvements. Postoperative distention of the augmented bladder appears to be an important factor for the success of this procedure. Thus, some authors have advocated routinely increasing bladder outlet resistance with seromuscular enterocystoplasty and the avoidance of concomitant intravesical procedures when possible.[138]

Surgical technique

Seromuscular enterocystoplasty is initially begun by isolating a segment of stomach, ileum or colon. (Figure 56.12). The isolated segment of stomach or bowel is then detubularized. The most difficult and

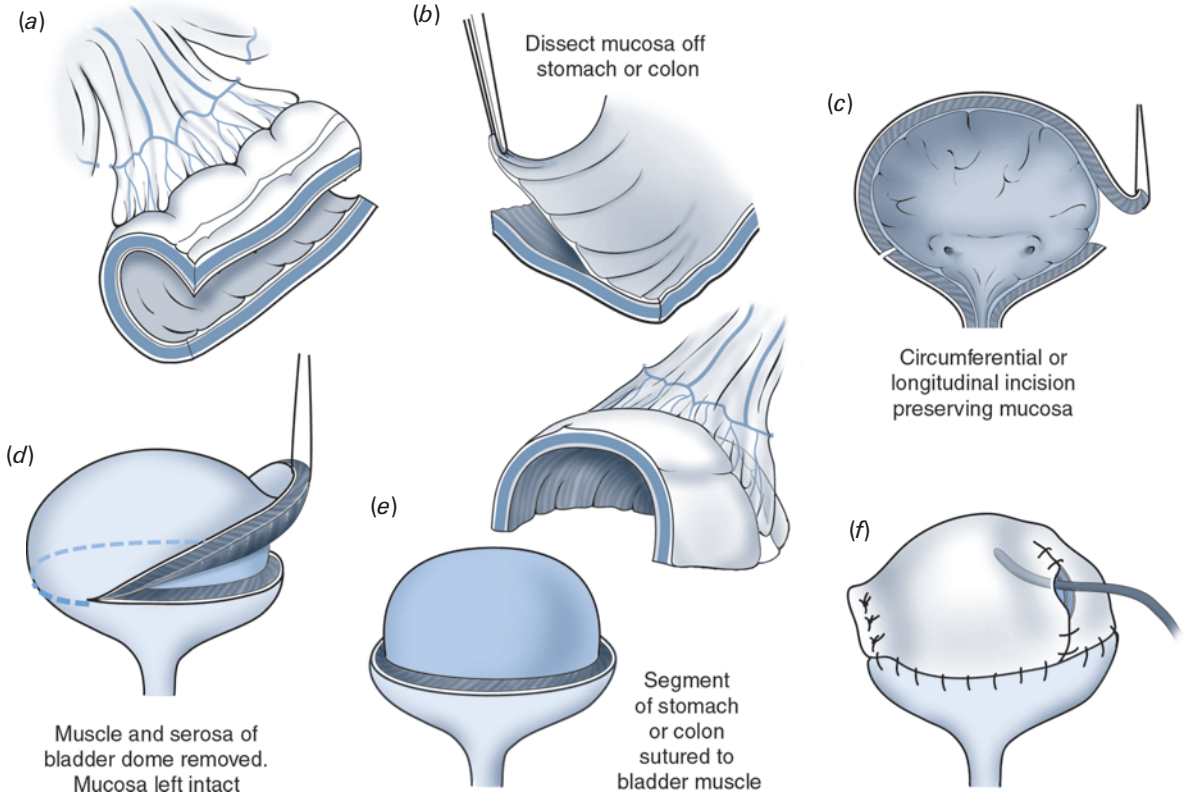

Figure 56.12 Seromuscular enterocystoplasty. (*a*) A portion of stomach or colon is isolated. (*b*) The mucosa is removed with sharp dissection. (*c* and *d*) An autoaugmentation is then performed, resulting in an exposed diverticulum of bladder mucosa. (*e*) The demucosalized flap of stomach or colon is laid on top of the exposed mucosa and anastomosed to the edges of bladder muscle. (*f*) A drain can be placed in between the flap and the mucosa to facilitate adherence of the two surfaces. (Adapted from Buson et al,[168] with permission.)

technically demanding portion of this procedure is demucosalization of the flap. The plane of dissection and whether the submucosa should remain with the seromuscular flap is a point of contention. It has been suggested by some authors that the muscularis mucosa (which is contained in the submucosa) needs to be removed in addition to the enteric mucosa to prevent regrowth of intestinal mucosa and flap contracture,[171] whereas others have argued that preservation of the submucosa with the flap is necessary to prevent flap contracture during the immediate postoperative period.[172] Once the plane of dissection is established, removal of the mucosa can be accomplished with sharp dissection and intermittent use of electrocautery. Usually, the mucosa can be progressively peeled away from the underlying muscle once the proper plane has been established. Occlusion of the arterial blood supply during this dissection can be done to decrease blood loss and facilitate visualization.[173] Since some have postulated that the trauma of demucosalization is a factor that contributes to flap contracture, alternative methods of mucosa removal have been developed, including use of an argon beam laser.[174] Alternatively, the bowel segment can be distended with a Foley balloon prior to detubularization and the seromuscular flap can be dissected off of the underlying mucosa from the outside.[175]

If the seromuscular enterocystoplasty is to be performed alone without autoaugmentation, the demucosalized flap is placed onto the bivalved bladder as is routinely done for intestinocystoplasty. Postoperatively, some authors have suggested the need for diversion of urine from the bladder with externalized stents and distention of the augmented bladder with a silicone balloon for the first couple of weeks postoperatively to avoid flap contraction.[176]

If the seromuscular enterocystoplasty is to be combined with autoaugmentation, the flap is placed on top of the exposed mucosa following completion of the autoaugmentation, as described in the previous section. Adherence of the bladder mucosa to the raw surface of the seromuscular flap is felt to be critical to the long-term success of this operation. Several techniques have been suggested to facilitate this process. A small, flat Jackson–Pratt drain has been used to prevent the formation of a hematoma or seroma between the urothelium and the seromuscular flap that could prevent adherence between the two surfaces. Multiple mattress sutures can also be used to secure the flap to the native bladder urothelium. As with autoaugmentation, postoperative distention of the bladder with intermittent irrigation or constant distention of the bladder to 20–30 cmH_2O appears to be important for success. Carr et al[173] have described the use of a Helmstein balloon in the bladder postoperatively to produce partial distention and compaction of the urothelium against the denuded muscle.

Results

Initial preliminary reports by Dewan and Gonzalez in both animal models and humans were encouraging.[167,168,177,178] In a series of 16 patients undergoing seromuscular colocystoplasty using sigmoid colon, bladder capacity was increased to almost 2.5 times the preoperative volume and end filling pressures decreased by approximately 50%.[178] Dewan and Stefanek[177] reported on five patients undergoing seromuscular gastrocystoplasty. Four of the five patients had urodynamic evidence of improved bladder capacity and compliance during the first postoperative year. Despite these initial encouraging results, it is important to note that the follow-up in these early series was relatively short, and that approximately 25% of patients have eventually required a secondary operation due to either complications related to the seromuscular flap (contracture) and/or failure to improve adequately bladder capacity and/or compliance.

A subsequent report from Carr et al[173] described 13 patients that underwent seromuscular gastrocystoplasty with variable success. The mean follow-up was 50 months. Five patients had a 'good' outcome and four had a 'fair' outcome with regard to objective urodynamic and subjective clinical improvement. The remaining four patients had a poor result and required reaugmentation. Evaluation of preoperative urodynamic and radiographic data in these patients again demonstrated that it was not possible to predict preoperatively which patients would do well after seromuscular gastrocystoplasty.

More recent large series with long-term follow-up have now been reported with more encouraging results. Lima et al[176] reported on 129 patients that underwent seromuscular enterocystoplasty, of which 24 were done without concomitant autoaugmentation: sigmoid was used in 104 cases and ileum was used in the remaining 25; median follow-up was 51 months; a 329% increase in bladder capacity was noted and a sevenfold increase in bladder compliance; no significant mucus production was noted in any patient and no cases of perforation were observed; and 10% of patients did require reaugmentation. The authors attributed their improved success to several modifications in technique, including demucosalization of the

seromuscular flap from the outside using an intraluminal Foley balloon during this important dissection, routine postoperative distention of the bladder, and diversion of the urine for 2–3 weeks. Jednak et al[179] have also reported favorable results in 32 patients: all were done in conjunction with autoaugmentation; mean follow-up was 1.6 years; and a near twofold increase in bladder capacity was noted with a 12.5% reaugmentation rate. A more recent report from the same group has also demonstrated the ability to combine seromuscular enterocystoplasty with placement of an artificial sphincter with no increase in the complication rate.

Recurrent or persistent intestinal mucosa has been found in several patients after seromuscular enterocystoplasty.[171,179] Whether this partial intestinal regrowth is progressive or clinically relevant remains to be determined. As mentioned above, it has been suggested and supported by animal studies that removal of the submucosa may prevent re-epithelialization of the seromuscular flap with islands of native enteric mucosa.[171]

Ureterocystoplasty

The use of ureteral tissue for bladder augmentation was first described in 1992.[180,181] Since then, its use in children has become more popular.[182–184] For many reasons native ureter is the best tissue available for augmentation cystoplasty. It is autologous, lined with urothelium, backed by muscle, distensible, and compliant. However, few patients in need of bladder augmentation have widely dilated ureters available for such use. Patients who are candidates for ureterocystoplasty should have either a non-functional renal unit that can be removed, making the ureter and renal pelvis available, or a functional renal unit that is associated with a massively dilated, tortuous, and elongated ureter.[182,185] The lower ureter can then be used for augmentation while kidney drainage is re-established either by reimplantation of the straightened upper ureter into the bladder or by transureteroureterostomy.

One of the challenges that one faces in selecting the appropriate patient for ureterocystoplasty is determination of whether the ureter that is to be used is going to be adequate for successful augmentation. Recent clinical experience and long-term urodynamic follow-up suggests that the detubularized and reconstructed ureter following ureterocystoplasty remains compliant, but that the overall compliance, distensibility, and volume may not increase significantly as compared with the dilated intact ureter in its preoperative state. Thus, postoperative urodynamic studies in a patient with a refluxing ureter that was used for ureterocystoplasty may not show a significant increase in volume and compliance of the augmented bladder compared with preoperative studies (when the ureter was refluxing and intact).[186] However, if the ureter that is to be used is not refluxing, then improvement in urodynamics following ureterocystoplasty would be expected and may be directly related to the degree of ureteral dilatation that is present preoperatively. Given this, preoperative urodynamic studies can be very valuable in select patients in predicting success or failure following ureterocystoplasty, especially in the setting of refluxing ureter.

Ureterocystoplasty can also be appropriate in patients with end-stage renal failure on dialysis who are awaiting transplantation and are in need of augmentation owing to bladder dysfunction. As is the case with conventional intestinocystoplasty, the augmented bladder following ureterocystoplasty and subsequent transplantation has been shown to function adequately.[187]

Anatomy and physiology

Preservation of the ureteral blood supply is paramount when performing ureterocystoplasty. The normal ureter receives its blood supply from branches of numerous vessels including the aorta and renal, gonadal, and common iliac arteries (Figure 56.13). The upper ureter receives its blood supply medially, whereas the lower ureter receives it posterolaterally. There are extensive anastomosing plexuses in the adventitia of the ureter that are important to preserve if viability of the ureter is to be maintained. Careful attention to these vessels allows for long segments of ureter to be mobilized without vascular compromise. Ureteral urothelium is contiguous with the urothelium from the bladder and has similar physiologic characteristics. Peristalsis of the ureter depends on autonomic innervation and input from intrinsic pacemaker sites in the minor calices of the renal collecting system.[188] Although the ureter is detubularized and its inherent innervation is disrupted with ureterocystoplasty, it appears that the ureteral tissue still maintains some ability to contract.

Advantages and disadvantages

There are several advantages in using the ureter for augmentation. As is the case with autoaugmentation, the major advantage of ureterocystoplasty is that the

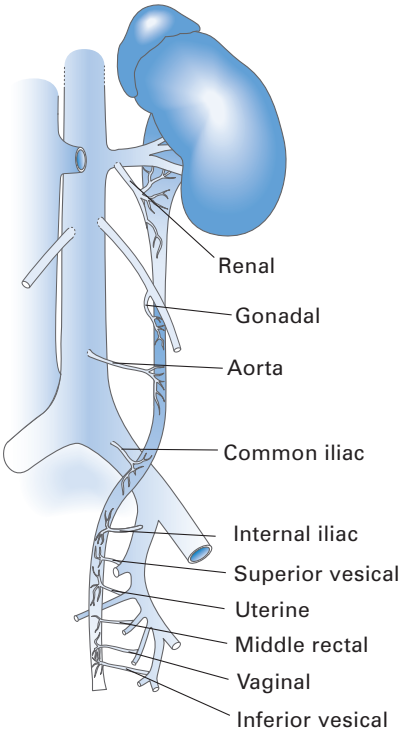

Figure 56.13 Arterial blood supply to the ureter. (Adapted from Lindner,[17] with permission.)

native urothelium is preserved, thereby avoiding the specific potential problems associated with the use of bowel. Unlike some cases following autoaugmention, the full-thickness opened ureter does not tend to shrink with time, unless the vascular supply is compromised. In patients with end-stage renal disease, the procedure can be performed extraperitoneally, thus preserving the peritoneum for future peritoneal dialysis. Alternatively, it can also be performed with laparoscopic assistance for the nephrectomy and upper ureter mobilization.[20,189,190] When needed, concomitant procedures in the bladder may also be performed. It seems likely that the risk of tumor formation will be avoided, and perforation of the augmented bladder may be less probable. However, long-term follow-up will be needed to confirm these possibilities.[182] Finally, there is increased potential for spontaneous voiding postoperatively, especially in patients who are able to empty their bladders adequately preoperatively.

The main disadvantage of ureterocystoplasty is that it is only applicable in a minority of patients. More recently, the use of ureterocystoplasty has been expanded in an attempt to take advantage of this valuable tissue and make it available to more surgical candidates. Its use has been reported in patients with a duplex system in which either the upper or lower pole is non-functioning.[191] In patients with a duplex system and a dilated ureter in conjunction with a functioning renal segment, drainage of that segment can be accomplished with an ipsilateral pyeloureterostomy or a ureteropyelostomy with preservation of the distal portion of the ureter for augmentation. Ahmed et al[192] also described the tandem use of bilateral megaureters for ureterocystoplasty.

Efforts are being made to produce dilated ureters to make ureterocystoplasty available to more patients. Lailas et al[193] have demonstrated in a rabbit model that a temporary cutaneous ureterostomy can be used to perform hydrostatic distention of the ureter with subsequent successful ureterocystoplasty. Others have reported that placement of a tissue expander in pig ureters adequately dilates the ureter.[194,195]

Surgical technique

Patients undergoing ureterocystoplasty should have a full bowel preparation and sterilization preoperatively in case the ureter is not suitable for augmentation. The procedure can be performed either through a midline incision with transperitoneal approach to the urinary tract or via two incisions such as is used for nephroureterectomy.[196] The latter approach is extraperitoneal. This may be advantageous in patients with severe renal insufficiency who may subsequently require peritoneal dialysis. A nephrectomy is performed initially, preserving the renal pelvis. The upper portion of the ureter and renal pelvis are then mobilized (Figure 56.14). Efforts should be made to preserve as much renal pelvis as possible since this increases the surface area of the augmentation. One should include any available periureteral tissue to protect the network of vessels within the ureteral adventitia. Although the blood supply from the lower ureter (which is derived posterolaterally) can maintain the viability of the upper ureter via this adventitial network, efforts should also be made to preserve collaterals from the gonadal vessels and the main renal vessels. These vessels supply the renal pelvis and upper ureter directly and their preservation helps to ensure adequate vascular supply to the upper portion of the ureter. As Churchill et al[197] have noted, preservation of the upper ureteral blood supply is most important when previous reconstructive surgery has compromised the collaterals involving the distal ureter.

Following mobilization of the renal pelvis and ureter, the ureter is detubularized and reconfigured to form a patch. The bladder is then opened. The bladder incision extends from the ipsilateral ureteral

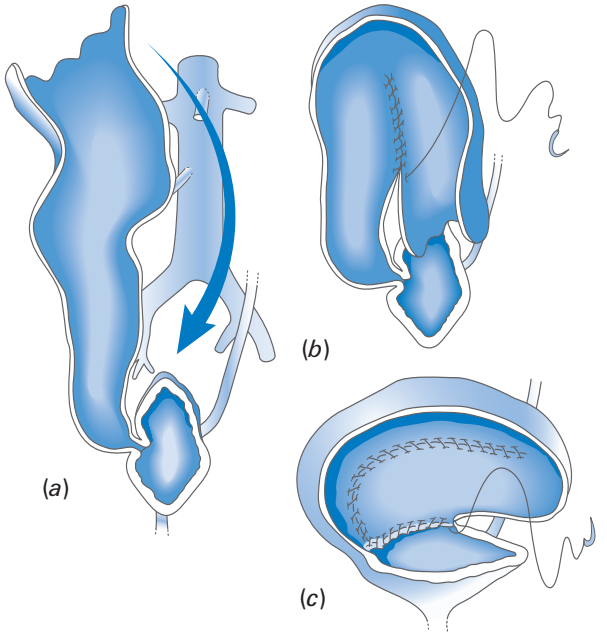

Figure 56.14 Ureterocystoplasty. A standard nephrectomy is performed with preservation of the renal pelvis. (*a*) The proximal ureter is mobilized, with preservation of the medial blood supply. (*b*) The ureter is then detubularized, with the incision for detubularization connecting with the off-center cystostomy. (*c*) The ureter is folded on itself and anastomosed to the opened bladder.

orifice to the contralateral ventral quadrant of the bladder. The incision is carried through the ipsilateral ureteral orifice so that it unroofs the intravesical ureter and meets the detubularization incision in the ureter. This allows the bladder to be opened sufficiently for ureterocystoplasty without much risk of an hourglass deformity. Alternatively, to preserve vascularity, the incision can stop short of the orifice, maintaining the normal configuration of the distal ureter for a few centimeters.[181] Once the bladder is adequately opened, the reconfigured ureteral segment is sutured to the defect in the bladder, creating a wide anastomosis. Prior to closure, a suprapubic tube is placed through the native bladder, and left indwelling for 2–3 weeks. Postoperative care is essentially the same as for routine enterocystoplasty, except that daily irrigation for mucus is not required.

Results

Since its original description in 1992, wide experience has been gained with ureterocystoplasty. Early reports demonstrating its efficacy have led to increased enthusiasm for this technique and a desire to use ureter instead of intestinal segments whenever adequate ureteral tissue is available. Churchill et al[182] initially reported on 16 patients: there was a 218% increase in bladder capacity, a 284% increase in pressure-specific bladder capacity, and a 227% increase in bladder compliance. In a follow-up to this study, Landau et al[198] compared the urodynamic results between patients treated with ileocystoplasty and those with ureterocystoplasty. They reported no significant differences in the postoperative mean increase in bladder capacity and pressure-specific bladder volume. Both procedures produced in excellent functional results. Hitchcock et al[199] described similar excellent short-term results in eight patients.

Subsequent reports have also demonstrated that ureterocystoplasty can be an effective augmentation procedure, but have further clarified which patients are most appropriate for the procedure and what amount of ureter is needed for success. Pascual et al[200] described 22 patients in which only the distal ureter of a single ureter was utilized for augmentation. Whereas increases in capacity and improvement in compliance were noted, only 50% of the patients reached the expected age capacity of the bladder and the overall results were less successful than other reported previous series in which the entire ureter was utilized. In the largest series to date, Hussman et al[186] reported on 64 patients from multiple institutions. In 40 of the patients, augmentation was performed with a complete single or double collecting system. In 9/40 patients, reflux was not present and postoperative success directly correlated with a preoperative ureteral diameter of >1.5 cm. In the remaining 31 patients, reflux was present preoperatively. In these refluxing patients, if the system on preoperative urodynamics demonstrated only mild non-compliance (>20 ml/cmH_2O), ureterocystoplasty improved compliance onefold and was adequate. However, if the system preoperatively demonstrated poor compliance, ureterocystoplasty did not adequately improve capacity and compliance, resulting in 81% of patients having either undergone or being considered for reaugmentation.

Collectively, these results suggest that the ideal patient for ureterocystoplasty is one with a massively dilated ureter in which most (or all) of the ureter can be used for augmentation purposes. If reflux is present preoperatively, then preoperative urodynamics can be predictive of future success. If a poorly compliant system is present in the setting of a dilated refluxing ureter, then failure and the need for reaugmentation are likely. Novel techniques to make ureterocystoplasty more readily available for patients that

do not have massive dilation of the ureter are currently being investigated.

Tissue-engineered bladder

The complications associated with using various portions of the gastrointestinal tract for genitourinary reconstruction in both adults and children, described in this chapter, have stimulated the development of tissue-engineering techniques for bladder reconstruction. Current research efforts are focused on the development of biodegradable materials that are well characterized with predictable behavior. Although attempts at bladder reconstruction via bladder regeneration are not new,[201] the major obstacle has been the lack of a biomaterial, either permanent or biodegradable, that will function as a suitable scaffold to allow the process of regeneration to occur either naturally or with the addition of cultured cells. The ideal graft material is one that would be replaced by the host tissue, provide a low-pressure reservoir, and serve as a scaffold for regeneration of the bladder wall with normal functional characteristics. If a suitable graft material were developed, the need for autogenous tissue and the associated complications of intestinal segments could be eliminated. Currently, two types of tissue-engineering technology have been shown to induce bladder regeneration in preliminary studies: 'unseeded' and 'seeded' technologies.

Unseeded technology

The first technique currently being investigated for bladder regeneration is unseeded technology. This involves the use of tissue matrix grafts that are biodegradable, acellular, collagen based, autologous, or xenogenic.[202–204] This technology involves placement of the graft into the wall of the host bladder. The body then provides the needed environment for subsequent cell growth and tissue generation. This represents an unseeded bladder regenerating process.

Thus far, the major obstacle to unseeded tissue-engineering technology has been the inability to develop an optimal biomaterial that will act as a suitable scaffold for the 'natural' process of regeneration. Synthetic non-biodegradable materials such as silicone, rubber, polytetrafluoroethylene, and polypropylene have been tried without success because of host–foreign body reactions.[205–209] As a consequence of these failures with non-biodegradable materials, synthetic biodegradable materials were developed. It is anticipated that these grafts will allow the host bladder adequate time for regeneration but dissolve before the onset of foreign body reactions. These materials have been used experimentally and have shown less graft encrustation and fewer infectious complications than non-biodegradable materials. However, graft shrinkage still limits the potential clinical utility of these materials.[210] Non-synthetic biodegradable materials such as placenta, amnion, and pericardium have been investigated and have shown a clear ability to host bladder regeneration.[211–214] However, despite initial encouraging laboratory results, none of these materials has been found to be suitable for clinical use. The reasons for this are not entirely clear. It can only be speculated from the available literature that long-term experimental results with these biodegradable materials did not replicate the initial results and, therefore, clinical trials were not undertaken.

Recently, new types of biodegradable material have been developed that have shown tremendous potential for the induction of bladder regeneration with unseeded tissue-engineering technology. These materials are acellular extracellular matrix (ECM) grafts that are derived from various organs. The graft is made acellular by a mechanical process that lyses the cells and/or by detergent and enzymatic extraction. These types of ECM grafts have been derived from full-thickness bladder and stomach and the submucosal layer of small intestine.[202,215,216]

The most thoroughly studied collagen-based ECM graft for bladder augmentation and urinary reconstruction using unseeded technology is small intestinal submucosa (SIS).[217] SIS is a xenogenic membrane derived from pig small intestine in which the mucosa is mechanically removed from the inner surface and the serosa and muscularis are mechanically removed from the outer surface. This results in a thin, translucent membrane (0.1 mm wall thickness) composed mainly of the submucosal layer of the intestinal wall. Production of SIS is reminiscent of the manufacture of sausage casing. This unique material has been shown to function well as an arterial or venous graft, with rapid replacement by native tissues and evidence of tissue-specific regeneration.[218–220]

SIS grafts have been shown to promote full-thickness bladder regeneration in both rat and canine animal models.[221] The regenerated bladder tissue is composed of all three layers of the normal bladder wall (urothelium, smooth muscle, and serosa). In addition, the regenerated segment is contractile, compliant, and functionally innervated. Urodynamic studies in a long-term canine augmentation model have demonstrated that the

SIS augmented bladder maintains normal bladder capacity and compliance for at least 15 months postoperatively.[222] In-vitro muscle strip studies on the regenerated portions of the bladders also demonstrate contractility and compliance that is similar to normal bladder.[223]

SIS has been shown to be non-immunogenic, with over 1000 cross-species transplants and direct challenge testing elucidating no response.[224–226] In addition, SIS is unique from other biomaterials that have been studied thus far in that it contains a combination of active intrinsic growth factors, cytokines, structural proteins, glycoproteins, and proteoglycans that may assist in cell migration, cell-to-cell interaction, and cell growth and differentiation during the regenerative process.[227–229] These inherent elements within SIS may prove to be vital to the regenerative process. It has been recently published that different segments of SIS may have different regenerative potentials for the bladder. Kropp et al[230] have been able to show more reliable bladder regeneration when utilizing distal ileum from a 3-year-old sow as compared with the proximal jejunal segment from the same age sow.[231] The reasons for this variable regeneration are not yet clear and are under investigation.

Acellular ECM grafts similar to SIS have also been shown to induce bladder regeneration. Preliminary work by Sutherland et al[203] and Piechota et al[232] demonstrated successful morphologic and functional regeneration of the rat urinary bladder with homologous bladder acellular matrix grafts (BAMG). Reddy et al[216] also reported on partial bladder substitution with porcine bladder acellular matrix allografts (BAMA) in a porcine model. They demonstrated that the regenerated urothelium with BAMA was multilayered and that there was also histologic evidence of organized smooth muscle regeneration and neoangiogenesis at 30 days.

The above experience with SIS and other similar ECM-derived biomaterials clearly demonstrates that bladder regeneration using unseeded tissue-engineering technology is feasible without the complications of graft shrinkage, encrustation, and infection. These observations have significant clinical ramifications. The ability to augment the bladder without the use of bowel or other native host tissue would eliminate many of the complications of conventional enterocystoplasty and would simplify the technical aspects of this operation. Further research into the individual composition of the various biomaterials,[233,234] the cell-to-cell interactions, and the growth factors[203,235–237] that are involved in the bladder regenerative process will be required before clinical use of these grafts. Advances in this type of mechanistic research will bring us closer to having an off-the-shelf, acellular, clinically available product for bladder augmentation.

Seeded technology

The second type of tissue-engineering technology, the seeded technique, involves the use of biodegradable materials that act as cell-delivery vehicles for cultured cells from the patient. This technique has been applied to the urinary bladder. Initially, this process is begun by harvesting native bladder tissue for the establishment and expansion of primary cultures of both bladder smooth muscle and epithelial cells. Cilento et al[238] demonstrated that it is possible to expand a bladder epithelial cell culture from a single biopsy specimen such that the cultured cells could cover a surface area of over 400 m^2 within 8 weeks. Once the cells are grown, they are seeded on a biodegradable membrane in vitro and then transplanted back into the host for continuation of the regenerative process. Atala et al[239] demonstrated the successful use of non-woven polyglycolic acid polymer sheets that allow the seeded growth of rabbit and human bladder epithelium and smooth muscle cells. Further work demonstrated that these cell–polymer constructs could then be implanted into athymic mice, with the subsequent formation of organized layers of bladder epithelial and smooth muscle cells. Yoo et al[240] and Oberpenning et al[241] reported on the feasibility of dog bladder augmentation using allogenic bladder submucosa or polyglycolic acid polymers seeded with urothelial and smooth muscle cells. Organized bladder histology was noted in the regenerated bladder tissue. More importantly, the regenerated bladder tissue was found to increase bladder capacity and was urodynamically compliant.

Recently, many other materials have been shown to support the growth of bladder cells, both in vitro and in vivo.[242,243] In addition to research looking at different types of biomaterials to support cell growth, both biologic and synthetic new approaches to deliver cells back to the host are being explored. These include the development of a capsule around the bladder and the use of de-epithelialized bowel segments.[244–247] The importance of new or pre-existing vasculature to provide a conduit for nutrients to the regenerating tissue is evident. This has initiated new research efforts to create a vascularized matrix[248] and other novel methods to induce neovascularization in

the regenerating tissue. Further advancements in biomaterial development, methods of cell attachment, and angiogenesis will be areas of intense future research aimed at improving the type of tissue regeneration that results from seeded technology.

It is clear that bladder regeneration is possible using both unseeded and seeded tissue-engineering technologies. Further advances in current techniques will eventually revolutionize urologic reconstructive surgery as we know it today. Additional work is needed before clinical application of these techniques. One of the concerns that has been expressed is that all of the animal studies performed thus far have been in animals with a normal bladder. It is not known whether normal bladder regeneration can be achieved with either unseeded or seeded technology in an animal or a patient with a neuropathic bladder. Lin et al[249] recently demonstrated that cultured cells from the neuropathic bladder retain functional differences in vitro. Ongoing work is aimed at determining whether these functional differences are retained in vivo when these cells are utilized in a seeded fashion to regenerate bladder tissue. This must be understood before tissue-engineering technologies can be applied clinically. Additional information is needed to understand the differences between the unseeded and seeded approaches and the resultant regenerated bladder, such that the best aspects of each technology may be used to achieve a superior result. It is hoped that future chapters on bladder augmentation will discuss the use of intestinal segments as an historical footnote, and the major focus will be on the indications and methods for various types of tissue-engineering technologies.

Urinary diversion

57

Mark P Cain, Peter D Metcalfe, and Richard C Rink

Introduction

The past 30 years have seen unprecedented advances in lower urinary reconstruction in children. The majority of congenital urologic abnormalities can now be addressed by primary reconstruction with the exception of urinary and fecal continence. These procedures can be performed even in small infants. Thus, the need for permanent conduit diversion with the storage receptacle outside the body as a bag has dwindled, and is now used primarily in children who can never live an independent lifestyle. In children where permanent urinary diversion is required, it is nearly always with a continent urinary reservoir that is then emptied by intermittent catheterization. This chapter will focus primarily on continent urinary reservoirs (CURs).

Some urologic problems are still encountered where severe urinary obstruction in the neonate may prevent definitive reconstruction. In this patient population temporary diversion may be necessary. Intubated diversions are generally reserved for patients requiring a short duration (weeks to a few months) of urinary drainage. These may be especially useful in the setting of an unstable or a small premature child that requires relief of obstruction, or when renal function cannot be adequately assessed without first alleviating the obstruction. These non-continent urinary diversions will be briefly discussed.

Temporary urinary diversion

Temporary intubated diversions

Urethral catheter

The most frequently used intubated urinary diversion is the urethral catheter. The most common pediatric urologic condition managed initially with a urethral catheter in the neonate is posterior urethral valves (PUV). A 5 or 8 Fr feeding tube is usually placed to drain the bladder temporarily prior to endoscopic valve fulguration. In males with dilatation of the posterior urethra, the catheter will occasionally coil in the prostatic urethra and incompletely drain the bladder. In this scenario, a small lacrimal duct probe can be used as a catheter guide. It is sometimes helpful to place a finger in the rectum to elevate and straighten the prostatic urethra during catheter placement. Whenever the catheter is difficult to pass, it is appropriate to obtain an abdominal radiograph, after injecting a small amount of contrast through the catheter, to ensure its proper position in the bladder. In the older child who requires bladder drainage, a 6 or 8 Fr balloon (Foley) catheter is a reasonable alternative. Intermittent catheterization is another option for children with urinary retention and has proven to be safe in even the neonate.

Complications of urethral catheters in children are usually related to improper placement or prolonged use, and include urethral injury, urethritis or meatitis, urinary tract infection (UTI), urethral stricture, and bladder stones. Care must be taken when using a feeding tube as a catheter in the small infant/neonate to avoid coiling the catheter in the bladder, which can result in a knot in the tube that will often require a cystotomy to remove.

Percutaneous suprapubic cystotomy

In rare circumstances when a urethral catheter is contraindicated or cannot be placed, a suprapubic cystotomy tube can provide short- or long-term bladder drainage. Percutaneous cystotomy is very useful in the infant or child with urethral trauma or following a reconstructive procedure for epispadias or complex

hypospadias in the older child. Kits are available that allow catheter placement either simultaneously with the trocar (Stamey percutaneous suprapubic catheter set; Cook Urological, Spencer, Indiana, USA) or through it (Cystocath suprapubic drainage system; Dow Corning, Midland, Michigan, USA). A full bladder is an absolute prerequisite to percutaneous catheter placement and can be confirmed sonographically if needed. If necessary, the bladder can be filled with a small urethral catheter or by placing a small percutaneous angiocatheter or spinal needle into the bladder for localization, and filling the bladder until it is easily palpable. When attempting to place a suprapubic tube in the awake child, conscious sedation and infiltration of the skin and fascia with 1% lidocaine can be used to prevent anxiety and pain. It is helpful to establish the distance from the skin to the bladder lumen with a small needle to prevent injury to structures posterior to the bladder. The trocar is passed with gentle pressure until urine is obtained and the catheter is passed 1–2 cm beyond the trocar. Alternatively, the percutaneous cystotomy tube and obturator needle are passed together into the bladder until urine is obtained, then the catheter is advanced over the obturator. A recently described technique using the light from a flexible cystoscope to help localize the position of the bladder dome may allow percutaneous tube cystotomy in the more difficult cases.[1] In children with a history of prior reconstruction bladder surgery, it is often safest to use the site of a prior suprapubic tract that is fixed to the posterior abdominal fascia to place a suprapubic tube. The catheter is fixed to the skin with permanent suture. These tubes are designed for temporary bladder drainage, and long-term use has been associated with bladder wall thickening and contracture, UTI, bladder stones, and upper urinary tract dilatation.[2,3]

Surgically placed cystotomy

Because of the relative ease and safety of percutaneous cystotomy tube placement, open suprapubic tube placement is rarely used except in the context of a more extensive reconstructive procedure, or for placement of a large-bore drainage tube following urethral or bladder trauma. Another indication for the open technique is in a patient that has had prior extensive pelvic procedures which may have resulted in bowel adhesions to the anterior dome of the bladder.

With the patient in the supine position, the prevesical space is exposed using either a low transverse abdominal incision or a low vertical midline incision for those that may later undergo a transabdominal reconstructive procedure. After mobilizing the bladder dome, stay sutures are placed and a small cystotomy is made. The catheter is first brought through a small skin incision and then through the rectus fascia and muscle. After the tube has been placed in the bladder, it is pulled to the dome of the bladder, and secured with a purse-string suture at the bladder. Bladder muscle adjacent to the tube is secured to the posterior fascial wall with absorbable suture, and the suprapubic tube is sutured to the skin.

Ureteral stents

Ureteral stents are frequently used for temporary upper tract drainage following reconstruction, trauma, or stone surgery in children. There are two general options available: either an entirely internal stent or an external ureteral stent with one end brought out through the skin or via the urethra. External stents have traditionally been used more frequently in children following open surgery, as they do not require an anesthetic for removal and do not carry the same risk of proximal migration found with internal stents. Problems that can be associated with JJ stents in children[4] include:

- obstruction
- encrustation/stone formation
- infection
- proximal migration
- stent fragmentation
- discomfort/bladder spasms
- requirement of anesthesia for removal of stent
- hematuria.

Internal JJ stents can be placed either at the time of open surgery, endoscopically, or by means of an antegrade approach through a percutaneous nephrostomy tract. Endoscopic placement of internal stents is usually done fluoroscopically over a wire in the small patient because of the smaller size of the working port of pediatric cystoscopes that will not permit passage of the stent under direct vision.

Percutaneous nephrostomy

Improvements in the expertise and availability of pediatric interventional radiologists has led to percutaneous nephrostomy tube drainage almost completely replacing the need for open nephrostomy tube placement in children. Indications for nephrostomy tube drainage in children include obstruction, renal/ureteral calculi, pyonephrosis, fungal bezoar, or

for a diagnostic Whitaker test. Although general anesthesia will often be required in the young or uncooperative child, the procedure can frequently be performed with sedation only,[5] and has been performed with just local anesthesia in small neonates in the intensive care unit.[6] The technique most commonly used is the Seldinger technique. A small needle is placed into the renal pelvis with radiographic guidance. A small guidewire is then passed into the renal pelvis and the tract is dilated until a nephrostomy tube can be easily advanced. Several types of nephrostomy tubes are commercially available, most of which rely on a 'pigtail' curl to maintain their position within the renal pelvis. It is critical that broad-spectrum intravenous antibiotics be initiated before tube placement, especially in the child with obstruction and infection to prevent urosepsis. Complications directly related to the procedure are rare[7,8] and include:

- hemorrhage
- urosepsis
- arteriovenous fistula/pseudoaneurysms
- urinary extravasation
- pneumothorax
- bowel injury
- air embolism.

Percutaneous nephrostomy tube placement and irrigation with antifungal agents comprise the first-line therapy for neonates with obstructing fungal bezoars.[9–12] In addition to draining the obstruction and providing access for intermittent irrigation of the obstructed collecting system, the fungal ball can be fragmented with the guidewire at the time of tube placement, which will lead to more rapid clearance of the fungal debris.

Open nephrostomy tube

Open nephrostomy tube placement is rarely necessary, and only utilized when nephrostomy is technically not possible, or carries an unacceptable risk. High-risk conditions include low platelet count, a solitary kidney, abnormal renal position following a complicated reconstruction of the renal pelvis, and exploration for renal trauma when significant injury to the ureter or pelvis has occurred. The kidney is exposed through a flank incision and mobilized until the renal pelvis is identified. Stay sutures are placed, and the renal pelvis is opened. A clamp is placed into an inferior calyx. A small nephrotomy is made and the Malecot catheter is advanced into the renal pelvis, as shown in Figure 57.1. The catheter is secured to the renal capsule with a purse-string chromic suture. The nephrostomy tube is brought out through a stab incision in the skin and secured. A small Penrose drain is left in the renal fossa. Some newer catheters come preassembled as either simple nephrostomy catheters or nephrostents, often with an attached trocar that can be advanced in a retrograde fashion out of the selected calyx.

Temporary non-intubated diversion

Cutaneous vesicostomy

Cutaneous vesicostomy continues to be the most widely used and simplest method for temporary bladder drainage. Most commonly it is used for patients

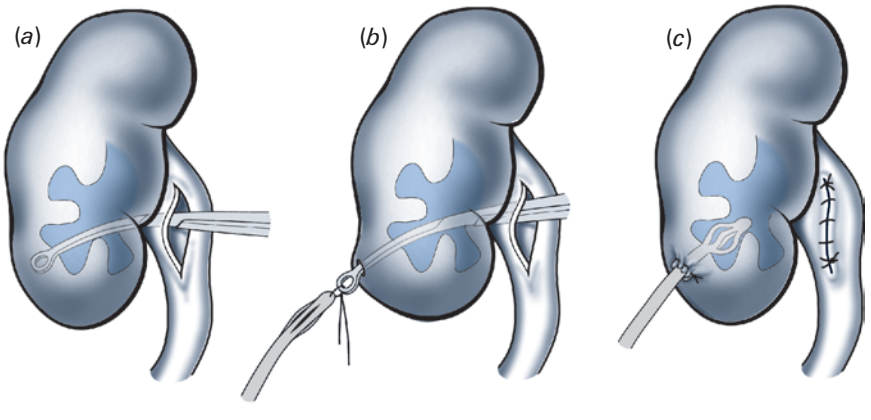

Figure 57.1 Technique for open nephrostomy. A small Randall forcep or right angle clamp is passed through an inferior calyx via a small pyelotomy incision. The renal capsule is incised with electrocautery and the catheter is advanced into the calyx. The catheter is secured to the renal capsule with absorbable suture. The pyelotomy is closed with either running or interrupted, absorbable suture.

with a neuropathic bladder or PUV, in situations where clean intermittent catheterization (CIC) is not possible. In multiple series temporary diversion with vesicostomy has resulted in significant improvement in urinary tract dilatation, stabilization of renal function, and decrease in the frequency and severity of febrile UTIs.[3,13–15] The introduction of CIC in early infancy has limited the role of vesicostomy in some centers, and has provided equivalent long-term results.[16] One concern regarding temporary cutaneous vesicostomy is potential impairment in bladder function due to inadequate cycling of the detrusor during the period of diversion.[17] Jayanthi et al reported on a large group of patients who underwent cutaneous vesicostomy and eventual bladder closure. They found no significant alteration in eventual bladder capacity or function.[18] These findings were also supported in a series of patients with PUV managed with either valve ablation or urinary tract diversion, with no evidence of bladder dysfunction based on urodynamics findings in those who had diversion with vesicostomy.[19]

Two basic techniques have been described for cutaneous vesicostomy in children. The procedure described by Lapides involves creation of extensive skin flaps to allow a tension-free anastomosis of the bladder to the skin, and a very wide stoma that is less prone to stenosis.[20] This procedure was initially intended as a semi-permanent form of vesicostomy in the adult patient, where the bladder position is deeper in the bony pelvis. Because of the complexity of both creating and taking down the Lapides vesicostomy, there is limited application for the majority of pediatric patients. The more popular technique for vesicostomy in children was described by Blocksom and modified by Duckett, as outlined in Figure 57.2.[3,21] Key technical points are adequate mobilization of the bladder dome for a tension-free anastomosis to the fascia and skin, use of the dome of the bladder to create the stoma, and creating an adequate caliber stoma (at least 22 Fr) that is flush with the skin.[3,22]

Common problems following vesicostomy are listed in Table 57.1. The majority of complications that lead to stomal revision are secondary either to technical errors of stomal placement inferior to the dome of the bladder, inadequate stomal diameter, or primary bladder pathology that results in an extremely thick-walled bladder that does not allow for straightforward creation of an adequate-caliber stoma.

Bladder prolapse through the vesicostomy stoma is usually due to placement of the stoma too inferior, allowing the posterior bladder wall to evert through the stoma. Acute prolapse can usually be managed with manual decompression and bladder drainage with a catheter through the vesicostomy until the edema subsides. On rare occasions, the prolapsed bladder will incarcerate due to vascular congestion. This requires emergency reduction under anesthesia. Revision of the vesicostomy by moving the stoma to a more superior position in the dome of the bladder will prevent recurrence.

Table 57.1 Complications of cutaneous vesicostomy

Complication	Frequency (%)
Stomal prolapse	9–17
Stomal stenosis	3–12
Peristomal dermatitis	3–14
Stone formation	3–7
Parastomal hernia	3–4

From Skoog.[22]

Stomal stenosis will often present with either UTI or hydronephrosis. Stenosis is thought to occur secondary to excess tension on the skin anastomosis or too small of a fascial opening, and is more frequent in patients with very thick-walled bladder or patients with prune belly syndrome.[3,22] Simple revision with creation of a wider-caliber stoma or use of a small V-shaped skin flap to disrupt the circumferential stomal scar tissue will usually correct the problem and prevent recurrence.

Cutaneous ureterostomy

The indications and need for temporary and permanent urinary diversion with cutaneous ureterostomy or pyelostomy have been significantly reduced over the past several decades. Advances in percutaneous and endoscopic techniques and the ability to perform these procedures even in the smallest neonates or infants have contributed to the trend away from cutaneous upper tract diversion. In addition, we have a better understanding of the pathophysiology and natural history of the dilated ureter in childhood, which has led to observation with radiographic surveillance instead of early surgical intervention in many circumstances. There are still clear indications for ureterostomy to decompress massively dilated upper tracts, for example in the neonate or infant who is not a candidate for reconstruction because of size or acute UTI, or when there is a question of recoverable function in the involved kidney. In this latter instance, an interval of diversion may help one to decide between reconstruction and nephrectomy.[23]

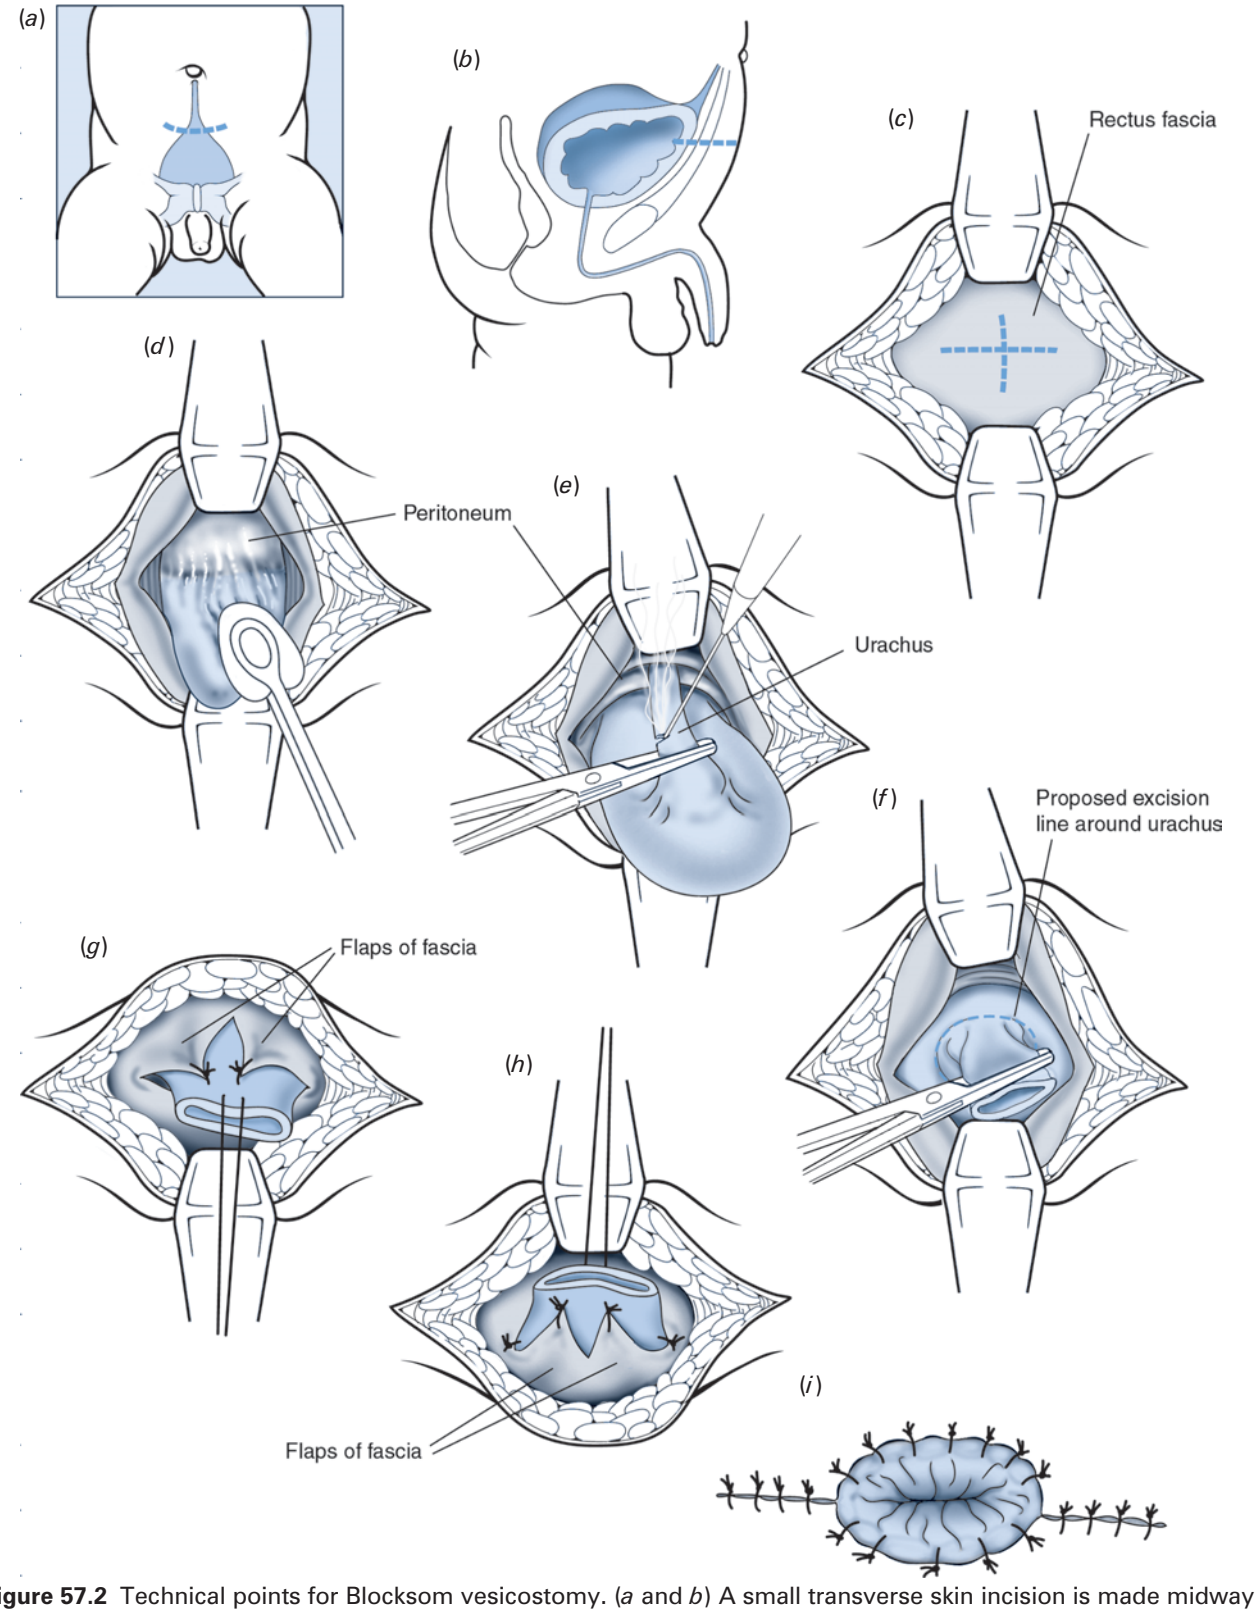

Figure 57.2 Technical points for Blocksom vesicostomy. (*a* and *b*) A small transverse skin incision is made midway between the pubis and umbilicus. (*c*) The rectus fascia is opened vertically and horizontally and the muscle is retracted laterally. (*d*) Stay sutures are placed in the bladder and the peritoneum is bluntly mobilized superiorly, exposing the bladder dome. (*e*) The urachus is identified and divided. The urachal segment is mobilized until it reaches the skin without tension. (*f*) The urachus is excised, ensuring an adequate caliber opening into the bladder (22–24 Fr). (*g*) The detrusor is circumferentially secured to the rectus fascia. (*h*) The lateral edges of the fascia are closed, allowing easy passage of a 22–24 Fr sound. (*i*) The bladder mucosa and detrusor are secured to the skin, and the lateral skin edges are closed in layers.

Controversy still exists with respect to the benefit of more proximal diversion in patients with PUV who have persistent severe hydronephrosis and azotemia despite ablation of the valve or diversion with vesicostomy. Earlier studies suggested that proximal ureteral diversion would result in relief of functional obstruction at the ureterovesical junction and improve eventual glomerular filtration rate and somatic growth potential.[24,25] More recent studies have challenged this concept, demonstrating no difference in eventual renal outcome in children who were managed with primary valve ablation compared with patients who underwent upper tract diversion.[26,27] Those who oppose routine proximal diversion think that the improved renal function following diversion is attributable to normal transitional nephrology that occurs with or without diversion.[27,28] In a study of 26 patients managed with bilateral high diversion for PUV, Tietjen et al reported renal dysplasia on biopsy in 85% and true ureterovesical junction obstruction based on Whitaker tests in only 4%.[28]

The benefits of upper tract diversion include the ability to perform renal biopsy for determining renal prognosis, the ability to accurately monitor the function of each kidney individually, and allowing a period of observation time to decide on eventual reconstruction. Potential problems of ureterostomy relate to the need for a more complex reconstructive procedure at a later date, the potential for impaired ureteral vascularity, and difficulty in covering the stoma with an appliance as the child grows.

The techniques for proximal diversion have not changed significantly for several decades. There is still debate over the preferred technique:[23] i.e. whether a pyelostomy, loop, or Y-ureterostomy should be utilized. The Y-ureterostomy as described, by Sober, allows for urine flow to the bladder, preserving some degree of bladder cycling.[29] This avoids the potential later problem of carrying out a complex lower tract reconstructive procedure into a small, defunctionalized bladder. Regardless of the technique used, adhering to three basic operative principles is critical for a successful outcome:[30] (1) during mobilization the ureter should only be manipulated with fine stay sutures and not grasped with forceps; (2) ureteral mobilization should be minimized to preserve maximal blood supply, yet be adequate to allow a tension-free skin anastomosis; and (3) kinking of the ureter or compression by the abdominal wall at the stomal site must be avoided.

Techniques for high ureterostomy are illustrated in Figure 57.3. All of these procedures can be accomplished through a subcostal or flank incision, which allows mobilization of the ureter proximally to the renal pelvis and creation of a tension-free anastomosis to the skin. Loop ureterostomy is preferred by some surgeons because of the simplicity of the procedure. Closure of the ureterostomy and lower urinary reconstruction are often staged but can be performed simultaneously if there is careful attention to the periureteral vasculature.

Distal, end ureterostomy is useful in children with massively dilated ureters secondary to distal obstruction that for any reason are not candidates for immediate reconstruction. The benefits of temporary diversion include stabilization or recovery of renal function, and decompression of the ureter which may allow the ureteral diameter to decrease sufficiently that tapering of the ureter is not required at eventual reimplantation. The surgical approach is usually through a low transverse muscle-splitting incision that allows access to the retroperitoneum. The ureter is carefully mobilized to the level of the bladder hiatus and transected, taking care to preserve the periadventitial and retroperitoneal blood supply. The ureteral stoma can be brought out either in the lateral margin of the incision or in the midline. A V-shaped skin flap can be used to prevent stomal stenosis, but this occurs infrequently with a dilated ureter.[31]

Cutaneous pyelostomy

Cutaneous pyelostomy is an excellent option for upper tract diversion but is only useful in patients with a dilated extrarenal pelvis that can reach the skin without tension. The advantages of this procedure are the minimal disturbance of ureteral blood supply during both formation and closure of the stoma, as well as direct urine drainage from the kidney, avoiding the potential stasis in the dilated distal ureter. The surgical approach is through a flank incision or a dorsal lumbotomy.[25] The renal pelvis is mobilized and exteriorized superior to the ureteropelvic junction through the skin incision, taking care to avoid angulation (Figure 57.4).

Conduit urinary diversion

With the advances made in bladder reconstruction for urinary continence, the indications for permanent, non-continent urinary diversion in children have significantly decreased. Initial enthusiasm for conduit diversion several decades ago has been tempered by long-term follow-up that has demonstrated significant problems with renal deterioration, especially in

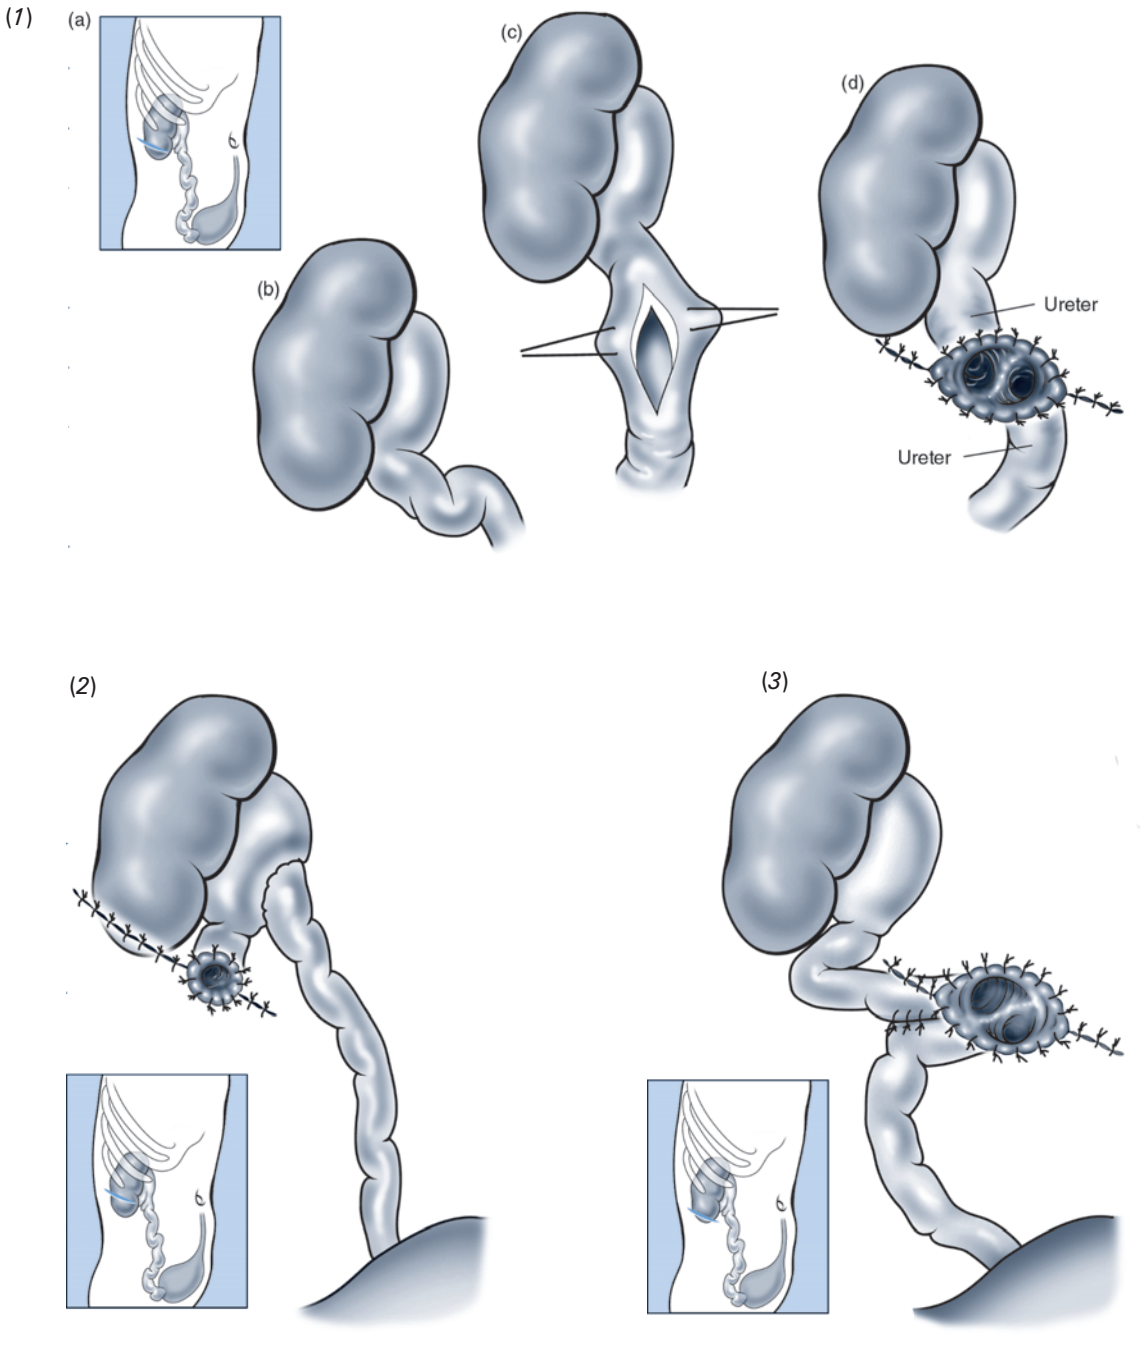

Figure 57.3 Various options for high cutaneous ureterostomy: (*1*) loop ureterostomy; (*2*) Sober ureterostomy; and (*3*) ring ureterostomy. Care is taken with each technique to preserve the medial blood supply and create a tension-free skin anastomosis.

children with a long life expectancy.[32–37] Despite the associated risks to the kidney, conduit diversion still remains the best option for a small group of children. Patients with limited ability to care for themselves due to physical or mental disability and children with malignancies who have undergone extensive pelvic/abdominal radiation or who have limited life expectancy may be candidates for non-continent urinary diversion. As opposed to recommendations in the adult population,[38,39] renal failure in children is not an absolute indication for conduit diversion, as most children will be candidates for renal transplantation and will have a better eventual outcome with primary bladder reconstruction.[40,41]

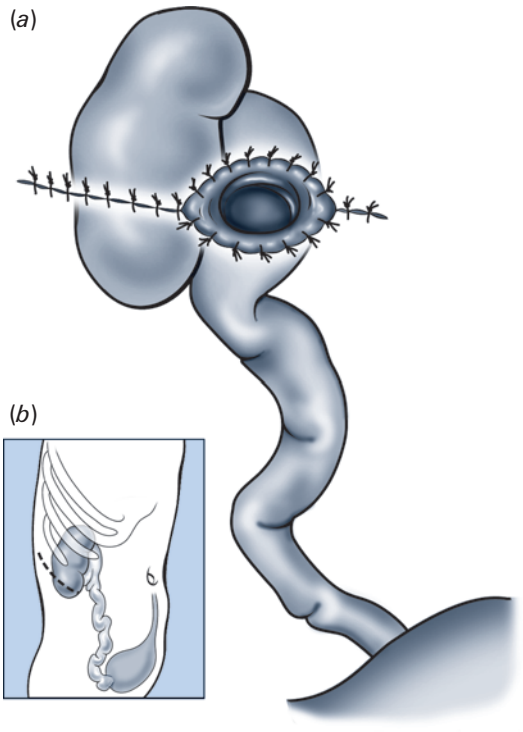

Figure 57.4 Cutaneous pyelostomy. (*a*) The renal pelvis is approached through a subcostal, posterior flank or dorsal lumbotomy incision. The kidney and dilated renal pelvis are mobilized until the renal pelvis can reach the skin without tension. (*b*) The renal pelvis is opened widely and secured to the skin with interrupted, absorbable sutures.

Any segment of small or large intestine can be used to create a urinary conduit; however, ileum and colon are most frequently selected. Some surgeons prefer using colon conduits in children because of the lower risk of late renal deterioration associated with the non-refluxing ureterocolonic anastomosis.[33,36]

The ability to incorporate the colon segment into a continent reservoir at a later date without the need to revise the ureteral anastomosis is also advantageous.[42] Jejunal conduits carry an unacceptably high risk of severe metabolic problems and are not recommended. The primary electrolyte problem with incorporating jejunum into the urinary tract is hypochloremic, hyponatremic, and hyperkalemic metabolic acidosis.[42]

The important technical aspects of creating a conduit are similar whether using ileum or colon. This starts with an appropriate mechanical and antibiotic bowel preparation, which may need to be altered based on specific patient needs in the pediatric population. For example, the child with myelomeningocele frequently has significant chronic constipation, and will require initiation of the mechanical bowel preparation 3–4 days earlier than patients with normal bowel motility. The standard pediatric bowel preparation involves admission to the hospital on the day before surgery for intravenous antibiotics to sterilize the urinary tract and whole gut lavage with a polyethylene glycol solution (GoLYTELY) via nasogastric tube until stools are clear. Another key aspect of the preoperative preparation is identifying an appropriate location for the stoma, which is most effectively done with the input of an enterostomal therapist with the child awake before surgery. Several locations should be identified that allow optimal fitting of the appliance with the patient in the sitting, standing, or supine position. This is most critical for the wheelchair-bound patient who may have significant abdominal girth.

Although the incidence of postoperative complications may differ slightly for colon or ileal conduits, the types of associated problems are very similar and can be divided into early or late complications (Table 57.2). Both ureteroenteric and stomal complications are generally related to surgical technique, representing the most common problems leading to reoperation. The general principles of minimal handling of the ureter, maintaining maximal adventitial blood supply, minimizing mobilization, preventing angulation of the ureter, and securing a mucosa-to-mucosa watertight anastomosis with fine absorbable sutures will decrease the potential for postoperative problems. The use of ureteral stents has been shown to significantly decrease anastomotic leaks.[43] Suspected ureteral leaks should be promptly investigated and, if present, treated by a percutaneous nephrostomy tube drainage and antegrade stent placement. Continuous

Table 57.2 Complications of ileal and colon conduits

Frequency (%)	Ileal conduit	Colon conduit
Early complications		
Bowel obstruction	10	4
Urinary leak	3	5
Pyelonephritis	12	13
Late complications		
Stomal stenosis/ parastomal hernia	24	20
Renal deterioration	18	15
Metabolic acidosis	16	5
Ureteroenteric stricture	8	9
Renal calculi	7	5

From McDougal.[39]

drainage of the conduit with a Foley catheter after surgery may also help to minimize extravasation.

Ureteral strictures can be seen early after surgery, or may take several years to form,[44] reinforcing the need for long-term periodic radiographic surveillance. Treatment of strictures at the ureteroenteric anastomosis can be initially attempted with endourologic techniques. Regardless of the technique used (balloon dilatation alone vs incision and dilatation), approximately 50% will eventually require open revision.[44,45]

Stomal problems may vary from a minor nuisance (bleeding, dermatitis) to more life-threatening complications such as stomal obstruction with UTI:

- bleeding
- bowel necrosis
- dermatitis
- parastomal hernia
- stomal prolapse
- stomal stenosis
- stomal retraction
- loop obstruction (early/late).

Problems with local skin irritation can be minimized by creating an everted nipple or loop stoma, so that the appliance can be fit snuggly to the adjacent skin. Stomal stenosis and parastomal hernia are the most common problems with conduit diversion that require surgical revision. The risk of these complications can be minimized by bringing the bowel through an adequately sized fascial defect without angulation, securing the conduit to the fascia in four quadrants, and creating a nipple stoma.[46] It was initially thought that colon conduits had a lower incidence of stomal stenosis than ileal conduits, but this has not been supported in more contemporary series.[47]

Tumor within the bowel segment has been reported in both ileal and colon conduits.[48] Although the risk for malignancy is unknown, it should be significantly lower than for ureterosigmoidostomy, where urine and stool are mixed.

Technique for ileal conduit

The abdomen is opened through a midline incision and the ureters are identified and mobilized at the level of the iliac bifurcation. The left ureter is brought across the midline in a retroperitoneal tunnel, taking care to avoid angulation. A 10–15 cm segment of ileum is selected that has an adequate vascular arcade, and the mesentery to this segment is isolated. The mesentery of the distal end of the segment is mobilized off the bowel to allow this end to be brought up to the skin as the stoma. The last 15 cm of distal ileum should be avoided, as this segment of ileum is important for iron and vitamin B_{12} absorption. The bowel segment is harvested and bowel continuity is restored

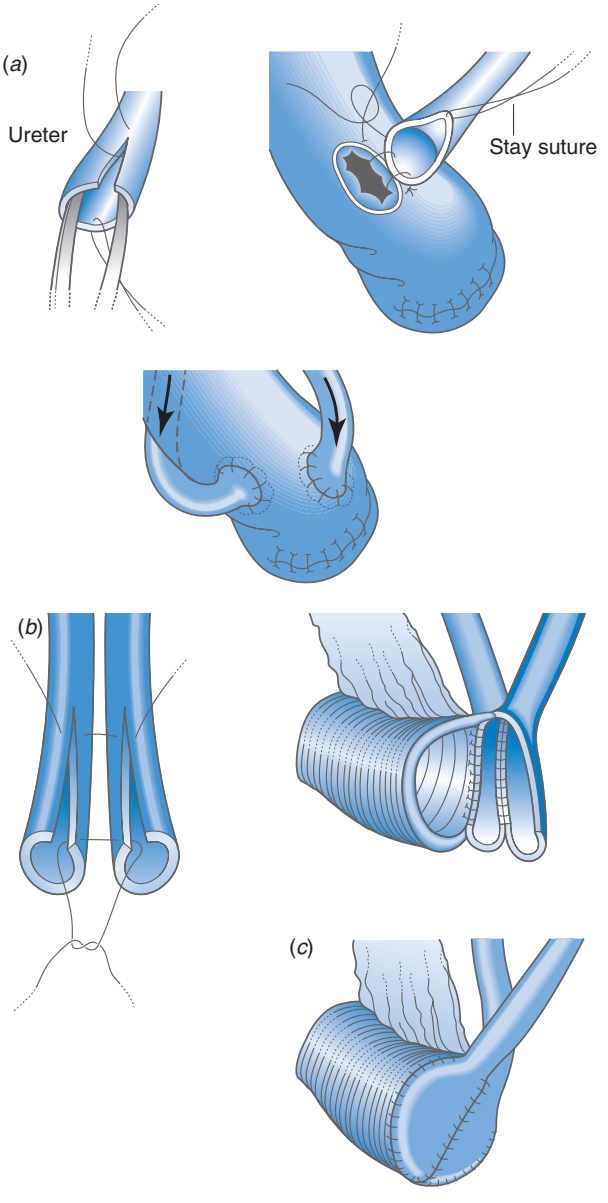

Figure 57.5 (*a*) The Bricker technique for ureterointestinal anastomosis. The ureter is spatulated, and following excision of a small ellipse of intestine, the anastomosis is secured with fine interrupted absorbable sutures. The external stent is placed across the anastomosis and brought out through the stoma. Both ureters are secured using an end-to-side anastomosis. (*b*) The Wallace procedure for ureteroileal anastomosis. The ureters are spatulated and joined at their medial borders using running or interrupted absorbable sutures. (*c*) The lateral edges of both ureters are then secured to the conduit in an end-to-end anastomosis.

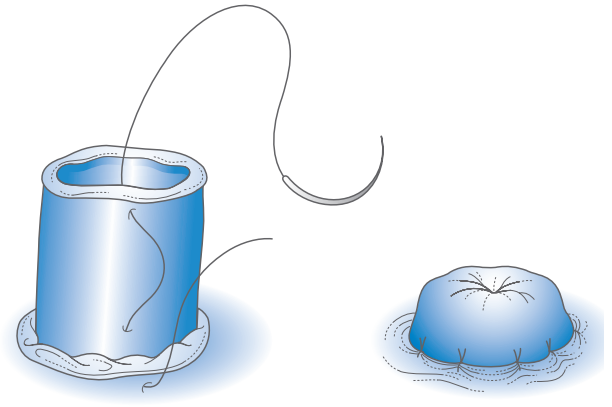

Figure 57.6 An everted stomal nipple is optimal for creating a snuggly fitting appliance. This is created by placing sutures between the skin/subcutaneous tissue, lateral bowel serosa, and distal edge of the stoma.

using either a side-to-side stapled or end-to-end hand-sewn anastomosis. The mesenteric defect is closed with permanent suture. The proximal end of the conduit is closed in two layers (after removing the staples if a stapling device was used to harvest the segment), and secured to the sacral promontory. Ureteroileal anastomoses are carried out using either the Bricker[49] or Wallace[50] technique (Figure 57.5) and the proximal end of the loop is brought out at the predetermined site for the stoma, and an everting nipple or loop stoma is created (Figure 57.6).

Technique for colon conduit

The colon conduit is constructed in a similar fashion to the ileal conduit with the exception of the ureteral anastomosis, which is usually created in a non-refluxing manner using the tenia (Leadbetter technique) (Figure 57.7). Alternatively, a submucosal tunnel may be created (Goodwin technique).[39] Injecting saline or dilute epinephrine under the mucosa will minimize bleeding and aid in the dissection. Because of the added risk of ureteral obstruction within the submucosal tunnel, stenting the ureteral anastomosis is recommended.

Most commonly a sigmoid segment will be used to create the conduit (Figure 57.8), but in children with a history of pelvic radiation or inadequate ureteral length the transverse colon should be used.

Ileocecal conduit

By using the non-refluxing properties of the ileocecal valve, the ileocecal conduit provides an alternative to the tunneled ureteral reimplantation used to achieve a

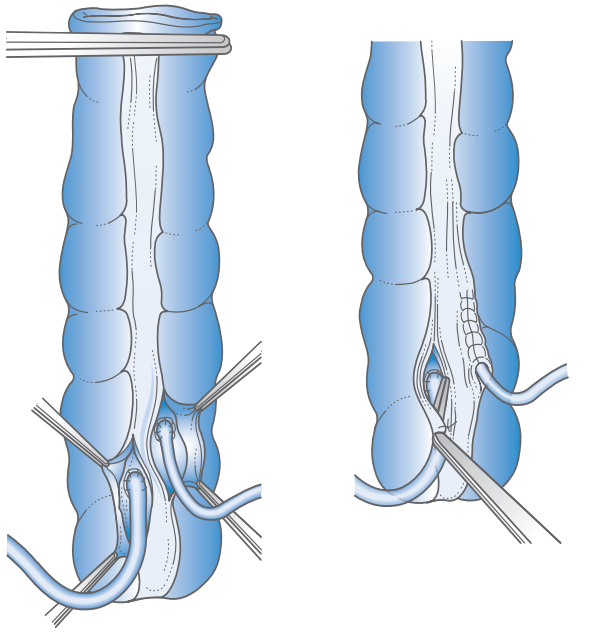

Figure 57.7 The non-refluxing ureterocolonic anastomosis described by Leadbetter. A submucosal tunnel is created by incising the tenia to create a submucosal trough, the ureter is anastomosed to the colonic mucosa, and the muscularis loosely closed over the ureter with absorbable suture.

non-refluxing ureteral anastomosis with other colon conduits. The ileocecal conduit can later be incorporated into a ureterosigmoidostomy with reduced risk of cancer, as the ileocecal valve will prevent the direct contact of feces and urine at the site of the ureteral anastomosis. The greatest concern in using this segment for urinary diversion is the theoretical risk of diarrhea and fecal incontinence in the myelomeningocele patient who may depend on the intact ileocecal valve to prevent rapid transit of liquid stool into the colon. The technique involves isolating a portion of the right colon and distal ileum (Figure 57.9). The ileocecal valve is reinforced with permanent plication sutures that intussuscept the valve into the cecum.[51] The ureters are reimplanted into the proximal portion of the ileum using either the Bricker or Wallace technique.

Continent urinary diversion

Defining the various types of urinary receptacles can be confusing, particularly when applied to the pediatric patient. A true CUR implies that a reservoir to store urine has been constructed from the gastrointestinal tract and is emptied by CIC, through an

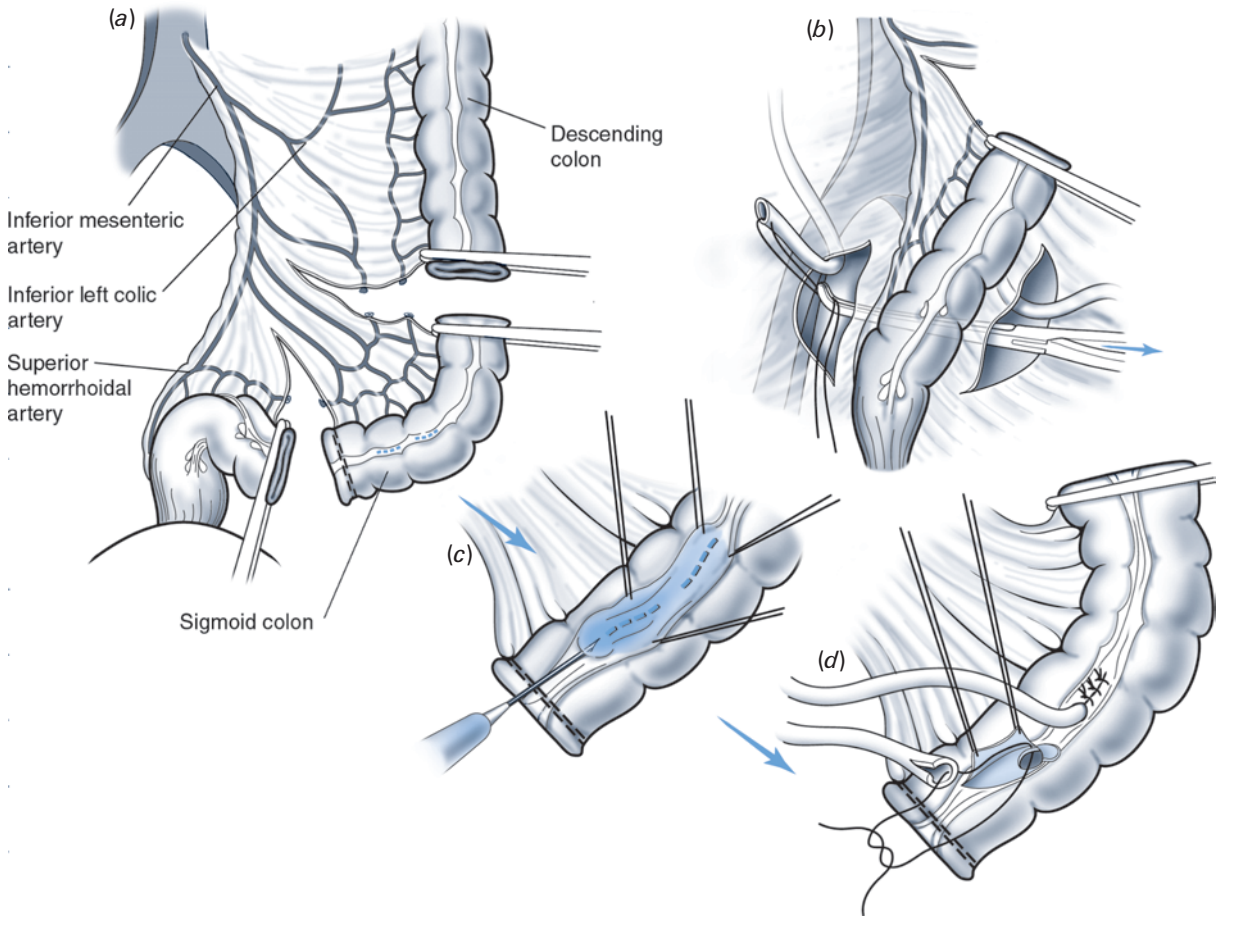

Figure 57.8 Surgical technique for creation of a sigmoid colon conduit. (*a*) A segment of colon is isolated, maintaining a wide mesenteric pedicle. (*b*) The ureters are mobilized through posterior incisions in the peritoneum and transected. The right ureter is brought across the midline in a retroperitoneal tunnel. (*c*) The tenia is incised to create a tunnel. (*d*) The ureters are anastomosed, as illustrated in Figure 57.5.

intestinal channel, usually to the abdominal wall. The native bladder or urethra is not used.

A neobladder is constructed from gastrointestinal segments attached directly to the native urethra, allowing the patient to spontaneously void. Neobladders are now commonplace in adults who require cystectomy for cancer, but are rarely used in the pediatric population. In children, the native bladder is often augmented with a gastrointestinal segment that is emptied by CIC through a catheterizable abdominal wall channel. Furthermore, simultaneous bladder neck reconstruction often prevents use of the native urethra. This, in effect is a CUR, but does not fit the classic definition. For the purposes of this chapter, we will not consider neobladders or use of the native bladder or urethra in the discussion of CURs.

Continent urinary diversion is not new; in fact, urinary diversion with a continence mechanism was first introduced in 1852 by Simon, who performed ureterosigmoidostomy on a 13-year-old boy with bladder exstrophy.[52] Whereas several other efforts at continent diversion were attempted, no significant advances were made until nearly 100 years later when Gilcrest and Merricks created the first modern-day reservoir by making a cecal bladder with continence based on the ileocecal valve, with the ileal 'urethra' brought to the abdominal wall.[53] Gilcrest et al reported good success with this, but others had difficulty in duplicating their results, and intermittent catheterization was not well accepted at the time.[54,55] Gilcrest continued to use this method and was able to achieve continence in 37 of 40 patients.[56,57] Bricker tried a similar reservoir at the time but could not achieve continence and therefore abandoned these efforts and popularized his well-known ileal conduit, which became widely accepted as the diversion of choice.[49]

A number of factors occurred in the 1970s to allow the explosion of reconstructive techniques we know

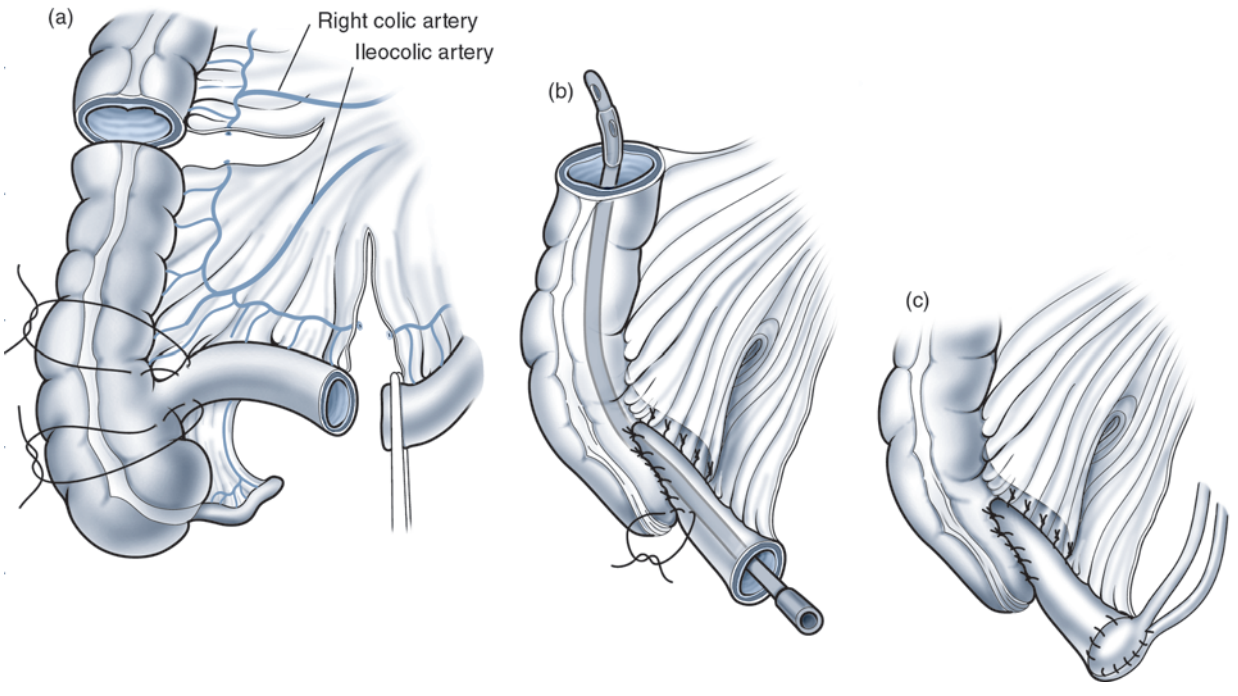

Figure 57.9 The non-refluxing ileocecal conduit as described by Zinman and Libertino. (*a*) The ileocecal segment is harvested based on the ileocolic artery. (*b*) The ileocecal valve is intussuscepted into the cecum with permanent sutures. (*c*) The terminal ileum is plicated into the cecum, also with permanent sutures. The ureters are anastomosed to the proximal ileal segment using either the Bricker or the Wallace technique.

today, the most important being Lapides' introduction of CIC.[58] With acceptance of CIC, volitional voiding was no longer required and therefore the reconstruction only needed to recapitulate the storage function of the bladder. In addition, accurate urodynamic evaluation in children[59] and reliable pediatric anesthesia, allowing long reconstructive cases to be safely performed, ushered in the era of continent reconstruction. Furthermore, Hendren's demonstration that the previously diverted urinary tract could be refunctionalized (undiversion) also spurred the decline of incontinent diversion in children.[60,61]

The first popular urinary reservoir was Kock's continent urinary ileal reservoir, which he adapted from his continent ileostomy.[62] This is now known as the Kock pouch and was refined and popularized by Skinner's team.[63–65] Over the past 25 years there have been more than 40 variations of CURs described. Gastrointestinal CURs have been used in the adult population primarily as a means of diversion following cystectomy. In these adult patients, the urinary and gastrointestinal tracts are usually anatomically and neurologically normal, allowing the surgeon to use one of the many 'named' procedures such as the Kock pouch, Indiana pouch, or Mainz pouch. The majority of children undergoing true CURs, such as those with classic exstrophy or myelomeningocele, have significant anatomic and/or neurologic abnormalities. Some have a combination of both abnormalities, such as the cloacal exstrophy patient, who also might have short-gut syndrome.[66] In these situations, creation of a standard named CUR may not be possible. These anatomic and neurologic abnormalities do not prevent continent urinary diversion in children, but they require the surgeon to have a fertile imagination and depth of knowledge of all options available, as well as a good understanding of the concepts necessary to provide a reliable reservoir.

Patient selection and preoperative evaluation

It is our belief that the urinary tract should remain intact whenever possible. In this regard, all efforts should be made to exhaust medical management prior to electing surgical options. Reconstruction is generally performed for one of two reasons: to protect the upper urinary tract or to achieve urinary continence. In the majority of children with lower urinary dysfunction these two goals can be achieved with CIC and/or pharmacologic management. In our experience with the neuropathic population, approximately

70% can be managed non-surgically. If this fails, then we would not hesitate to reconstruct the lower urinary tract, but this again usually involves reconstructing the native bladder by intestinocystoplasty and bladder neck reconstruction rather than CUR. For any reconstruction, the child must have adequate upper extremity function to catheterize reliably and the mental capacity to do so. The patient and/or family must be motivated and reliable. Both must understand that a lifelong commitment to CIC is required and failure to catheterize reliably may result in urinary infection, stone formation, reservoir perforation, or renal deterioration, even in the face of a technically perfect operation.

Preoperatively, the overall renal function should be determined by measuring serum creatinine and electrolytes. Benson and Olsson suggest that no patient should undergo reservoir creation if creatinine clearance is <60 ml/min.[67] With the incorporation of ileum or colon into the urinary tract, chloride and ammonium are absorbed and sodium and bicarbonate are excreted (Figure 57.10). This was first noticed by Ferris and Odel in patients with ureterosigmoidostomy.[68] Children with normal renal function generally tolerate this well, but in those with renal insufficiency, a severe metabolic acidosis may occur.[68–70] Mitchell and Piser noted that the chloride level increased and bicarbonate level decreased in

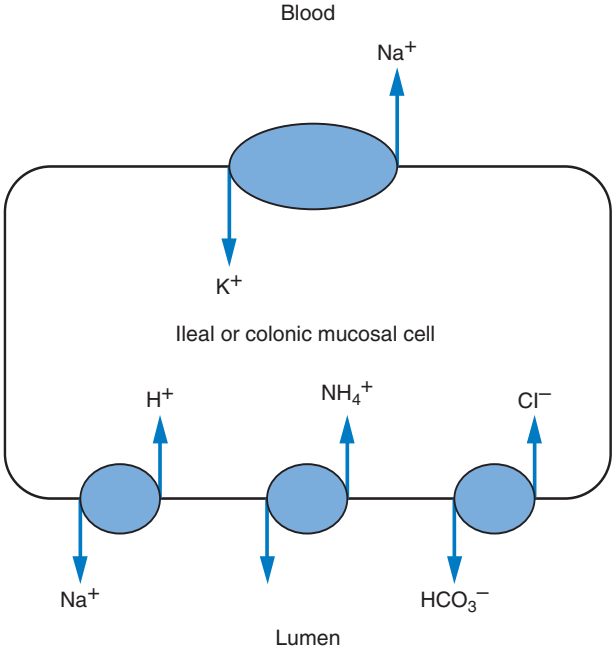

Figure 57.10 Ileal and colonic mucosa absorb ammonium, hydrogen, and chloride, while secreting sodium and bicarbonate.

every patient following intestinocystoplasty at their institution.[71] Rink et al later reviewed 231 patients and found 16% to have a serum chloride level above the normal range.[72] Those patients with severe elevations all had colonic segments in their urinary tract. Others have reported similar findings following CURs.[73–77] These changes would be expected to be more severe in CURs where the entire storage surface area is enteric, rather than with augmentation of the native bladder. Nurse and Mundy demonstrated that, following intestinocystoplasty, the blood gas values may be abnormal even with normal serum chloride levels.[78] There has been concern regarding poor linear growth from use of bony buffers in response to the chronic acidosis.[78–82] Others have found no significant difference in growth or bone density.[83,84] Regardless, both groups would agree that if acidosis exists following CUR, bicarbonate therapy should be started. Some would do this even in those patients able to maintain normal acid–base balance, but this is controversial.

Many children undergoing creation of a CUR have renal tubular dysfunction from primary urinary obstruction, resulting in a severe urine concentrating defect. The end result may be the excretion of very large volumes of urine. Therefore, a 24-hour urine for volume should always be checked preoperatively. The reservoir must be made large enough to handle the patient's urine output adequately at low pressures to allow emptying no more frequently than every 4 hours. A technically perfectly performed CUR would give poor results if it required every 2-hour catheterization plus awakening at night to catheterize. Graphs and guidelines have been developed to predict the length of a bowel segment needed to achieve a certain volume.[85] However, these graphs may prove cumbersome and are not routinely used.[86] Even if renal and bowel function are normal, it is better to err on making the reservoir too large than too small.

Liver function testing should also be carried out as suggested by McDougal.[39] Hyperammonemia can occur in patients with large or small intestine incorporated into the urinary tract when hepatic dysfunction is present, as these segments absorb ammonium.

In all children, the urinary tract must be imaged preoperatively. Radionuclide scanning best assesses renal function. Although rarely used today in pediatric urologic practice, an intravenous pyelogram will visualize the ureteral anatomy as well as provide some information regarding peristaltic activity. Reimplanting an aperistaltic, scarred ureter can be fraught with complications such as obstruction.[87,88] Even though

the native bladder is not used, a voiding cystourethrogram (VCUG) is helpful to define reflux, as these ureters are more likely to be scarred. If the patient has had previous urinary diversion, then a retrograde contrast study of the conduit (loop-o-gram) should be done to define anatomy.

Stomal location should also be determined before the operative procedure. Whereas this is less important for continent diversion than conduit diversion, it is still important to be certain the child will be able to pass the catheter easily. Skin folds and areas of abdominal wall scarring should be avoided. It is best if the patient can visualize the stoma. The stoma may be placed in an orthotopic location to allow catheterization of a normal urethral meatus, but in most patients this is not warranted. In a study by Horowitz et al, patients who had the opportunity to catheterize either their native urethra or an abdominal wall stoma overwhelmingly preferred the latter.[89]

Finally, latex allergy precautions must be observed in all patients with spinal dysraphism.

Principles of continent urinary diversion

The ideal reservoir (1) preserves the function of the upper urinary tract, (2) avoids reservoir–ureteral reflux and ureteral obstruction, (3) avoids urinary infection, and (4) has a reliable continence mechanism. As noted previously, spontaneous voiding by a voluntarily controlled native sphincter mechanism is essentially never achieved except following ureterosigmoidostomy or cystectomy in the neurologically intact patient. All other types of reservoirs require CIC. However, the remaining goals can be achieved by following the three principles of CURs: (1) creation of a high-capacity, low-pressure reservoir; (2) creation of a reliable antireflux mechanism; and (3) creation of a reliable continence mechanism that allows easy catheterization.

Creation of a compliant reservoir

The creation of the actual reservoir of the CUR requires knowledge of the underlying diagnosis and the patient's anatomy. It is important to know the pros and cons of the gastrointestinal segments that are available and the length and configuration of the bowel segment chosen. The surgeon must determine the type of antireflux and continence mechanism for the reservoir. Often, in children undergoing a CUR, the surgeon encounters what is similar to a puzzle. The urinary tract must be taken apart and then reconstituted in such a way that all principles are achieved.

When the bowel is maintained in its native tubular shape and used as a reservoir, very high reservoir pressures may be generated by the intestinal contractile activity. Fowler noted that intact cecum used as a reservoir may generate pressures of 60–90 cmH_2O at high volumes.[90] Peristaltic waves generating pressures as high as 75–100 cmH_2O have been found in the tubular ileal Camey procedure.[91] Kock, in his early work, found that both large and small bowel could generate pressures as high as 100 cmH_2O when used in a closed loop.[92] Light and Engelman demonstrated a mean maximum pressure of 90 cmH_2O in ileocecal and intact cecal segments used for augmentation.[93] They felt that the entire large bowel was capable of creating significant intraluminal pressures.[93] These high pressures can result in urinary leakage and upper urinary tract deterioration, and may even contribute to perforation.[94] In a landmark paper, McGuire et al reported a striking difference between myelodysplastic patients who leaked per urethra at <40 cmH_2O and those with pressures >40 cmH_2O.[95] No patient in the former group had reflux or ureteral dilatation, whereas 68% had reflux and 81% dilatation in the latter. It is now well accepted that intravesical (intrareservoir) pressures must be maintained <40 cmH_2O.

More recent data with laboratory research suggest that intravesical pressures far less than 40 cmH_2O may have a deleterious effect on the bladder.[96–98] Regardless of the gastrointestinal segment used, there are tremendous advantages to be gained by detubularizing the segment and reconfiguring it into a sphere (Figure 57.11).[99,100] Detubularization will dampen the contractile activity of the segment. Changing the segment from a cylinder to a sphere has the advan-

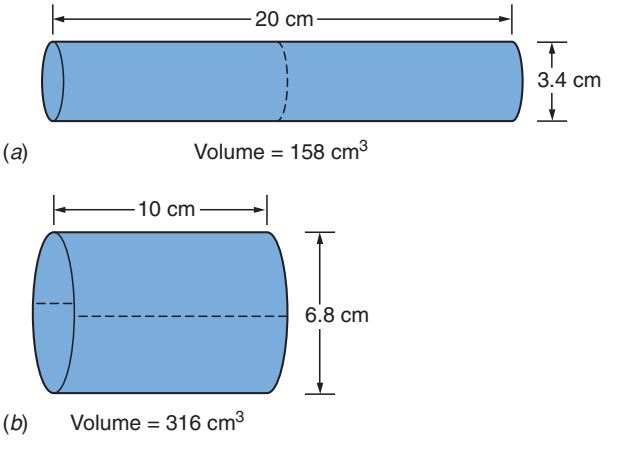

Figure 57.11 The effect of reconfiguring a cylinder to a sphere. The volume doubles. (From Hinman.[99])

tages of increasing the capacity from the same amount of tissue. Furthermore, from Laplace's law *(t = P/r)*, the larger the radius (r), the greater the wall tension (t), resulting in enlargement over time. Compliance also increases by reconfiguring and detubularizing the bowel segment. The surgeon must understand that contractile activity is not totally abolished by detubularization. In fact, Lytton and Green found contractions up to 60–110 cmH_2O in patients reconstructed with detubularized right colon.[101] Although the pressures diminished with time, Sidi et al noted average peak pressures of 41 cmH_2O following cup-patch sigmoid cystoplasties.[102] In evaluating the cystometric properties of ileum and right colon, mean maximal contractile pressures were 63 cmH_2O for tubular right colon and 42 cmH_2O for detubularized colon.[103] Even more impressive was the effect noted by detubularizing ileum, when the mean maximal pressures were 81 cmH_2O in the tubularized vs 28 cmH_2O in the detubularized ileal reservoir. Clinically significant contractions (>40 cmH_2O at volumes <200 ml) were observed in only 10% of the right colon and none of the ileal segments. Ileal segments were thought to be urodynamically superior, but only at large volumes. Cecal reservoirs were thought to have higher pressures than ileal reservoirs at corresponding volumes and 10 times greater motor activity.[104] This has very important clinical significance. The reservoir must be made large enough to allow catheterization at 4-hour intervals at low intrareservoir pressures, taking into account the volume of urine made by the patient. If upper tract deterioration or urinary leakage occurs, urodynamics must be repeated to determine whether significant contractile activity persists. In the author's augmentation cystoplasty population another segment of bowel had to be added in 19 of 323 patients owing to persistent contractile activity of the initial bowel segment.[105] Twelve of 87 undergoing colocystoplasty (13.8%), four of 30 undergoing gastrocystoplasty (13.3%), and only two of 145 ileo-cystoplasties (1.4%) required a secondary augmentation bowel segment.[105] The authors agree with Goldwasser and Webster that ileum is the least contractile intestinal segment, with cecum intermediate and sigmoid and stomach being the most contractile.[103,105]

Choice of bowel segment

Although some of the metabolic and contractile properties of the gastrointestinal tract have been discussed above, there remain several advantages and disadvantages of each segment (Table 57.3). Several studies have reported on experience with the various gastrointestinal segments used in reconstructing the lower urinary tract.[42,86,94,106] The majority of data in children come from augmentation cystoplasty rather than complete reservoir construction.

Table 57.3 Advantages and disadvantages of each segment

Segment	Advantages	Disadvantages
Ileum	Most compliant Less mucus	Diarrhea Vitamin B_{12} deficiency Short mesentery Hyperchloremic acidosis Poor muscle backing
Sigmoid	Readily mobilized Easily implanted Good muscle backing	Unit contractions Lower compliance Mucus Hyperchloremic acidosis Perforation risk
Ileocecal	Valve as antireflux/continence mechanism Good capacity reservoir Constant blood supply	Diarrhea Not always available Contractile
Stomach	Short gut/radiation Chloride pump Minimal mucus Few infections Ease of implantation Good muscle backing	Hypochloremic alkalosis Rhythmic contractions Hematuria/dysuria

Ileum, as noted previously, when reconfigured will provide the most compliant, least contractile segment. Mucus production, while greater than stomach, is less than with sigmoid or cecum and tends to decrease with time.[107] Hyperchloremic acidosis occurs with small and large bowel but seems to be less significant with ileum. Except in instances of short gut syndrome, as in cloacal exstrophy, there is generally an abundance of ileum available for reservoir construction and for the creation of catheterizable channels. If short ureters are present, a 'tail' of ileum extending from the pouch can be used to bridge the gap. However, at times the mesentery is short, making an anastomosis to an orthotopic catheterization site difficult.

The ileum is responsible for vitamin B_{12} absorption, which occurs in the terminal portion. If possible, the distal 15 cm of ileum should be preserved. Resection of long segments of ileum have resulted in vitamin B_{12} deficiency but may take several years to clinically manifest, as a megaloblastic anemia and neuropathy, as vitamin B_{12} stores may last for years.[42,108,109] Akerlund et al noted this problem in patients following Kock pouch construction.[110] However, Canning et al did not find any patients with a vitamin B_{12} deficiency among 26 patients evaluated following bladder augmentation using ileum, but this group was followed for only 3 years.[111] Resection of large segments of ileum has also been found to result in diarrhea and to increase the risk of cholelithiasis.[109,112] Roth et al reported the occurrence of chronic diarrhea in 11% of patients who had a CUR constructed from ileum.[113] Baker and Gearhart noted that if >100 cm of ileum is resected, steatorrhea and cholethiasis can develop.[114]

The cecum and ileocecal segments have been the most widely used tissues for CUR construction. The ileocecal segment has a constant, reliable blood supply that allows easy mobilization and placement of the pouch in the pelvic inlet, when necessary. The large cecal size makes for an excellent reservoir and the ileocecal valve can be used as either a continence or an antireflux mechanism. The appendix is also available for use as a continence mechanism. This segment is used in several of the most popular reservoirs, i.e. the Indiana pouch, Florida pouch, Mainz pouch, and Penn pouch.

The ileocecal segment has been less frequently used in children as the majority undergoing CURs have a neuropathic component. In this group of patients, the ileocecal valve seems to be important in maintaining fecal continence. Removal of the ileocecal valve has reportedly led to diarrhea in 10% of children.[115] Gonzalez and Cabral reported that a patient required replacement of the ileocecal valve to reverse or correct intractable diarrhea.[116] Roth et al noted that 23% of patients having an ileocecal reservoir had chronic diarrhea.[113] Furthermore, in cloacal exstrophy patients the colonic segment may have been absent or discarded at the time of previous surgery and thus not available for use. Cecal incorporation into the urinary tract may lead to hyperchloremic metabolic acidosis as well as significant mucus production.

The sigmoid colon has been extensively used in lower urinary reconstruction in children. It is often quite enlarged and redundant in the spinal dysraphism population, allowing it to reach easily any portion of the abdomen or pelvis. Its mucosa can be easily dissected to provide submucosal tunnels for antireflux or continence mechanisms. Whereas it seemingly has a number of advantages, it has the disadvantages of significant contractile activity in spite of detubularization and reconfiguration.[105] It also has the greatest mucus production[107] and highest rates of bacteriuria,[117] and is most likely to result in significant hyperchloremic metabolic acidosis. In the authors' hands, when used to augment the bladder it has resulted in the highest spontaneous bladder perforation rate.[94] However, this latter problem was not found in other series.[118,119] This difference may be in the means of reconfiguration. The authors no longer simply close the two ends of the segment and open the antimesenteric border,[120] but rather recommend complete reconfiguration of the sigmoid. If reconfigured appropriately, sigmoid apparently has no higher rate of perforation or other complications than any other segment.

The use of the stomach in lower urinary reconstruction in children was popularized with the initial report by Adams et al.[121] It was rapidly incorporated into the surgeon's armamentarium because of a number of demonstrable advantages. Stomach has excellent muscle backing and submucosal tunnels can be created in a manner similar to native bladder to allow ureteral reimplantation or tunneled continence mechanisms.[122] The stomach was also thought to be an ideal tissue for those who had undergone pelvic radiation, as it is generally outside the irradiated field. Bladder calculi, which have been a significant problem with the use of intestinal segments, have nearly been non-existent with the use of the stomach.[123–125] Kaefer et al found that only two of 70 patients developed stones with the use of stomach compared with 30 of 137 with stones following the use of other enteric segments. Perhaps most importantly, the

stomach differs metabolically from the other intestinal segments.[126] Gastric mucosa secretes chloride, which may be beneficial in those with azotemia.[126,127] Serum chloride has been noted to decrease and bicarbonate increase following the use of stomach in the urinary tract.[121,128] This net chloride excretion has led to a decrease in bacteriuria,[72,106] and, along with less mucus production, probably plays a significant role in the lower incidence of stone formation.

Unfortunately, the popularity of the stomach has diminished somewhat as two unique problems have been noted: profound hypochloremic metabolic alkalosis (in five of 37 patients) and the hematuria–dysuria syndrome (HDS) found in approximately one-third of patients following gastrocystoplasty.[106,129–134] The dysuria may be more debilitating in those with sensation and is worse in those with oliguria.[135] If a reservoir is to be constructed from stomach, the continence mechanism must be 100% reliable, as severe skin excoriation may occur with urinary leakage.[87,133,134] Stomach should be avoided if a period of anuria is anticipated, as the urine is necessary to buffer the gastric acid production, thus preventing irritation and perforation.[129] Pharmacologic therapy with H_2 blockers and hydrogen ion pump blockers may be helpful in reducing acid production.[136–138]

Another disadvantage of stomach is its contractile activity. Rhythmic contractions are reported in all large series, occurring in up to 62% of patients.[122,131,139] This is partly due to the small wedge segment of stomach actually used. Larger, more rhomboid segments, have improved the urodynamics but contractility can remain a problem, necessitating a secondary augmentation.[105,140]

No gastrointestinal segment will make the perfect bladder. Each segment has its own advantages and disadvantages, which must be weighed prior to CUR construction in relation to each patient. As noted previously, the anatomy and innervation are frequently abnormal and often the tissues are scarred from prior surgery. Any segment can work well if used correctly. Recently, stomach in combination with intestinal segments has been used to create a metabolically neutral reservoir.[66,141–143] The hypochloremic alkalosis associated with stomach is offset by the hyperchloremic acidosis associated with small and large bowel usage, creating a more 'balanced' reservoir (Figure 57.12). Only a relatively small (8 × 4 cm) gastric segment is necessary to achieve neutrality. Lockhart et al have demonstrated that larger segments may result in HDS. In 12 patients with long-term follow-up, 11 have normalized their mean serum HCO_3 levels.

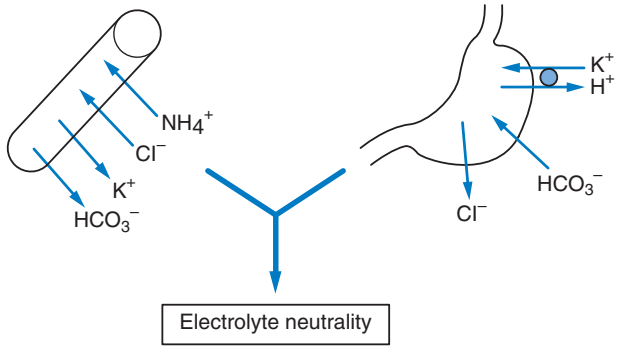

Figure 57.12 The effect of combining intestine with stomach. Electrolyte neutrality is achieved.

Serum pH levels have also been corrected, and only one patient has had persistent metabolic acidosis.[143] Gastroileal composite reservoirs seem to provide many advantages but take longer to construct as a second anastomosis is necessary and there is potentially significant blood loss.

Creation of an antireflux mechanism

The second of the three principles of CUR construction is the creation of a reliable antireflux mechanism. Whereas the necessity for this can be debated in the adult patient when a low-pressure, large reservoir has been constructed, it is widely agreed that this is very important in the pediatric population. The historic aspects and the various mechanisms were reviewed by Walker.[144] Antireflux mechanisms today are generally based on intraluminal or extraluminal tunnel techniques or by the creation of nipples by intussusception. These techniques are similar to those that are used to provide continence mechanisms, so will only be briefly discussed here.

Tunneling techniques into bowel have been modified over the years by a number of surgeons, but all have their basis in the original technique introduced by Coffey[145] (see the technique described for antireflux under colon conduit description). Developing submucosal tunnels in small intestine can be quite difficult. Two techniques to create ileal tunnels are worthy of mention. Le Duc et al described an intralumenal tunneling technique, whereby a 3 cm mucosal sulcus is created.[146] The ureter is brought through the bowel wall, placed in this sulcus, and secured. The intestinal mucosal edges are sutured to the ureteral adventitia and, with time, with mucosa will cover the ureter to create a tunnel with muscle backing (Figure 57.13). Abol-Enein and Ghoneim described an ingenious technique using a serosal tunnel, which is easily

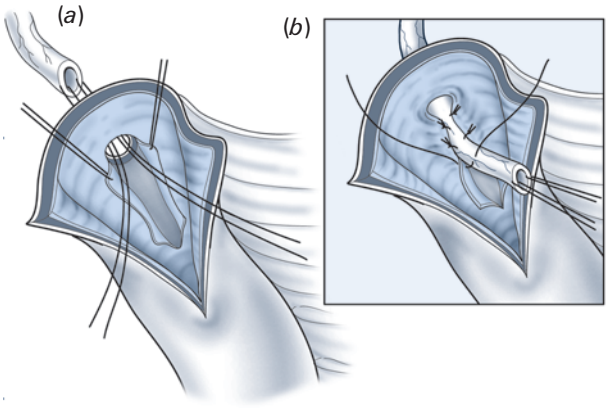

Figure 57.13 Le Duc reimplant. (*a*) A mucosal sulcus is created in the ileum. (*b*) The ureter is brought into the bowel segment and placed in the sulcus between the mucosal edges, which are tacked to the ureter. (Adapted from Le Duc et al,[146] with permission.)

constructed and appears to reliably prevent reflux (Figure 57.14).[147]

Nipple valves are generally constructed by intussuscepting ileum or using the ileocecal valve. These techniques will be covered under continence mechanisms as the technique is the same. The ureters are implanted by direct anastomosis to the bowel proximal to the nipple valve. As a general rule, antireflux intestinal nipple valves have had more complications than tunneling techniques and are more difficult to construct. In the authors' experience there has been nearly a 50% incidence of reflux noted on long-term follow-up in those in whom a reinforced intussussepted ileocecal valve was used as the antireflux mechanism. Therefore, other techniques are currently being used. A split-cuff nipple valve using ureter has been reported by several authors, and is very easily constructed and surprisingly reliable[103,148,149] (Figure 57.15). Stone and MacDermott noted mild reflux in only one of 35 ureters, all of whom had at least a 2-year follow-up.[148] This is particularly useful in the dilated ureter where tunneling techniques are more likely to lead to ureteral obstruction.

Overall, the results have been good. Walker noted success rates are slightly worse than reimplantation into native bladder.[144] Most interesting is the report by Lockhart et al, where 165 of 201 ureters were

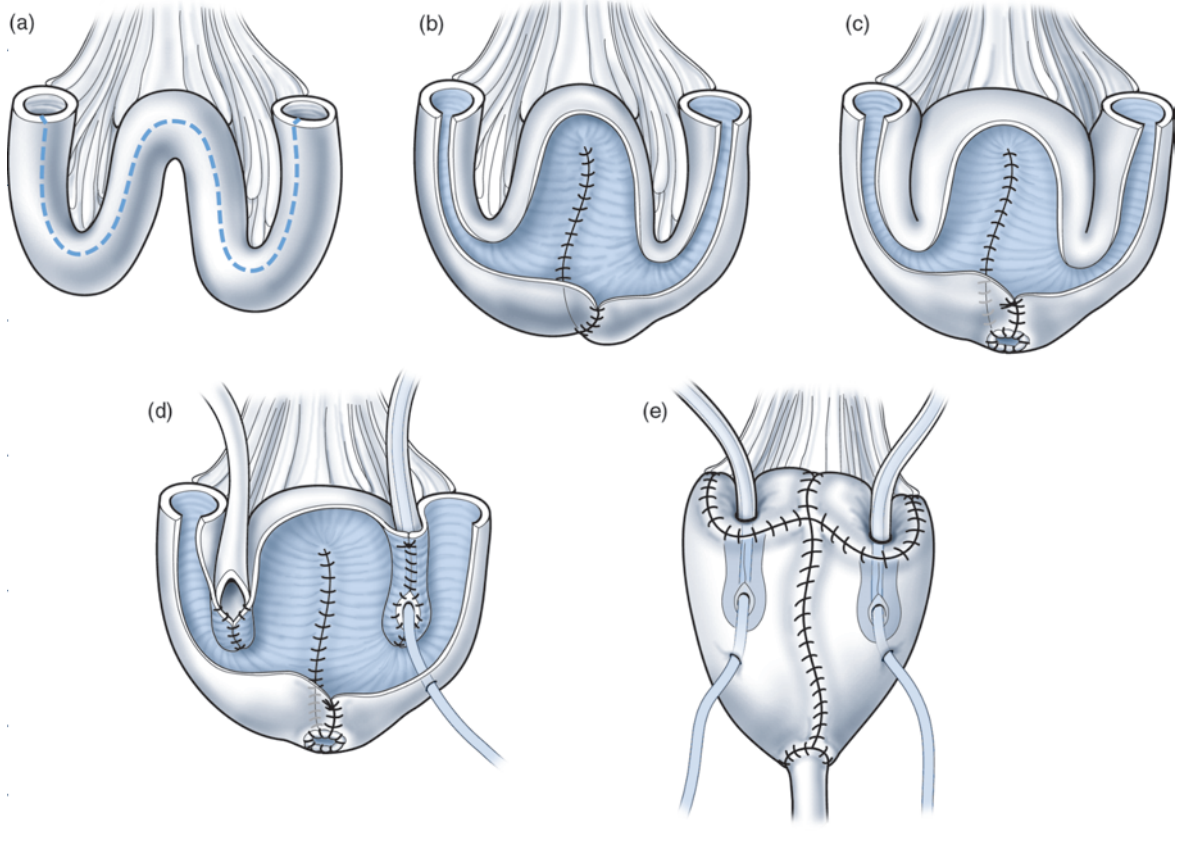

Figure 57.14 Abol-Enein and Ghoneium reimplant. (*a* and *b*) A W-shaped ileal segment is fashioned and the bowel is opened on the antimesenteric border. (*c* and *d*) Two serous lined troughs are created and the ureters are placed in the troughs with the ureteral meatus anastomosed to the intestinal mucosa. (*e*) The free bowel edges are closed over the ureter, creating a serosal lined tunnel. (Adapted from Abol-Enein and Ghoneim,[147] with permission.)

anastomosed end to side with no effort made to prevent reflux.[150] Neither reflux nor obstruction occurred in 87%. Tunneled reimplantations have successfully prevented reflux in >95% of patients.

Creation of a continence mechanism

The final and most important principle of CUR construction is the creation of a reliable continence mechanism that is easily catheterizable. The creation of the perfect reservoir with no reflux is of no value to the child who continually leaks urine onto the abdominal wall. Equally disastrous is having difficulty in catheterizing the completely continent reservoir, which puts the child at risk for reservoir perforation. As Benson and Olsson have observed, the integrity or failure of the continence mechanism determines the success or failure of the diversion.[151] Numerous techniques have been described to provide continence but they all fall basically into one of the following categories: nipple valves, plicated valves, flap valves, and hydraulic valves. Some techniques use a combination of these valve mechanisms. Examples of each type will be demonstrated. The interested reader should be aware of two excellent reviews of continence mechanisms by Sagalowski[152] and Austin and Lockhart.[153]

Nipple valves are generally created by intussuscepting an intestinal segment to create a sphincteric compression mechanism. These nipples are used in many of the most popular CURs. An ileal nipple is used in the Kock pouch (Figure 57.16) and the Mainz pouch (Figure 57.17). An ileocecal nipple is used in the pouch described by Mansson et al.[154]

When the nipple valve is within the lumen of the reservoir, the principle of equilibration pressures adds further to continence. Unfortunately, the intrareservoir pressure that compresses the nipple to provide continence also applies forces to evert, flatten, or destabilize the nipple (Figure 57.18). Because of the nipple's tendency to fail over time, many ingenious methods to stabilize the nipple have been reported. Hendren described dissecting the mesentery off the ileum to be intussuscepted and scarifying it to provide internal fixation.[155] The Kock pouch has been modified many times from its original application as a continent ileostomy.[156] The procedure reported in the first 12 patients involved the use of 60–70 cm ileum for the reservoir.[62] The middle 40 cm was folded into a 'U' shape after being opened on its antimesenteric border. In later patients, the nipple valves were constructed by intussuscepting the ileum into the reservoir. The nipples were stabilized by staples, and either Marlex mesh or fascia was positioned as a cylinder around the base of the nipples and secured to the reservoir. One nipple was used for continence and the other to prevent reflux. The Kock pouch has since been popularized by Skinner, who made further modifications.[63] There appears to be a steep learning curve, but in Skinner's hands the results have been reported to be excellent:[63] 16% suffered early complications and late complications have been noted in 22% of 531

Figure 57.16 Caption opposite

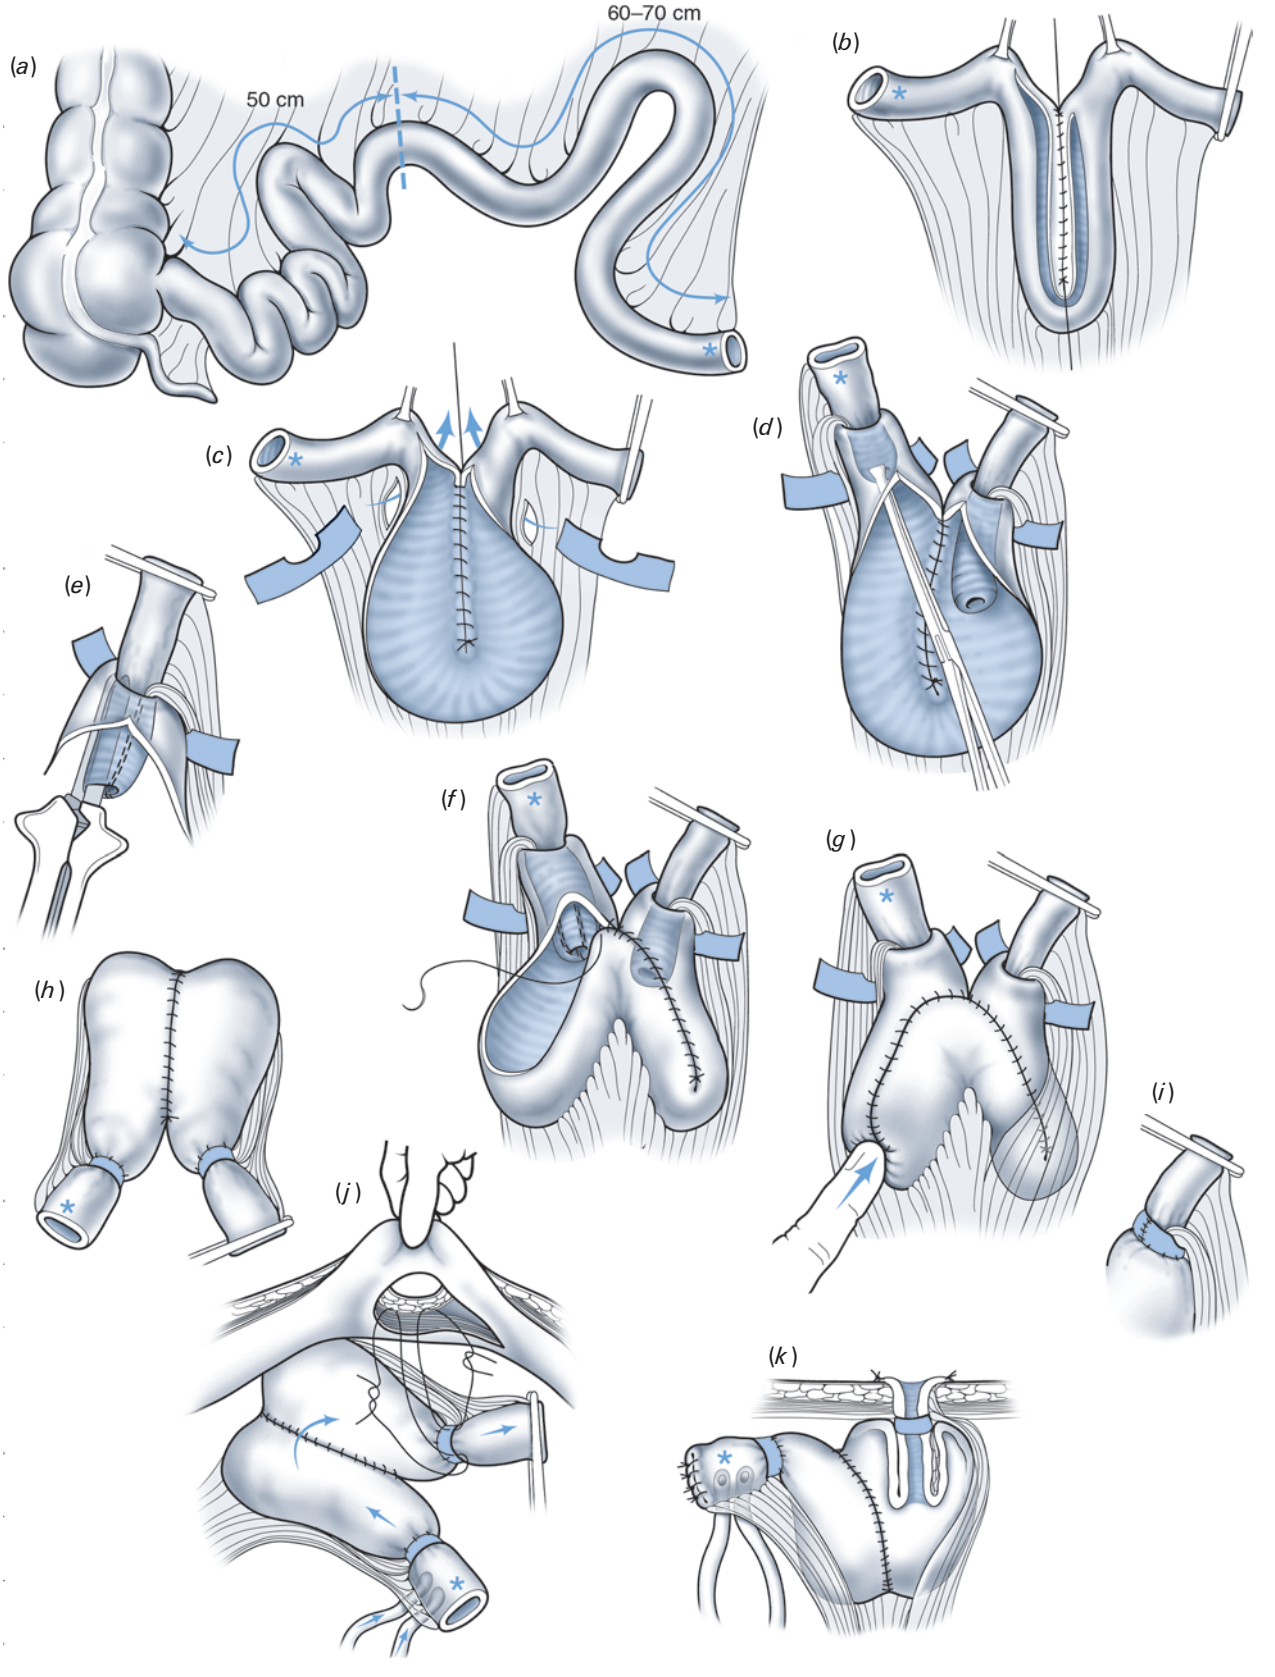

Figure 57.16 Kock pouch (continent ileal reservoir). (*a*) Bowel segment measuring 60–70 cm is isolated approximately 50 cm from the ileocecal valve and positioned as the letter U with the terminal end directed toward the head of the patient and the bottom of the U toward the left side of the patient. (*b*) The legs of the U are united at the antimesenteric border with continuous 3–0 polyglycolic acid sutures. (*c*) The intestine is divided adjacent to the suture line and the incision is continued for 3 cm on the afferent limb. The mucous membrane is sutured with continuous 3–0 polyglycolic acid sutures. Openings are made in the mesentery supplying the future base of the nipple valves. (*d*) Intussusception of the afferent and efferent segments into the future reservoir. (*e*) The nipple valves are secured with staples. (*f*) The reservoir is closed with two continuous inverting 3–0 polyglycolic acid sutures. (*g–h*) The reservoir is brought into its final position by pushing the corners of the reservoir downwards between mesenteric leaves. (*i*) A fascia of Marlex mesh encircles the base of the nipple valve, and the ends are approximated with three or four non-absorbable sutures. The reservoir wall is sutured to the cylinder with 3–0 polyglycolic acid sutures. (*j*) The cylinder at the efferent segment is attached to the opening and anterior rectus sheath with non-absorbable sutures. (*k*) The completed continent ileal reservoir.

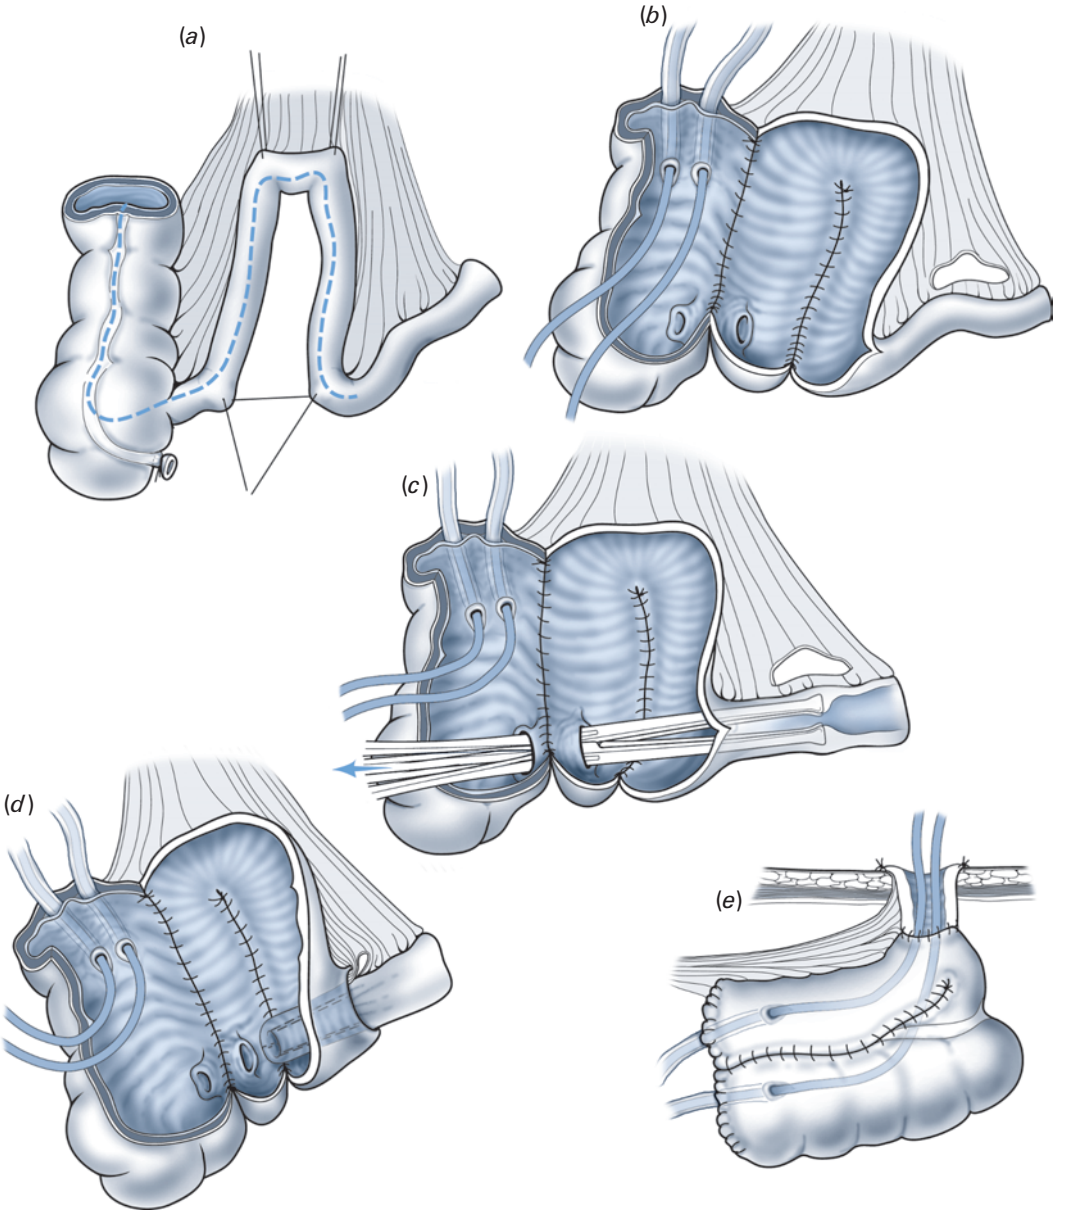

Figure 57.17 The Mainz pouch utilizes intussuscepted ileum pulled through the ileocecal valve (*c*) as the continence mechanism.

patients, with the vast majority involving the efferent nipple.[63] The large amount of ileum required (78 cm), the complexity of the procedure, and the requirement for two nipples with stapling and collar fixation, have deterred its widespread use in children, but it does provide the least contractile and most compliant reservoir, with pouch capacities ultimately over 700 ml.[67] Hanna and Bloiso achieved success in a small series in children, but modified the nipple to avoid the use of staples and Marlex.[157] Benson and Olsson noted that nipple failure occurs in approximately 15% in the best of hands, with the three most common complications of the nipple being pinhole fistulae at the base of the nipple, nipple valve prolapse, and shortening of the nipple length.[67] Because of this high complication rate, they no longer recommend its routine use.[151]

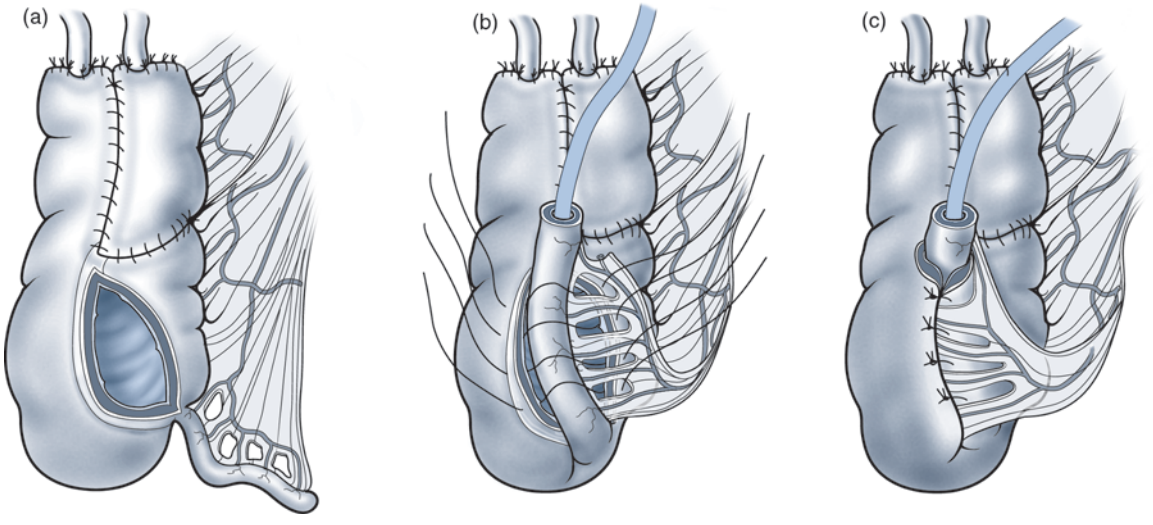

Figure 57.19 Mainz pouch with appendix. (*a*) The cecum has been patched with ileum. A seromuscular incision is made in the tenia. (*b*) Mesenteric windows are made in the mesoappendix. (*c*) The appendix is placed in the submucosal tunnel and the cecum is closed over it, avoiding the appendiceal vasculature.

The ileocecal valve is commonly used as a continence mechanism with the cecum acting as the reservoir. However, in its native form it is functionally adequate in only 25% of the population.[158,159] Rendelmen et al found that at 25 cmH_2O, the valve is incompetent in 25%.[159] This incompetence increases such that only 7% are continent at 50 cmH_2O pressure.[159] Reinforcement to achieve continence was achieved by Zinman and Libertino by wrapping the cecum around the ileum.[160] Intussusception of the ileocecal valve as a nipple to enhance its continence is the basis for the pouch described by Mansson et al.[154] The Mainz pouch (mixed augmentation with ileum and cecum) uses tunneled ureteral implants to prevent ureteral reflux and an unusual nipple valve for continence with the reservoir created by combining the cecum and ileum (see Figure 57.17). The ileum is intussuscepted to create a nipple, which is then pulled through the ileocecal valve and secured by stapling. Continence rates have been greater than 95% and reservoir capacities greater than 600 ml in 179 patients, 41 of whom were children.[161–163] Again, owing to nipple complications and the difficulty in constructing them, the Mainz group no longer uses the nipple but instead an in-situ appendix, which is imbricated in the cecum, as the continence mechanism (Figure 57.19). Stein et al reported 374 patients undergoing a Mainz pouch in which 116 had the appendix as the continence mechanism with 6.7% having early complications and 25% late complications.[164] All of the incontinence occurred with use of the nipple valves, while none of the appendiceal efferent stomas were incontinent. Gerharz et al[165] compared the two continence mechanisms in the Mainz pouch (96 appendiceal stomas, 106 ileal nipples) and noted that 17% of the appendiceal stomas required 23 reinterventions with all but two being for stenosis. Nipple valves required a second operation in 12.3%, but the revisions were much simpler in the appendiceal group and this has become their preferred method. If the appendix is not available, a Lampel tube of cecum (Figure 57.20a) or submuscular tube (Figure 57.20b) is now used.[166] The Mainz group also looked at vitamin A, B, B_2, B_6, D, and E and folic acid levels, as well as bone density, after these diversions, and all were within normal limits.[167] Vitamin B_{12} levels and bone density were normal in the 51 children, but dropped significantly in adults. They recommend checking vitamin B_{12} levels after 4 years.[167]

The appendix has also been used by others to create an intussuscepted nipple as a continence mechanism for a right colon pouch.[168–170] There is only minimal intussusception in the Bissada technique,[169] but Issa et al reinforced this with a mesh wrap similar to the ileal nipple in the Kock pouch.[168] Tillem et al reinforce the appendix only if leakage is demonstrated after filling the cecum to 60 cmH_2O.[170]

An interesting nipple valve was developed by Benchekroun[171,172] and modified by Guzman et al.[173] The ileum is inverted into itself to create an 'inkwell' system whereby urine enters between the walls and compresses the inner layer for continence (Figure 57.21). Benchekroun et al reported 136 patients with

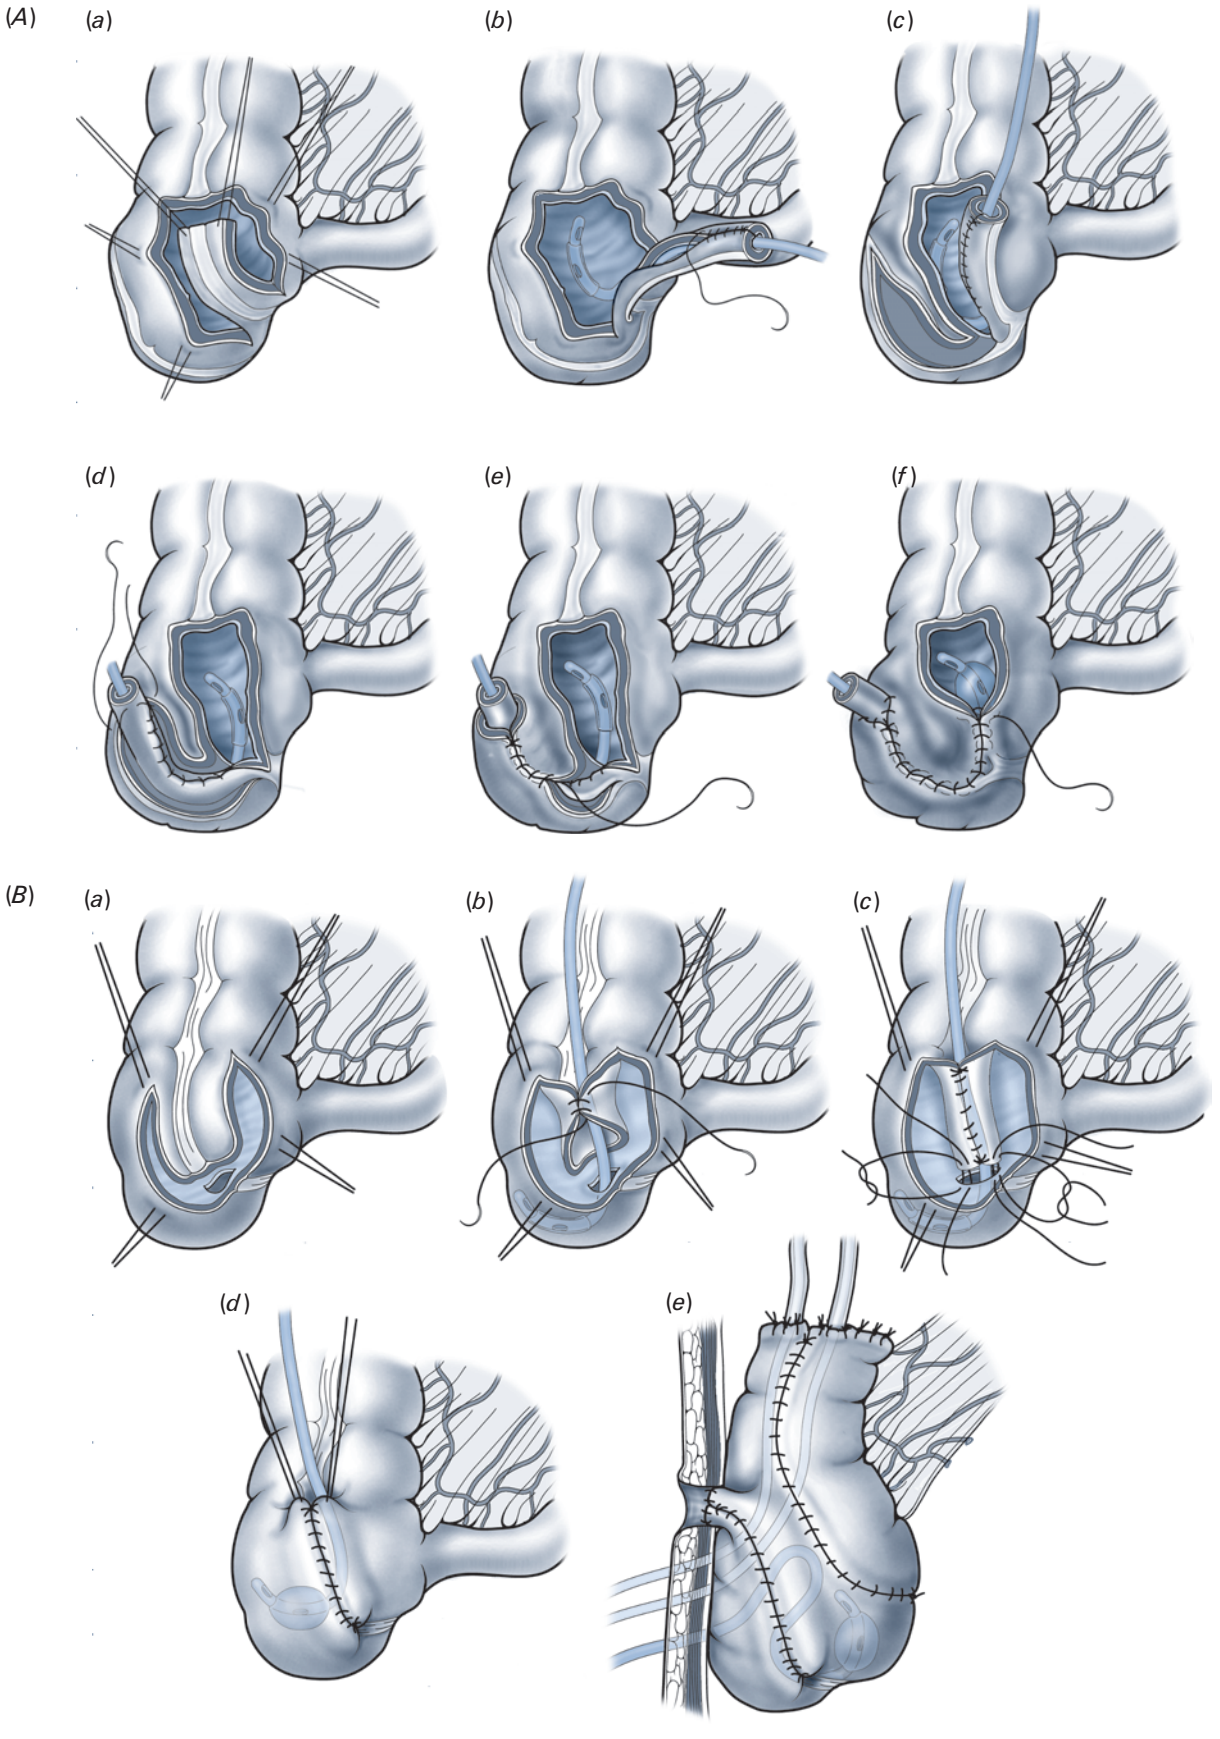

Figure 57.20 (*A*) Lampel tube. (*a–c*) A full-thickness bowel flap is elevated and tubularized over an 18 Fr catheter. (*d–f*) It is then placed in a submucosal subtineal tunnel and the bowel wall is closed. (*B*) Lampel seromuscular tube. (*a* and *b*) The elevated seromuscular layer is tubularized over an 18 Fr catheter and (*c*) anastomosed at its base to the mucosal opening. Figure 57.21 The Benchekroun ileo-nipple.

75% continence after the initial operation.[171] Another 17.6% achieved continence after revision. The results with this technique by the Johns Hopkins group were not nearly as good and, after initially recommending this procedure, they have now abandoned it, as stomal stenosis in children and destabilization are problems.[174,175] This hydraulic nipple valve, while ingenious, has not gained wide acceptance.

Plication techniques have been widely accepted as reliable continence mechanisms and have been popularized by the Indiana group in what has become known as the Indiana pouch. This pouch is based on a modification of Gilcrest and Merrick's cecoileal reservoir. It has undergone several modifications since the initial report in 1985.[176] In this procedure the cecum is detubularized and used as the reservoir. Reflux prevention is obtained by tunneling the ureters into the tenia or by the Le Duc technique.[177] The continence mechanism is based on plication of the ileum to the level of the ileocecal valve. The native ileocecal valve is reinforced by Lembert sutures (Figure 57.22). A very similar technique has been used by Lockhart et al in the Florida pouch.[178] The advantage of this procedure is its ease of construction, using techniques familiar to all urologists. Carroll and Presti compared plicated vs stapled ileal segments and noted that mean contraction pressures were higher in the stapled group (63 ± 27 cmH_2O at 41 ± 21 cmH_2O).[179] They have previously shown the contractions in the ileal segment always precede or are concomitant with cecal reservoir contractions.[180] Mean reservoir volumes were 675 ml, with mean reservoir contractions being 24 cmH_2O and mean plicated ileal pressures 40 cmH_2O in the reservoir. As would be expected from these data, continence rates have been quite good. Rowland reviewed several series and noted that one of 17 patients (6%) required repair of the efferent limb for leakage.[181]

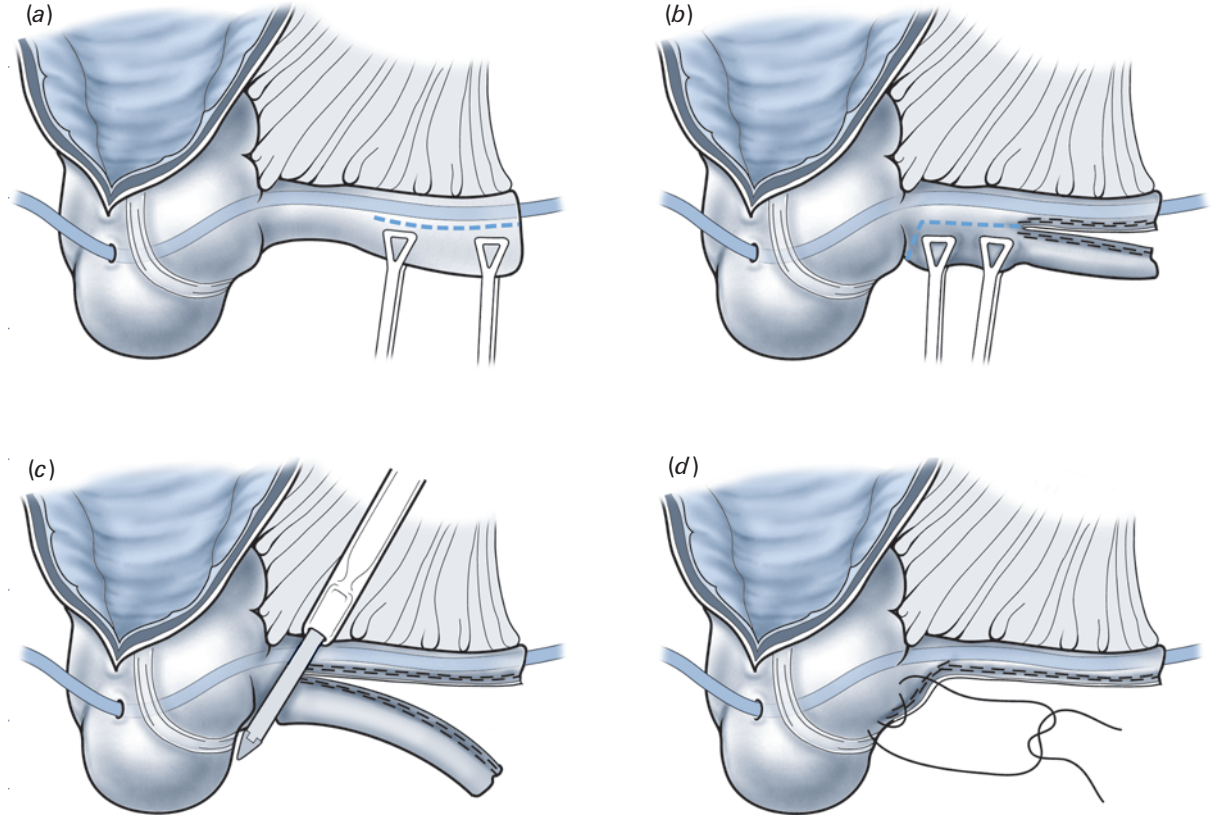

Figure 57.22 Continence is achieved by plicating the ileum to the level of the ileocecal valve. The ileocecal valve is reinforced (*d*).

However, Canning, reported that leakage occurs more readily with this mechanism than with nipples.[182] Ring and Hensle achieved a 95% continence rate in 29 children undergoing the Indiana pouch.[183] In Rowland's most recent report, five of the last 81 patients had incontinence secondary to high reservoir pressures;[184] however, the cecal reservoir with ileum may correct this.

Koff et al reported a technique to provide hydraulic compression to the efferent ileal limb of the Indiana pouch.[185] A segment of ileum is used to wrap around the efferent limb and is anastomosed to the cecal pouch. While this would increase resistance further, it adds complexity to an otherwise easily performed procedure that already has a high continence rate. Koff's approach has not gained widespread use.

Without question, the most commonly used continence mechanism in children is based on the flap-valve principle as introduced by Mitrofanoff.[186] Mitrofanoff reported the use of the appendix to tunnel into the neuropathic bladder (similar to a ureteral reimplantation to prevent reflux) to provide a continent catheterizable stoma into the native bladder. The procedure was popularized by Duckett and Snyder,[187,188] who extended the use of this technique to create a continent ileocecal pouch, the Penn pouch[189] (Figure 57.23). Since these early reports, many authors from around the world have reported their experience using not only appendix but also ureter, tapered ileal, colonic or gastric tubes, fallopian tubes, and vas deferens.[190–199] The continence mechanism is based on placing a supple tube in a submucosal tunnel with a 5:1 ratio of length to tube diameter. Firm muscle backing of the tube prevents reflux (Figure 57.24). It was initially thought that the tube itself must also be muscular, but bladder urothelium, colonic mucosa, and preputial skin alone have all been used successfully.[200–202]

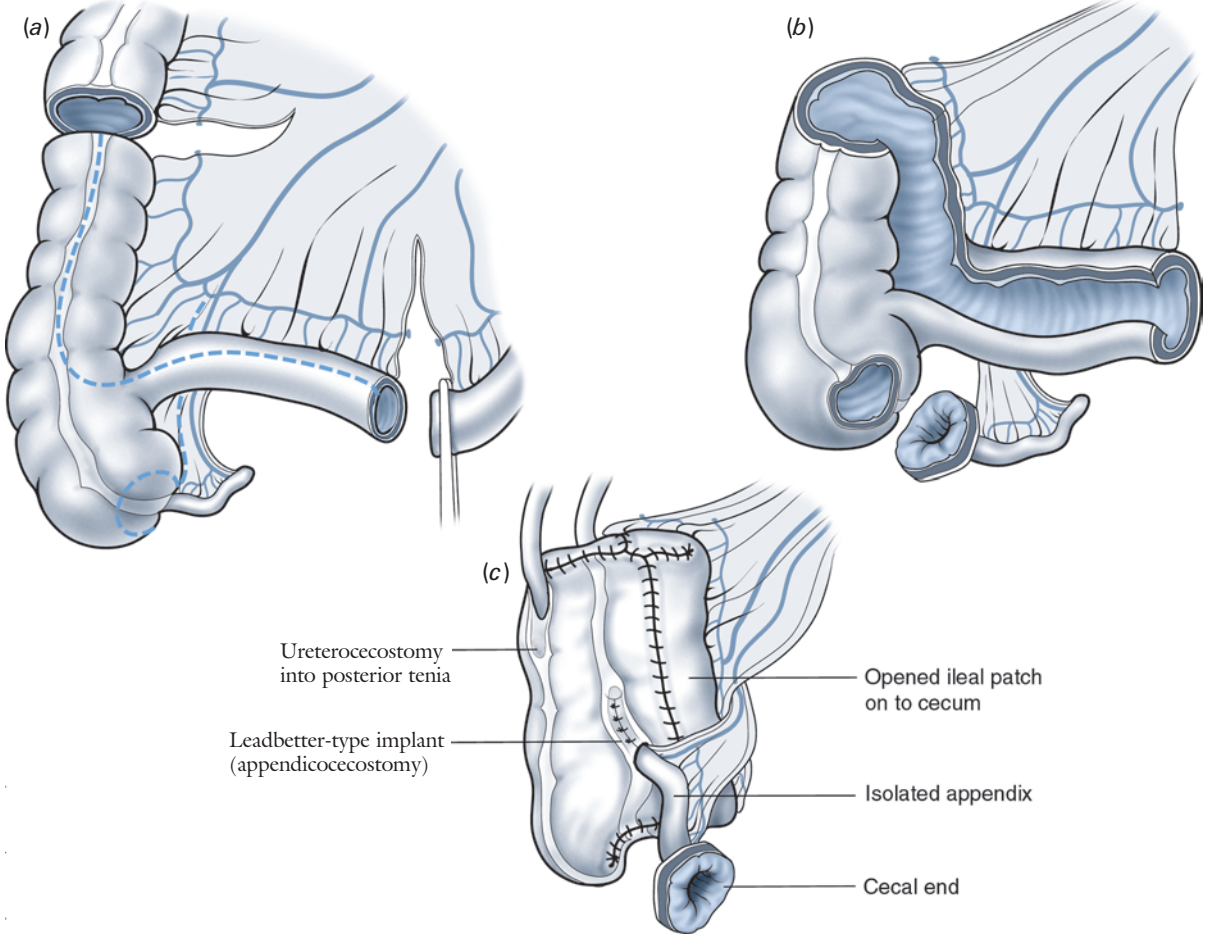

Figure 57.23 The Penn pouch. (*a*) The ileocecal segment is isolated and incised on its antimesenteric border; the ureters are implanted into the colonic segment. (*b*) The appendix is isolated in its mesentery. (*c*) The ileocecal segments are joined and the appendix is implanted into the cecum; the cecal end is brought to the skin as a catheterizable stoma.

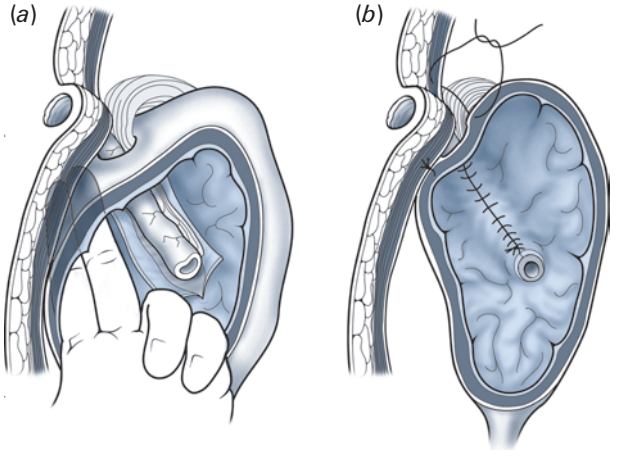

Figure 57.24 Appendicovesicostomy is performed by tunneling the appendix submucosally into the bladder. (Reprinted from Keating et al,[194] with permission.)

This is a relatively simple procedure using techniques familiar to pediatric urologists. It is also particularly useful in children who, as noted previously, often are not candidates for use of the ileocecal valve or long segments of ileum. Kaefer and Retik reviewed several series and found that continence rates ranged from 86 to 96%.[196] The most common complication reported is stomal stenosis. Khoury et al noted stomal stenosis in 5–57% of patients and described a technique of placing the stoma at the umbilicus.[203] The Mainz group concluded that the stomal stenosis is slightly higher when placed at the umbilicus. A high risk for stenosis has also been seen when using the appendix compared with tapered ileum.[204,205] The Great Ormond Street group has reported a decrease in the incidence of stomal stenosis using a VQZ skin-flap technique[206] (see Figure 58.3). Using the concealed umbilical stoma technique, the Pittsburgh group has seen a stomal revision rate of 7% at nearly 3 years mean follow-up.[207] At a minimum, a skin flap should be placed into the spatulated tube. In the authors' last 100 patients in whom the Mitrofanoff principle has been applied, there is a 99% continence rate. Stomal stenosis has occurred in 12% (5/57 appendix, 1/22 ileum, and 6/21 bladder).[208] In the Boston experience, five of 50 patients leaked at the stomal level, five had stomal stenosis, and one an appendiceal stricture.[196]

Since the introduction of the MACE procedure (Malone antegrade colonic enema), which used the appendix brought to the skin for irrigation of the cecum, it has become necessary to find other tissue to form a catheterizable urinary stoma. The Yang–Monti technique,[209,210] which uses only 2 cm of reconfigured ileum to form a tube, has been a great advance, and the technique has been used successfully[211] (Figure 57.25). Tunneling of these tubes into colon or stomach is easily accomplished but is difficult in ileum. A seromuscular trough for implantation has been described[194] and Plaire et al[212] have described a serosal reimplant similar to the Abol-Enein and Ghoneim ureteral reimplant (see Figure 57.14). It is now clear that the Mitrofanoff principle is a major advance and that virtually any supple tube placed in a tunnel that has adequate muscular backing will successfully provide continence.

Complete gastric reservoirs have been popularized by Mitchell's group,[143] and they have recently described three techniques to provide continence[213] (Figures 57.26 and 57.27). Two of these are based on the Mitrofanoff principle and one on a nipple valve.

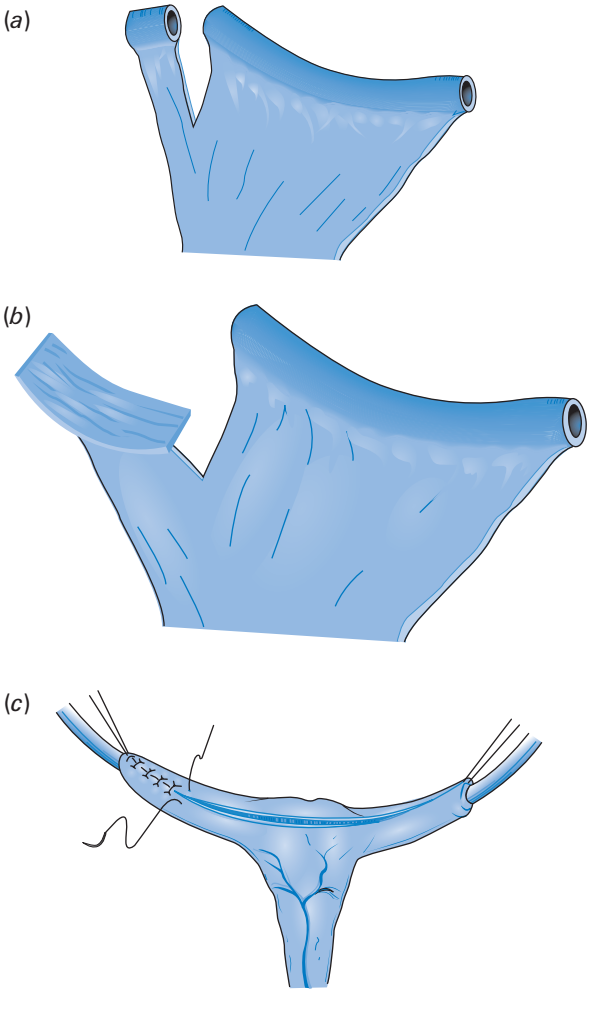

Figure 57.25 Yang–Monti. (*a*) A 2 cm segment of small bowel is isolated on its mesentery. (*b*) It is opened on its antimesenteric border. (*c*) The segment is retubularized by closing it in a longitudinal fashion (see also Figures 55.23 and 55.24).

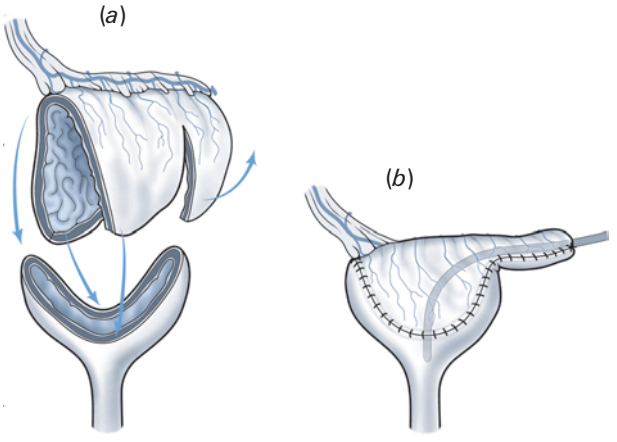

Figure 57.26 Gastric continence mechanisms. (*a*) A gastric wedge is harvested from the greater curvature of the stomach with an anterior strip mobilized for tubularization. (*b*) The anterior strip is tubularized with two sutured layers over a 12 Fr catheter. The proximal end is formed into a nipple for the continence mechanism. (Reproduced from Close and Mitchell,[213] with permission.)

Stomach is very receptive at tunneled reimplants for either antireflux or continence mechanisms. To reduce acidity, stomach may be used in combination with ileum as the reservoir, rather than using stomach alone.[142,143] Applying a Yang–Monti ileal tube tunneled into the stomach as the continence mechanism prevents the peristomal irritation sometimes seen with gastric tubes.[198,213]

The only reservoir that provides a volitional continence mechanism, which also happens to be the first continent reservoir, is the ureterosigmoidostomy.[52] Since its introduction, over 60 modifications have been proposed. Because of the problems with upper tract deterioration, occasional incontinence, acidosis, and the risk for adenocarcinoma, it has been largely abandoned. However, the opportunity to control continence without CIC continues to make it very attractive. It cannot be used in spinal dysraphism, as a neurologically intact anal sphincter is required. In children it has been used almost exclusively in the exstrophy population when continence cannot be achieved with bladder neck surgery. It has been suggested that oatmeal enemas be given preoperatively to check anal continence.[214] Classically, ureterosigmoidostomy has been done by simply tunneling the ureters into the rectum. However, the risk of cancer at the anastomotic site and night-time incontinence led surgeons to pursue other efforts to provide more of a reservoir effect and avoid direct contact of the ureters with the stool. Development of neoplasms seems to require urine to be in contact with stool and bowel mucosa.[215,216] Of 94 children with ureterosigmoidostomy followed at the Children's Hospital of Boston, seven developed adenocarcinoma of the colon, four of whom died.[217] Rink and Retik proposed that an ileocecal conduit be initially constructed and the conduit later anastomosed to the intact sigmoid by end-to-end colocolostomy.[217] Kock et al described a 'valved-rectum' with the colon intussuscepted at the rectosigmoid junction to prevent reflux of rectal contents and an ileal patch anastomosed to the anterior rectal wall.[218] This allowed the rectal capacity to increase from 200 to 700 ml with maximal pressures of only 24 cmH_2O and minimal metabolic disturbances.[218]

A hemi-Kock pouch anastomosed to the rectum has also been described,[218] but the complexity of cre-

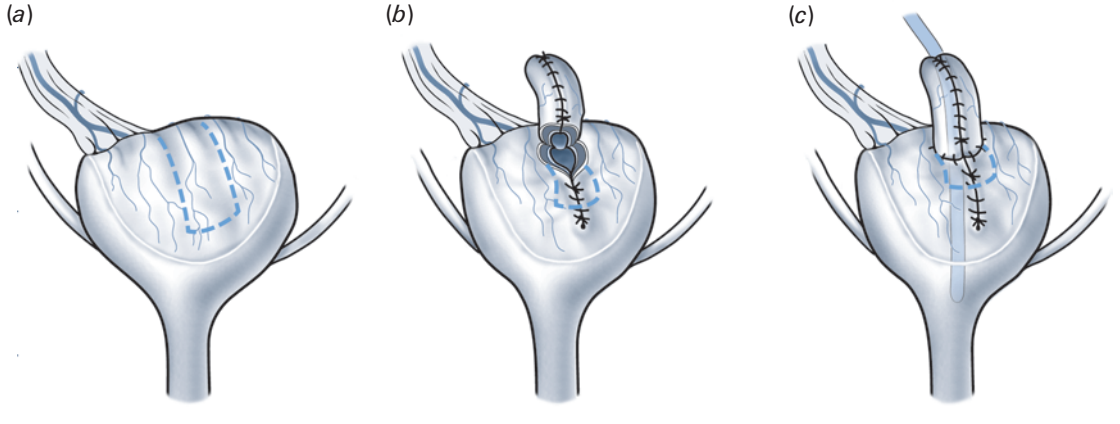

Figure 57.27 Gastroileal pouch with a Monti tube. (*a*) The flap to be tubularized is indicated on existing gastrocystoplasty. (*b*) The flap is raised and tubularized, and the bladder defect is closed. (*c*) Creation of a continent nipple valve by intussusception of gastric tissue as a cuff around the base of the gastric tube. (Reproduced from Close and Michell,[213] with permission.)

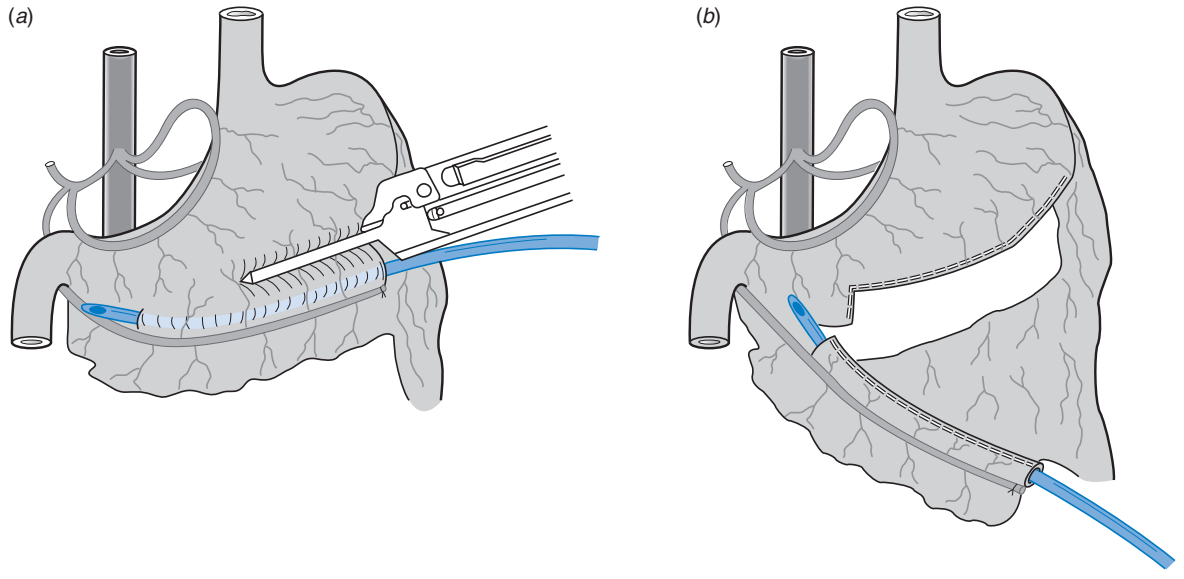

Figure 57.28 (*a*) An isolated gastric tube is harvested with a GIA-90 stapler over a 12 Fr catheter. (*b*) The mobilized isolated gastric tube is ready for placement into an augmented bladder or reservoir.

ating the colonic nipple in these two procedures makes them less attractive. The sigma rectum (Mainz pouch II) has been proposed from the group from Mainz as a means of lowering the very high pressures in the intact rectosigmoid colon without the need for nipples or augmentation[219] (Figures 57.28 and 57.29). Continence was achieved in 40 of 47 patients, with voiding five times per day, and extracolonic pressures remained low. The results in 34 patients of the Mainz II were reported by Gerharz et al.[220] All were continent during the day. One had night-time soiling and had creation of an ileal conduit due to recurrent septicemia. One ureteral obstruction led to a nephrectomy and two had mild hyperchloremic acidosis. Although lower pressures with the new procedures should reduce the risk for upper tract changes, the risk for adenocarcinoma still weighs heavily when contemplating any type of ureterocolonic diversion.

Postoperative care

In the early postoperative interval ureteral drainage is provided by stents, which are left indwelling for at least 1 week. Antibiotics are given until all tubes are removed. H_2 blockers are given temporarily if stomach is used. A large-bore silastic tube drains the reservoir for 3 weeks. The reservoirs are irrigated three times a day for the first 3 weeks and then slowly decreased to daily, for the rest of the patient's life. A pouch-o-gram is obtained before removal of the stents. The indwelling reservoir drainage tube is maintained until the patient and family demonstrate that they can easily catheterize the stoma and empty the reservoir. Demonstration of complete emptying is mandatory to prevent long-term problems of infection, stone formation, incontinence, and perforation, and to maintain stable renal function.

Renal and pouch sonography, abdominal radiographs, and serum creatinine and electrolytes are all obtained 3 months postoperatively, repeated at 6-month intervals, twice, and yearly thereafter. Vitamin B_{12} levels should be checked in the long term and somatic growth monitored. Endoscopic evaluation of the pouch should be carried out annually, starting 5–10 years postoperatively.

Summary

Tremendous advances have been made in lower urinary tract reconstruction in children. The entire urinary tract can now be completely replaced. Bladders can be constructed that are continent, ureters can be replaced with antireflux mechanisms easily achieved, and kidneys can be transplanted. Direct cutaneous diversion is generally only used as a temporary means to provide drainage. Non-continent diversion is only used in children who are incapable of independent care. It is ideal to maintain the native urinary tract intact, and reconstructive efforts should be directed to achieve this. If this cannot be achieved, a CUR should be provided. The limits of reconstruction are based

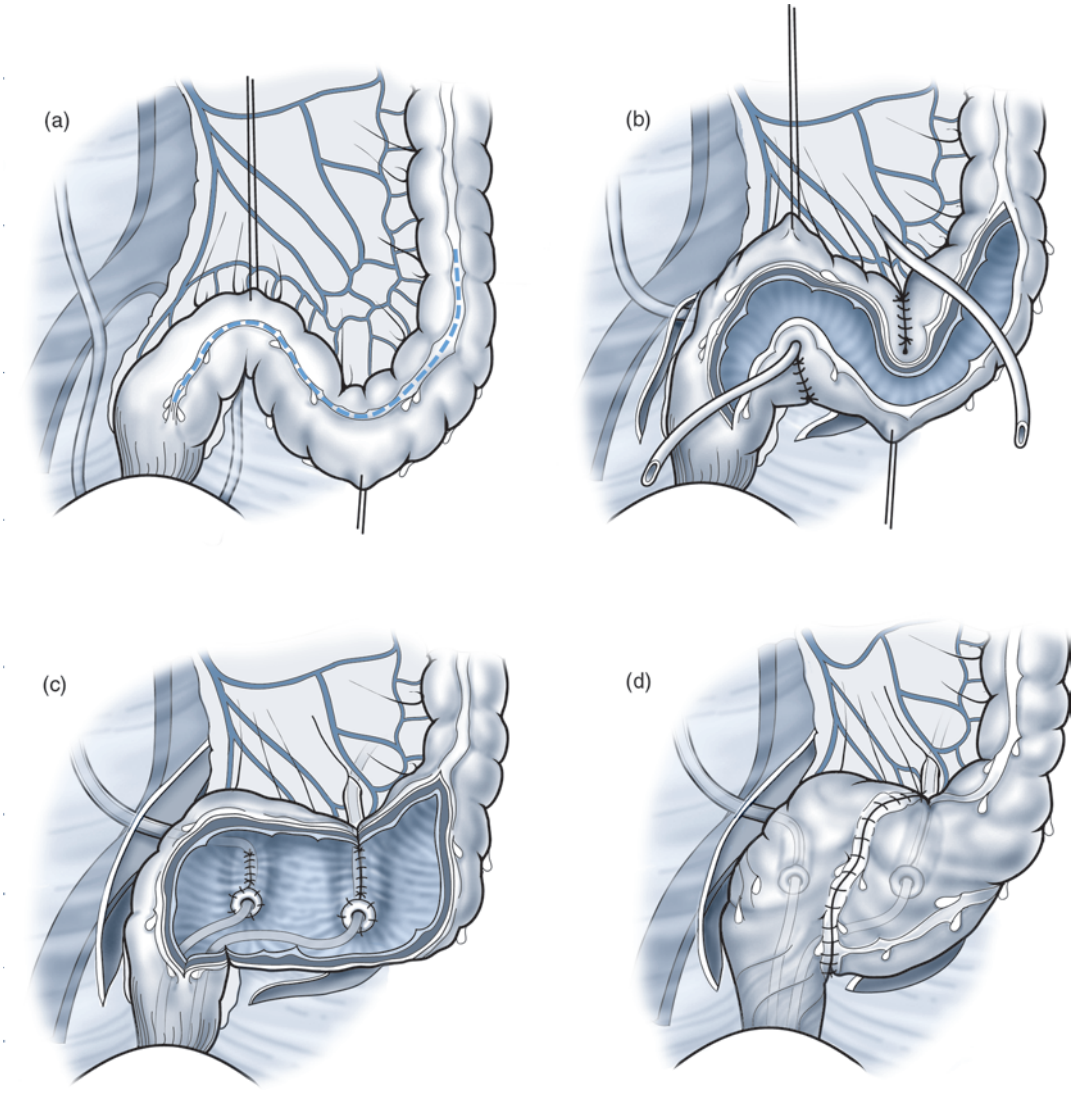

Figure 57.29 The Mainz pouch II (sigma rectum) has been presented as a means of reconstructing a low-pressure ureterosigmoidostomy.

only on the surgeon's imagination and skills. As long as the principles of CUR construction outlined in this chapter are met, a successful surgical result can almost always be achieved. True success, however, will always require the cooperation of a well-motivated child and equally motivated parents. Furthermore, this type of major reconstruction necessitates that the surgeon be surrounded by dedicated personnel who function as a team for the betterment of the health of these children.

The Malone antegrade continence enema (MACE)

58

Martin A Koyle and Padraig SJ Malone

Introduction

At first glance it may seem strange to devote a chapter in a textbook of pediatric urology to bowel care. However, congenital anomalies of the bowel and urinary tract frequently coexist, and constipation by itself may produce significant bladder dysfunction, leading to incontinence and urinary tract infection.[1] The pediatric urologist must be conversant with these bowel problems and play an active role in their management. Both systems should always be assessed simultaneously, and with present surgical techniques, it is the urologist who is often best placed to treat both urinary and fecal incontinence synchronously.[2]

The first antegrade continence enema (ACE) or Malone (MACE) procedure was performed in 1989, in an attempt to treat the intractable fecal incontinence associated with spina bifida. Koyle subsequently introduced the technique in North America in 1991.[3] Malone et al[4] reported that 53% of young adults with spina bifida suffered from fecal incontinence and similar results have been reported by Holschneider[5] in patients with anorectal anomalies, many of whom also had neuropathic bladder dysfunction.[6]

The MACE combined three well-recognized surgical principles that have been clearly described in many papers and in the previous (fourth) edition of this book, and will not be described in detail again here. The combination of these principles, applied to the colon, provided continent intermittent catheter access to the cecum or proximal colon for the administration of antegrade enemas while the patient sat on the toilet. This produced colonic emptying and fecal continence. The preliminary series was reported by Malone et al[7] and, subsequently numerous reports have been published so the procedure is now widely practiced around the world.[1,3,8–12] Many modifications have been introduced following the original description,[13] both to simplify the procedure and reduce the high complication rates initially reported.[8] This chapter reviews the techniques in current use, patient selection and preparation, the enema regimens, and the most recent results.

Patient selection and preparation

All conservative measures must be tried before resorting to the MACE. The underlying diagnosis is important, as it influences the success rate. In the Southampton experience, patients with a neuropathic bowel and anorectal malformation had a success rate of 73%, compared with 38% for patients with chronic idiopathic constipation.[14] The Colorado experience similarly showed that those whose primary bowel problem is constipation fare worse than those with other elimination problems. These results have been mirrored by the wider experience in the UK, where a success rate of 91% was also reported for patients with Hirschsprung's disease.[15] Recent personal communications from pediatric surgery colleagues suggest that the results for patients with chronic constipation have improved and a number of publications are in the pipeline. Kokoska et al[16] reported significant improvement in 91%, and continence in 64% of 11 children undergoing a MACE procedure for chronic constipation. The age at operation was also important. In Southampton there was a 70% failure rate for patients under 5 years of age compared with 24% for those aged over 5 years, a highly significant difference.[14] This was independent of the underlying diagnosis, and it probably reflected the inability of a child under 5 years of age to sit on a toilet for up to 1 hour before emptying is complete. Patient and caregiver motivation was vital in determining the success. A lack of

compliance to the washout regimen was a major contributory factor to failure in 9 patients in the early Southampton and Colorado experience. Detailed preoperative counseling and continued intensive postoperative support, ideally provided by a nurse practitioner, are essential to ensure adequate and continued motivation, without which the MACE is doomed to failure. It is an advantage to introduce the potential patient to a child and family with a functioning MACE prior to the surgical procedure.

In summary, the ideal patient for a MACE should be over 5 years of age, have a diagnosis of neuropathic bowel, an anorectal malformation or Hirschsprung's disease, be well motivated with a dedicated family, and have tried and failed all conservative measures first.

Operative technique

An aggressive preoperative bowel preparation is essential to facilitate the initial postoperative enema. A cleanout from below is often necessary, especially in the patient where constipation is the primary problem. Broad-spectrum prophylactic antibiotics that cover bowel bacteria are always administered perioperatively. In most instances, since coincidental urinary tract reconstruction is performed, a lower midline or Pfannenstiel incision is selected, depending upon the patient's body habitus, prior surgical scars, and preference. In the patient in whom a MACE only is indicated, without a urinary operation, a laparoscopic approach or an appendectomy incision can be employed.

It has been reported that it is not necessary to construct an antireflux mechanism, and some surgeons simply pull the appendix out to an abdominal stomal site. This may be done using a laparoscopic approach.[17] Both authors have attempted not using an antireflux mechanism on a number of occasions and, in some cases, the stoma was incontinent of flatus and/or stool, but in the majority the stoma was continent. It is recommended that an antireflux mechanism is constructed in open surgery, but this may be omitted to reduce technical difficulty if a laparoscopic approach is used. It is no longer necessary to disconnect the appendix from the cecum and reimplant it as one would for a continent appendicovesicostomy, as initially had been proposed by Malone. Rather, the in-situ appendix can be folded over with the cecal wall wrapped around it to produce the antireflux mechanism. This is an adaptation of the technique originally described for the Mainz pouch urinary reservoir.[12] This procedure is performed in slightly different ways by the two authors. Koyle simply wraps the cecal wall around the folded appendix using permanent sutures, similar to the technique for a Nissen fundoplication, On the other hand, Malone continues to produce a submucosal tunnel along one of the tenia and inlays the appendix into this, finally closing the seromuscular layer over it with absorbable sutures (Figure 58.1). Both authors recommend catching the serosa of the appendix wall with covering sutures in order to prevent it from pulling out of the tunnel. The mesentery of the appendix is fenestrated to prevent the wrap from compromising the blood supply to the appendix. Currently both these techniques are performing satisfactorily without significant long-term leakage. Once the antireflux mechanism has been constructed, the cecum or colon is sutured to the posterior aspect of the anterior abdominal wall to ensure that the conduit is not lying free in the peritoneal cavity, as this can lead to kinking and difficulties with catheterization. The technique needs to be modified if simultaneous MACE and appendicovesicostomy procedures are being performed. If the appendix is long enough and the vascular anatomy is suitable, it is possible to split the appendix, and both authors have done this successfully.

If the appendix is not suitable to split, or if it is absent, another technique must be instituted. The tubularized cecal or colonic flap[18] is no longer recommended because of the unacceptably high complication rates associated with this technique.[3] There are two options to using the appendix that are worthy of serious consideration. The first is the Monti procedure.[19] This is an ingenious technique where a segment of ileum is harvested on its pedicle and transversely detubularized on its antimesenteric border (see Chapter 55). The rectangular patch is tubularized along its longitudinal axis to create a catheterizable conduit of approximately 7 cm in length. The internal valvulae coniventes run in the longitudinal direction of the conduit, thus facilitating easy catheterization. Both ends of the conduit are free of mesentery and this makes the creation of the antireflux mechanism easy. When a Monti conduit is used, the Mitrofanoff flap valve principle is followed and a submucosal tunnel is created along one of the tenia, which is wrapped around it. This is similar to the original description of the MACE.[13] If the patient is obese, it is possible to use two segments of ileum or colon and produce a 14 cm conduit ('The Full Monti'), which is long enough for virtually all

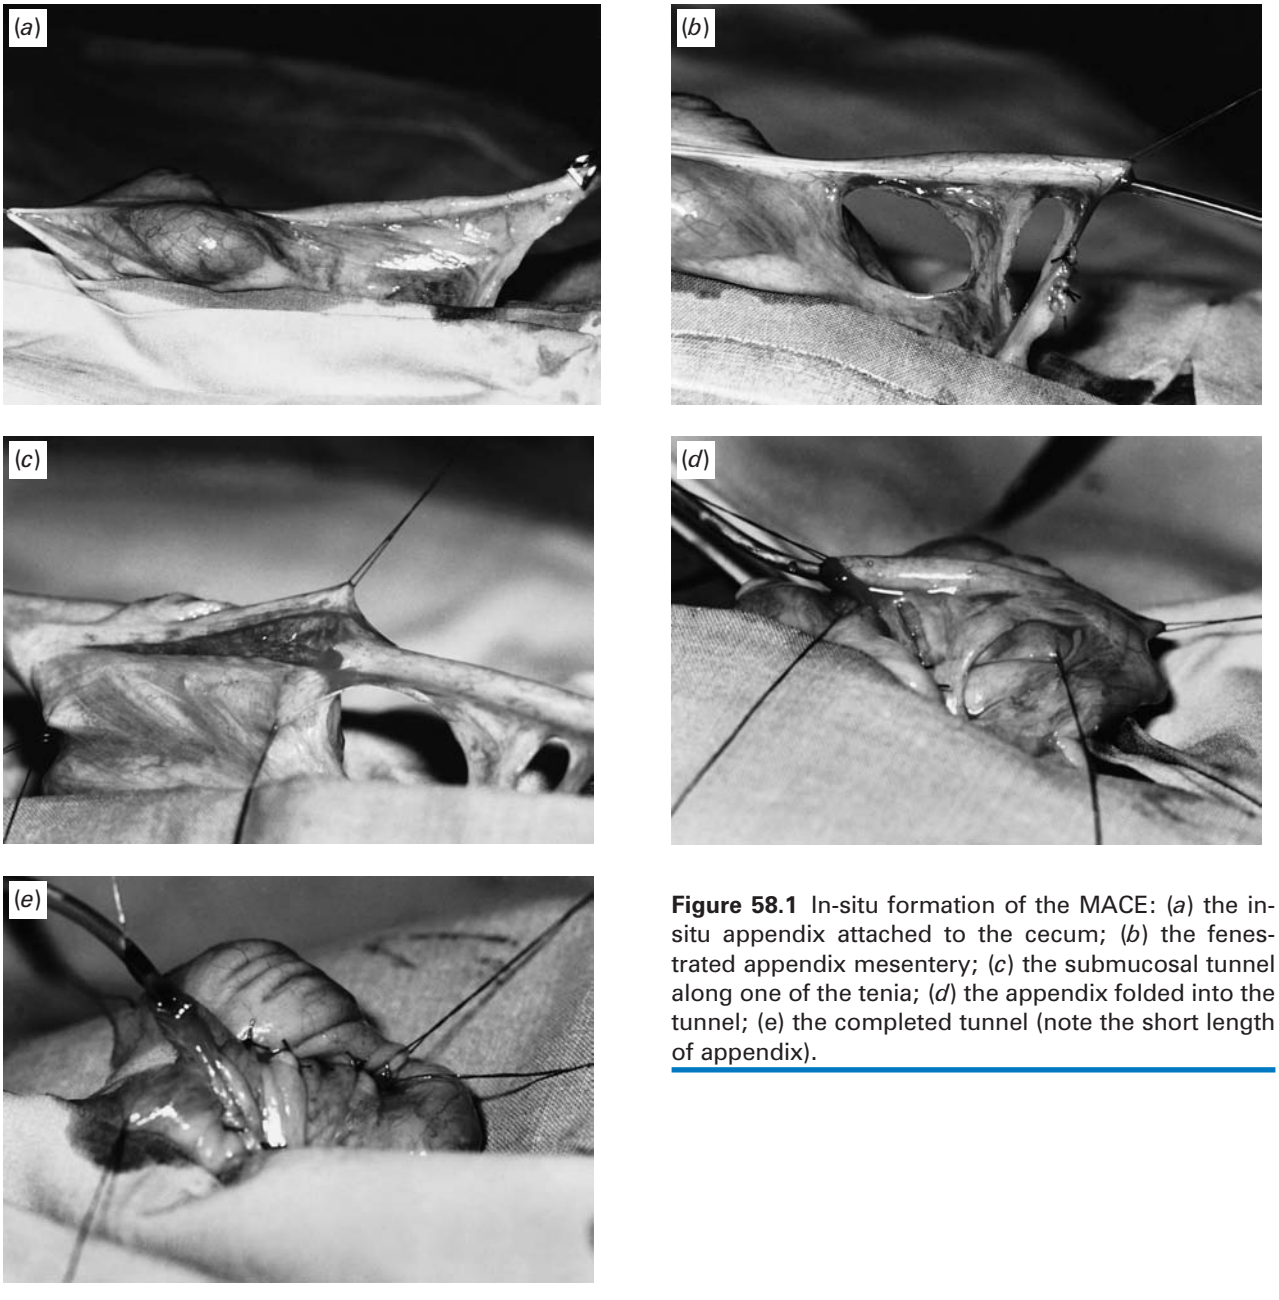

Figure 58.1 In-situ formation of the MACE: (*a*) the in-situ appendix attached to the cecum; (*b*) the fenestrated appendix mesentery; (*c*) the submucosal tunnel along one of the tenia; (*d*) the appendix folded into the tunnel; (e) the completed tunnel (note the short length of appendix).

patients. This is the procedure of choice when the appendix is not available.[20]

The other technique worthy of consideration is the use of a cecostomy tube and cecal button. Shandling et al[21] described a technique for the percutaneous placement of a cecal tube that could be changed at a later date to a low-profile cecal button (similar to a gastrostomy button), which is then used to administer the enema. A number of patients in both the Colorado and Southampton series manage their MACEs using a button, with results no different from those obtained using an appendiceal MACE (Figure 58.2). The indications for the button were:

- sloughing of cecal tubes formed when the appendix was absent,
- refusal by children/caretakers to catheterize their stomas, and thus the buttons are being used semi-permanently in these cases,
- patients who developed stomal stenosis on at least one occasion and the families have preferred the non-operative button option to that of repair under anesthesia.

Our greatest worry has been erosion or skin problems as the abdominal wall girth increases with age; hence, a close follow-up is mandatory The tubes are

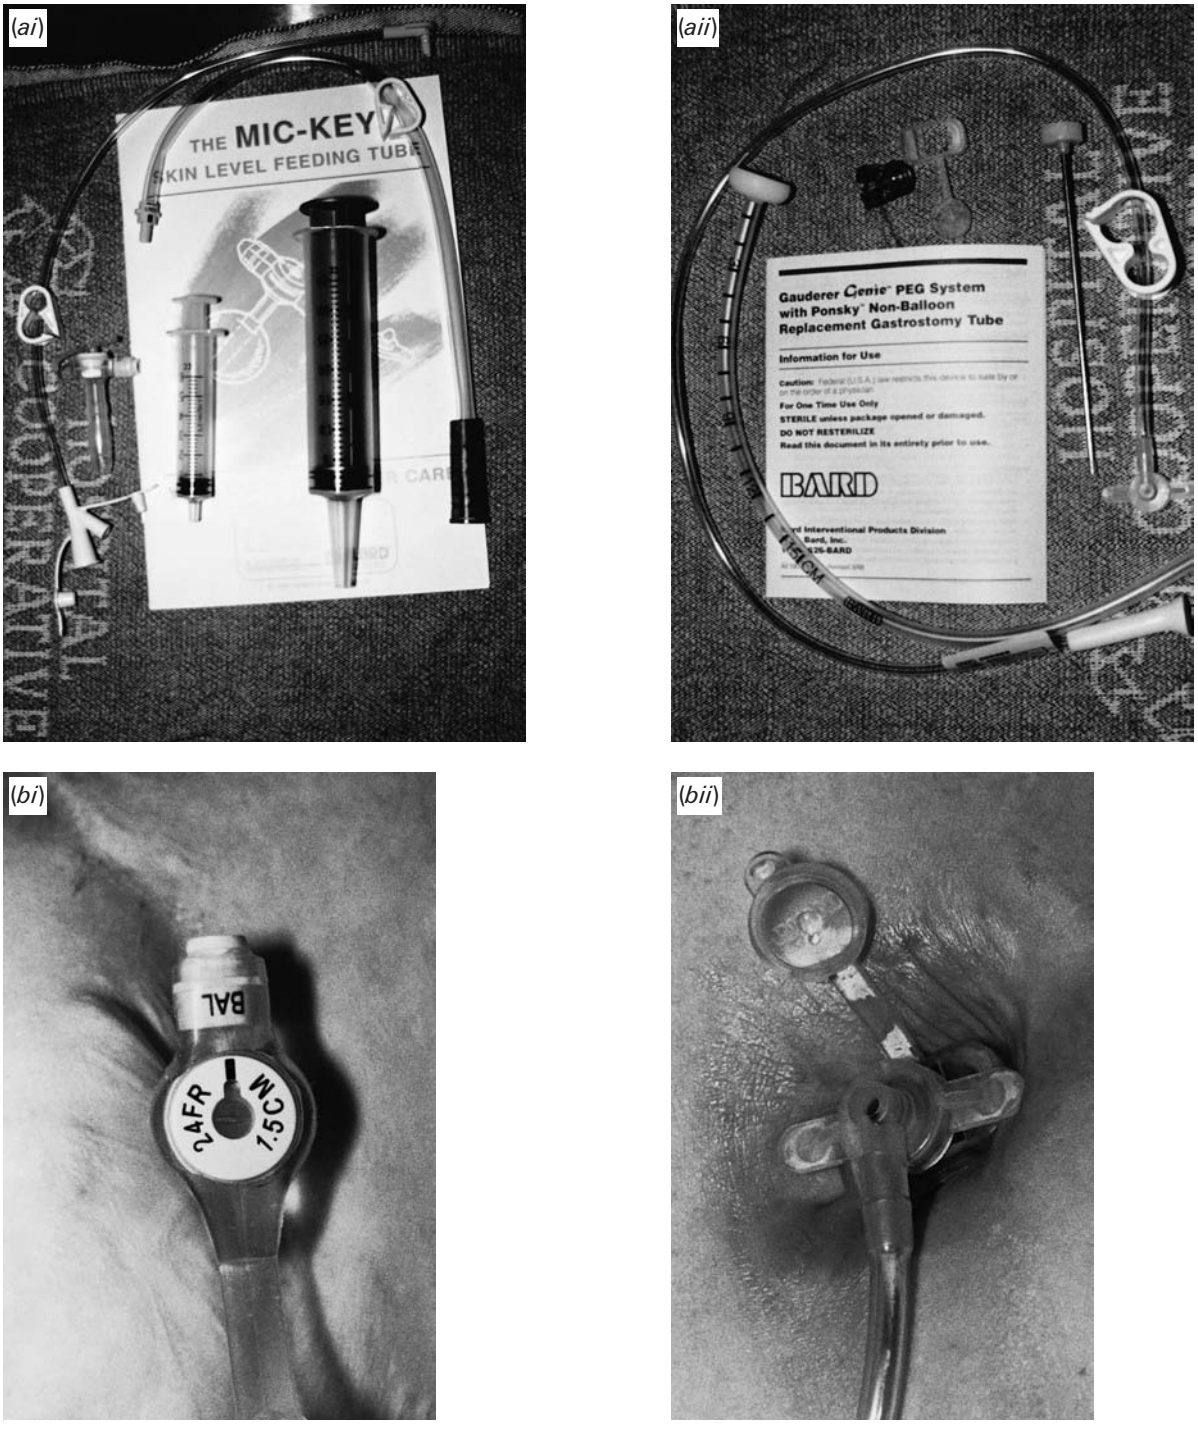

Figure 58.2 (*a*) (i) MIC-KEY (Ballard Corporation) and (ii) Genie (Bard) button kits. (*b*) (i) MIC-KEY button in right lower quadrant MACE stoma and, (ii) genie in umbilical stoma.

unsightly, and occasionally leakage around the tube will occur that leads to embarrassment. In a survey of 300 MACE procedures performed in the United Kingdom, 19 cecal buttons were used and they worked well in most cases.[15] Chait et al[22] placed buttons percutaneously under local anesthesia with good results. Fonkalsrud et al[23] placed Broviac silastic intravenous catheters rather than buttons, using an open technique. They reported successful results in a series of 24 patients. Longer follow-up is required before we could routinely advocate the button in place of an intestinal conduit.

One of the problems encountered in some patients with the MACE, particularly those with constipation, is the time it takes for the washout to work. This has led to failure and abandonment of the procedure in a number of patients.[9] In an attempt to overcome this problem, some surgeons have placed a Monti-MACE conduit in the left colon to reduce the length of bowel that has to be washed through and thus the time taken. Preliminary results with this approach are very encouraging, and in the Southampton series this has salvaged the procedure in five patients in whom an original cecal MACE failed.[24–26]

A left MACE should always be considered in patients with severe associated constipation. Recently, a new development embracing the principles of minimally invasive surgery and the left-sided MACE has occurred. Following bowel preparation, a colonoscopy is performed and with the scope in the distal descending colon, a colostomy tube is inserted, as one would insert a percutaneous endoscopic gastrostomy (PEG), the percutaneous endoscopic colostomy (PEC). Washouts can commence the next day, and, once the tract has matured, patients have a choice of either keeping the tube, exchanging it for a button, or having a formal conduit created. They have knowledge that the MACE will work, having had a trial of it via the PEC. Therefore, there are a number of different approaches to the MACE at the time of writing. If the patient requires a synchronous bladder reconstruction, a formal conduit is constructed using the in-situ appendix in the cecum or a left-sided Monti-MACE if constipation is a severe problem. If the MACE is all that is required, a laparoscopic MACE (LACE) would be the procedure of choice for cecal placement or a PEC if the patient is constipated and a left-sided placement is needed.

By adopting these newer techniques, complications such as incontinence of the conduit or difficulties catheterizing it are rare. Now, it is also easy to perform simultaneous MACE and Mitrofanoff urinary diversion, offering patients the chance of complete continence for the first time.[2,27]

The remaining aspect of operative technique is the construction and placement of the stoma. The commonest complication of the MACE in the earlier series from Southampton and Colorado was stomal stenosis. Curry et al[14] reported an incidence of 55% in the Southampton series, of whom 6/31 (19%), and 22% of the Colorado group, required surgical revision. In an attempt to reduce this stenosis rate, patients were advised to intubate the stoma twice a day, and this seemed to be reduce the problems with stenosis. The initial description of the MACE advocated a cutaneous V-flap, but both centers changed to using modifications of the Ransley VQZ-flap when the MACE was positioned in a location other than the umbilicus to try to reduce the incidence of stenosis still further. This has been shown to significantly reduce stomal problems in the Mitrofanoff procedure.[28] This method uses two separate skin flaps and can be constructed on the abdominal wall (Figure 58.3) or in the umbilicus (Figure 58.4). The conduit is left intubated for a period of 2 weeks (Southampton) to 4 weeks (Denver) postoperatively before intermittent catheterization is begun. McAndrew and Malone[29] reviewed the Southampton experience of all continent catheterizable conduits. They found no difference in the complication rates between the Mitrofanoff or MACE procedures: 97% of the conduits were continent and the stomal stenosis rate was 31%. There was no difference relating to the type of conduit or the site of the stoma. Stomal stenosis occurred in 41% of V-flap stomas and 25% of modified VQZ-flap stomas, and, although this did not reach a statistical level, there was certainly a trend in favor of this stoma. More recently Barqawi et al[30] reported the Colorado experience. They reported very similar results to Southampton, with a continence rate of 98% and a stomal stenosis rate of 18%.

In summary, these data suggest that the ideal MACE should use the in situ-appendix or the Monti conduit with an antireflux mechanism. A two-flap cutaneous stoma should be used, placed either on the abdominal wall or in the umbilicus.

The enema regimen

The first enema is given via the indwelling catheter when bowel activity returns, usually around the 3rd to 5th postoperative day. In those patients whose primary problem is constipation, it may be necessary to clean out the bowel from above and below initially, until an effective MACE regimen has been achieved. The time of day that the enema is administered is patient dependent. Most families prefer to give the enema during the early evening hours just after dinner. This time is chosen to allow a sufficient interval to achieve the desired result before bedtime.

Many enema regimens are used in the different centers performing the MACE, and patients frequently modify them to suit their own particular needs. One of the most important points is to advise patients not to expect immediate success. Each individual regimen

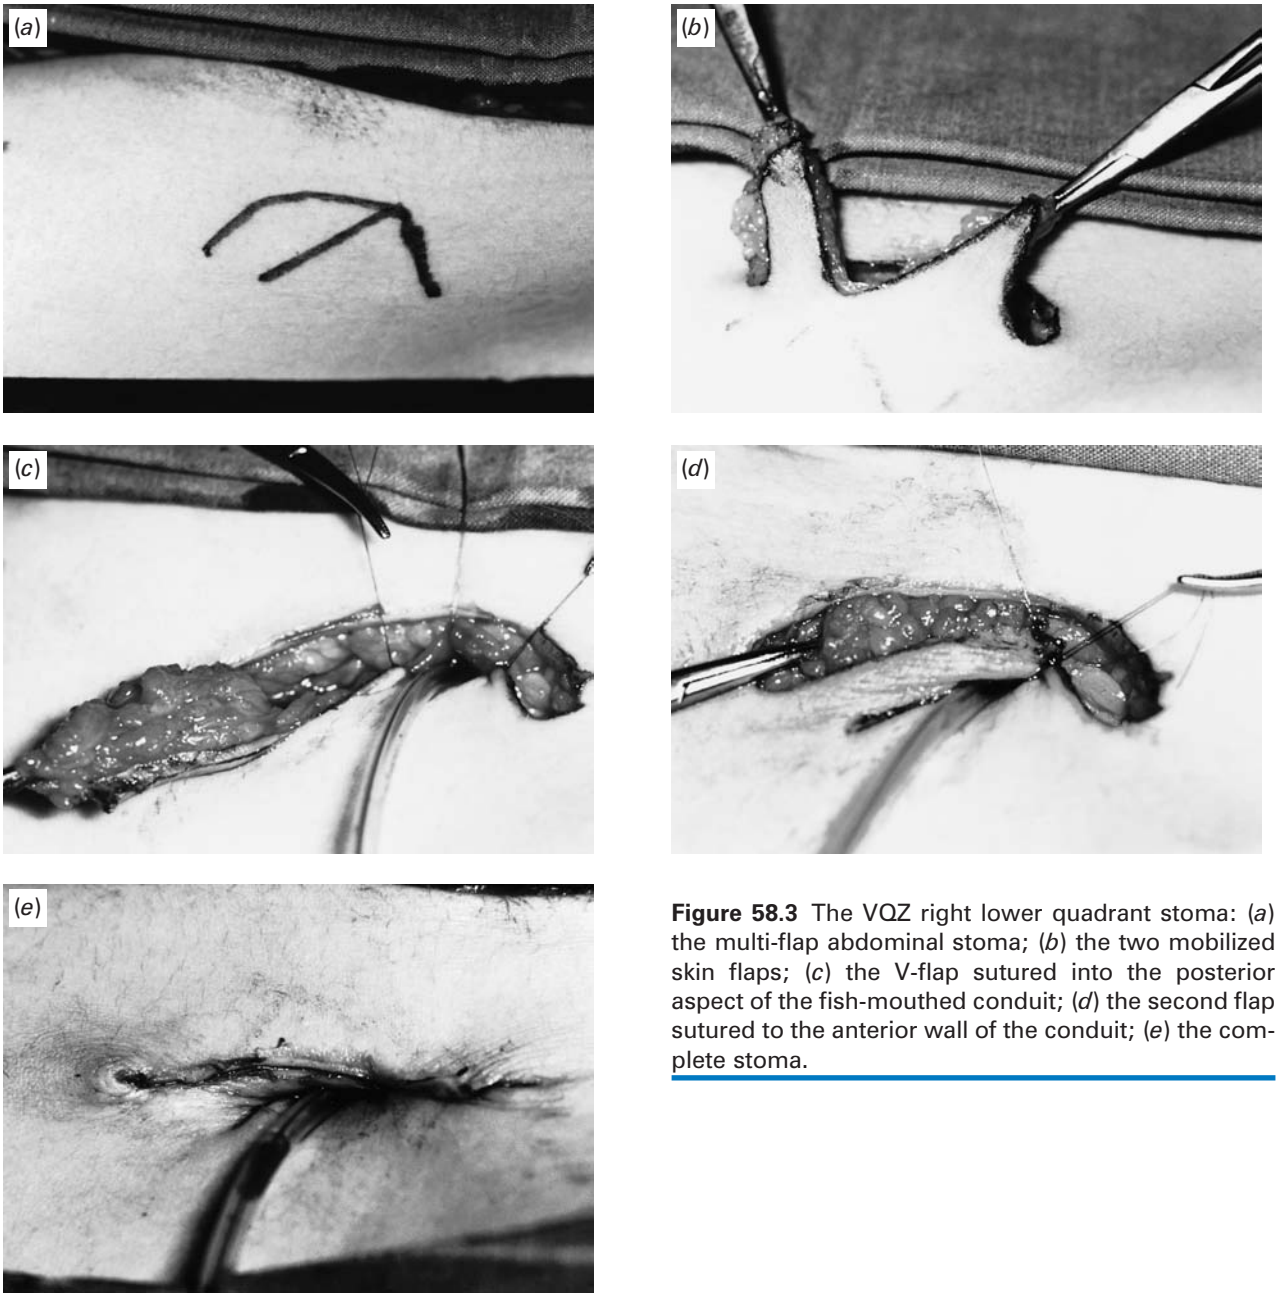

Figure 58.3 The VQZ right lower quadrant stoma: (*a*) the multi-flap abdominal stoma; (*b*) the two mobilized skin flaps; (*c*) the V-flap sutured into the posterior aspect of the fish-mouthed conduit; (*d*) the second flap sutured to the anterior wall of the conduit; (*e*) the complete stoma.

usually takes up to 1 month and is established by trial and error. In the Southampton series,[14] many children did not achieve a steady state or a successful MACE for periods of up to 6 months. It is necessary to counsel patients about this preoperatively, as early disappointment can lead to complete failure. Many patients experience a degree of rectal leakage within the first few hours of the washout, but this is rarely a major problem. While the washout regimen is being established, it is vital to maintain regular contact with the nurse specialist. Initially, daily washouts are recommended, but once the patients are comfortable with the procedure, they may attempt to decrease the frequency to alternate days. Once a steady state has been achieved, there is no benefit from interfering with the regimen. In the Southampton and Colorado series, the mean time taken to perform the washout was 39 minutes (range 20–60 minutes) and 34 (11–68 minutes), respectively. It is essential that patients and caregivers are aware of the time commitment that is required and are prepared to devote this time to bowel care, because if they do not, the MACE will fail. Because patients have to sit on the toilet for a long time, one of the complications encountered is

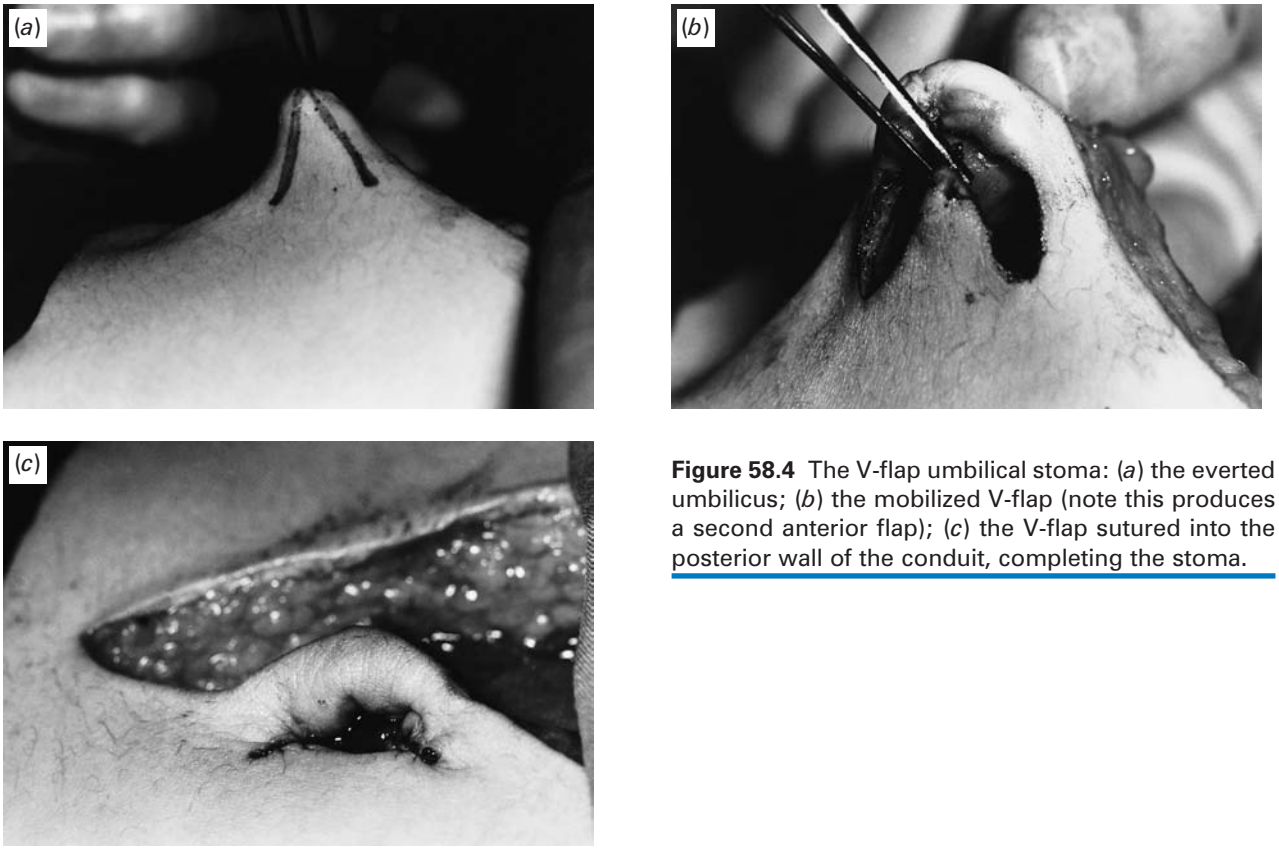

Figure 58.4 The V-flap umbilical stoma: (*a*) the everted umbilicus; (*b*) the mobilized V-flap (note this produces a second anterior flap); (*c*) the V-flap sutured into the posterior wall of the conduit, completing the stoma.

pressure sores on the buttocks. It is possible to obtain padded toilet seat covers and their use is recommended, particularly for the neuropathic patient with reduced or absent sensation.

The enema given differs from center to center, with most centers in the UK favoring the use of a stimulant, whereas those in the United States use mainly saline or tap water. In Southampton, the common regimen uses a phosphate enema (Fletchers' phosphate enema, Pharmax, UK). Initially, 50 ml of enema solution is made up to 100 ml with tap water (this has replaced the saline initially used), and this is rapidly instilled, followed by approximately 500 ml of water. Depending on the response, adjustments are made to the strength and volume of the phosphate, up to a maximum of 100 ml of undiluted phosphate enema. Although a few patients achieve successful results with the phosphate alone, the majority require the additional water lavage. Care must be taken when using phosphate, and the dose will need to be adjusted depending on the age of the child. If the enema does not produce a result, a second one should not be given, as phosphate toxicity may occur if it is retained, and this is a potentially life-threatening complication.[31] Three patients in the Southampton series have experienced phosphate toxicity. If the enema does not produce an immediate result, patients should be advised to wait 1 hour and then perform a further water lavage. If that is unsuccessful, they should be admitted to a hospital for a retrograde enema and observation. However, care must be taken, irrespective of the agent, used, as there are anecdotal reports of deaths occurring when too much salt was added to tap water. In Colorado, tap or salt water is instituted at 50 ml/day and increased by doubling the volume every 3 days until reliable evacuation occurs. If there is no success after reaching 500–600 ml, alternatives are sought, including mineral oil, Go-LYTELY, or Fleet's enema through the MACE, or altering the frequency of the enema.

Several difficulties have been experienced during establishment of the MACE. The most common problem has been pain during the enema, which occurred in 58% of patients in the Southampton series.[14] In the majority of patients, the pain subsided during the first 3 months, but it persisted and was a major contributory cause to the failure of the MACE in three patients. Strategies for the reduction of pain include lowering the concentration of the phosphate, reducing the rate of the infusion, using an antispasmodic prior

to the enema (Colovac, Solvary, UK), or changing the enema agent to a licorice root solution, which produces less peristalsis than the phosphate. Three inches (7.5 cm) of licorice root or 5 ml of commercially available licorice granules are microwaved with 100 ml of saline until the mixture boils. It is allowed to cool to room temperature and then diluted with a further 200 ml of saline prior to administration. It is also possible to vary the concentration of the licorice, depending on the response and whether the patient experiences pain. Many patients in the UK are now successfully using this regimen and it seems to produce much less pain. It is also possible to use many of the other laxatives, such as bisacodyl or docusate sodium, by instilling them directly into the colon via the MACE. In North America, where balanced fluids are used primarily, pain has been less of a problem. Usually, reducing the volume of infusate or the route of administration alleviates the problem.

Despite regular washouts, some patients get constipated and this produces pain and washout failure. Under these circumstances, a Fletchers' arachis oil retention enema (Pharmax, UK) instilled 12 hours before the washout was recommended, but because of possible peanut allergy this has now been replaced by mineral oil. In Southampton, saline enemas by themselves have been tried, but this seems to lengthen the time taken to achieve a successful washout and the authors continue to recommend a stimulant such as phosphate or licorice.

One of the problems encountered with the MACE is the time taken for the enema to pass and achieve a result, over 1 hour in some cases. In the Southampton series,[14] the commonest cause of failure was the inability to pass the enema, which occurred in 9/12 (75%) cases that failed. In Colorado, if passage time has been greater than 45 minutes, compliance and hence success has also been reduced. The constipated, as opposed to the incontinent group, clearly constitutes the majority of these patients. It is in these patients that the left-sided MACE is to be recommended, preferably commencing with a trial of the PEC tube as described above.[24,25] Liloku et al[25] described six patients with a left Monti-MACE, with a washout time of 10–30 minutes, with five being clean. Churchill et al[26] reported 18 patients with a left-sided MACE, with a mean washout time of 18 ± 12 minutes and an 83% continence rate.

In summary, many different enema regimens exist, but they are all established in the individual patient by a process of trial and error and may take up to 6 months to stabilize. The frequency of the enema should not be less than alternate days, and patients should be prepared to spend up to 1 hour on each enema.

Results

The results of the MACE have been classified as follows:[14]

- Full success: totally clean or minor rectal leakage on the night of the washout.
- Partial success: clean but significant rectal leakage, occasional major leak, still wearing protection, but perceived by the parent or child to be an improvement.
- Failure: regular soiling or constipation persisted, no perceived improvement, and the procedure was abandoned, usually to a colostomy.

Curry et al[14] reported on 31 patients with a mean follow-up of over 3 years. The MACE failed in 12/31 (39%) patients, and this included five of the eight patients treated for chronic idiopathic constipation and the one patient with Hirschsprung's disease. When patients with neuropathic bowel and anorectal malformation were analyzed separately, partial and full success rates were 75% and 70%, respectively. Curry and Malone[15] reported on a survey of MACEs performed by members of the British Association of Paediatric Surgeons (BAPS), in which 300 cases were identified and the success rates were dependent on the original diagnosis (Table 58.1).

The overall success rate, including full and partial success, for this large national series was 69%. It is also interesting to note that complication rates were lower than in earlier historical series. In particular, the stomal stenosis rate was down to 30%.

Shankar et al[32] assessed the results of 40 patients who had an ACE more objectively by using a quality

Table 58.1 The MACE: success and failure based on original diagnosis

Diagnosis	Full success (%)	Partial success (%)	Failure (%)
Spina bifida	63	21	16
Anorectal	72	17	11
Hirschsprung's disease	82	9	9
Constipation	52	10	38
Other	44	25	31

of life improvement (QOLI) score. A score of 5 denoted a perfect result, and the mean score for all patients was 3.5. They found the score to be significantly lower in wheelchair-dependent patients with spinal dysraphism (2.5) than in all other mobile patients (4). More recently, Aksnes et al[33] reported important improvements in self-esteem and psychosocial function in 20 patients with myelomeningocele 6 months after a MACE procedure. By using these objective measurements, the MACE has been shown to be successful.

Finally, it is valuable to assess those patients undergoing synchronous bladder reconstruction and MACE procedures. Wedderburn et al[2] reported fecal and urinary continence in 76% of 46 patients undergoing synchronous procedures but the rate of revision surgery was high. Kajbafzadeh and Chubak[34] reported similarly good results for synchronous surgery, with all of their 40 patients being clean and dry and an overall 7.5% complication rate.

Conclusions

Despite the relatively high complication rates, the MACE offers almost 80% of patients with neuropathic bowel and anorectal malformation a chance to be clean. When successful, it transforms patients' lives, and it does not interfere with the final option of a colostomy should that become necessary. No patient should undergo lower urinary tract reconstruction without a complete bowel assessment, and if necessary, a simultaneous MACE should be carried out. A simultaneous procedure does not jeopardise the success of either individual component and double continence rates range from 76 to 100%. The reconstructive urologist is the best person to manage the bowel, as the operative techniques involved are those routinely employed in lower urinary reconstruction. Furthermore, the infrastructure should be in place for meticulous follow-up. This combined approach should enhance the quality of life for these unfortunate patients.

Minimally invasive approaches to lower urinary tract reconstruction

59

Christina Kim and Steven G Docimo

Introduction

In the past 30 years, minimally invasive surgery in pediatric urology has evolved from simple diagnostic procedures to a method for performing complex reconstructive surgery. The goals of laparoscopy are to maintain the principles of open procedures while minimizing morbidity for the patient. This chapter discusses the indications, techniques, and outcomes for minimally invasive lower urinary tract reconstruction.

Principles of bladder reconstruction

Pediatric bladder reconstruction is commonly indicated for patients with neurogenic or non-neurogenic voiding dysfunction associated with high pressures or low volume. In order to protect the upper tracts from damage, and to enhance or enable urinary continence, surgery is sometimes necessary to enlarge the bladder and lower the filling pressures. In addition, surgery is sometimes necessary to enhance outlet resistance and provide for methods of emptying.

Bladder enlargement may be achieved with or without the use of bowel segments. If a bowel segment is needed, it is detubularized and reconfigured to minimize internal contractions and maximize volume.[1,2] When the circular muscle fibers are divided in a longitudinal fashion, the source for the strongest generation of contractions is stopped.[3] Theoretically, detubularization doubles the volume of the original segment. Although studies have shown the detubularized segments ultimately retain some internal contractions, detubularization is the best method available to decrease its frequency and strength.[4]

Emptying the bladder regularly will reduce the risk of infections and protect renal function. Emptying may be through voiding or may require intermittent catheterization. Catheterization may be achieved through the native urethra or a constructed Mitrofanoff or Monti continent stoma.[5] If bladder outlet resistance is low, this can be treated with bladder neck reconstruction, insertion of an artificial sphincter, placement of a periurethral sling, or bladder neck closure.

Benefits of laparoscopic reconstruction

By creating a continent system, bladder reconstruction allows the patient more independence and better quality of life. Traditionally, the only way to access appendix, small bowel, stomach, colon, as well as other pelvic organs was by making a long midline incision.[6,7] Laparoscopic assistance allows the same access and manipulation through 5 mm ports and a lower midline or Pfannenstiel incision.

The number of visible scars has been shown to inversely correlate with pediatric patients' level of happiness and satisfaction.[8] In addition, scars associated with reconstructive surgery have been associated with lower self-esteem and poor body image.[9] It is reasonable to consider that these associations and outcomes are even greater in the pediatric and adolescent populations. Not only surgical scars but also the appearance of stomas can have an impact. The development of a concealed umbilical stoma is a major step towards improving body image,[10] as well as decreasing the likelihood of stomal stenosis.[11]

Laparoscopy is associated with decreased morbidity and improved cosmesis. The outcomes in pediatrics have mirrored the outcomes in adults. The use of laparoscopy has been associated with lower narcotic requirements, shorter hospital stays, and quicker return to normal activities. In addition, and perhaps

more important to long-term health, it has been shown that fewer adhesions develop after laparoscopic surgery compared with open surgery.[12–14]

Most minimally invasive bladder reconstruction falls into one of three categories: laparoscopic autoaugmentation, laparoscopic enterocystoplasty, and laparoscopic-assisted bladder reconstruction. This chapter reviews the principles, techniques, and outcomes of these surgeries.

Indications and contraindications

The primary indications for bladder reconstruction in children are to improve bladder filling pressures, improve urinary continence, or reduce the incidence of urinary tract infections. Candidates usually have reduced bladder capacity, poor bladder compliance, and/or uninhibited detrusor contractions. Current options for bladder expansion include autoaugmentation, ureterocystoplasty, and enterocystoplasty.

As with open reconstruction, some contraindications for laparoscopic bladder reconstruction are uncorrected coagulopathy, poor patient compliance, or the patient's inability to perform clean intermittent catheterization. Relative contraindications for laparoscopic bladder reconstruction are short gut syndrome, severe inflammatory disease of the bowel or bladder (e.g. inflammatory bowel disease, bacterial cystitis), multiple open abdominal procedures, or prior radiation therapy with significant intra-abdominal adhesions.

Neither a history of previous abdominal surgery nor the use of peritoneal dialysis are contraindications for laparoscopic bladder reconstruction. In addition, it is safe to perform laparoscopic surgery in patients with an existing ventriculoperitoneal shunt.[15]

Preoperative evaluation

Preoperative evaluation is similar to screening for open bladder reconstruction. All patients undergo complete urodynamic evaluation to assess bladder capacity, bladder compliance, and Valsalva leak point pressure. In addition, patients undergo a voiding cystourethrogram to assess for vesicoureteral reflux. In children with hydronephrosis, concominant ureteropelvic or ureterovesical junction obstruction must also be ruled out. Existing renal function is assessed with a measurement of serum creatinine level and possibly a nuclear renal scan.

Patients must be prepared to perform clean intermittent catheterization. This may be done through a new catheterizable stoma, a newly reconstructed bladder neck, or through the native urethra. It is not uncommon to require that the patient and family comply with a preoperative routine of regular catheterizations which may be over a few weeks or even a few months.

Other considerations include the possible need for bowel continence mechanisms. If a Malone antegrade continence enema (MACE) is needed, it should be accomplished at the same time.[16]

Laparoscopic bladder autoaugmentation

The concept of bladder autoaugmentation was first described in 1989 as an alternative method of increasing capacity.[17] Since then, laparoscopic bladder autoaugmentation (LBAA) has been described through a transperitoneal and extraperitoneal approach.

Transperitoneal approach

The first transperitoneal laparoscopic bladder augmentation in a child was described in 1993. This was a case report of an 8-year-old boy who underwent an LBAA in 75 minutes. His initial outcomes looked favorable.[18]

In 1998, a case series in children was reported by Braren and Bishop.[19] Seven children had a laparoscopic autoaugmentation performed. Age range was 7–15 years old (with a mean age of 10 years 8 months). These were approached through the peritoneal cavity.

A 5 mm trocar was placed at the umbilicus. This can be done with either an open or a needle approach. Two 5 mm working ports were placed in the left and right lower quadrants. Using direct visualization, both ports were placed lateral to the inferior epigastric vessels (Figure 59.1).

The peritoneum overlying the bladder was divided. An elliptical incision is used to wedge out a segment of detrusor muscle while leaving the mucosa intact (Figure 59.2). Using an endoshears or harmonic scapel, a plane was created between the detrusor muscle and mucosa. The bladder was filled with normal saline to assess the size of the created diverticulum and to assess for any leakage.

Operative time ranged from 55 to 93 minutes. Two

patients sustained a bladder perforation that was repaired at the time of autoaugmentation. Postoperatively, patients had a Foley catheter in place between 48 hours and 1 week. No patient required reinsertion of the Foley catheter or intermittent catherization. No patient went into retention. The majority of patients were sent home the same day of the procedure.

Patients were followed between 10 months and 4 years. Bladder capacity increased from 55 to 95% of the original volume. Six patients achieved complete dryness. Time needed to achieve dryness varied from immediate to 6 weeks postoperatively. The average time to dryness was 3.5 weeks. The one patient with incomplete dryness did improve from several accidents per day to twice a week. Patients who achieved complete dryness were weaned off their anticholinergic medications. In addition, they were taken off their antibiotic suppression 1 month postoperatively.[19]

Cost analysis showed no significant difference between laparoscopic and open bladder autoaugmentation. Although it was not objectively measured, the return to normal activities was quicker for the laparoscopic group.

Extraperitoneal approach

Only one case of a preperitoneal laparoscopic bladder autoaugmentation has been reported. This was performed in a 26-year-old female.

To begin, cystoscopy was performed and ureteral catheters were placed bilaterally. The patient was placed supine with both legs abducted. A skin and fascial incision was made in the midline between the pubic symphysis and umbilicus. Dissection was started under the anterior fascia and along the posterior pubic symphysis. The dissection was continued with a homemade balloon dilator.

A laparoscopic port was then placed through this incision and a 30° scope was used through that port. A 12 mm port was placed on the lateral aspect of the rectus abdominis muscle along the same horizontal plane as the camera port. Also along the same horizontal plane, a 5 mm port was placed on the lateral border of the right rectus abdominis muscle. Another 5 mm port was placed along the lateral border of the rectus abdominis muscle and approximately 2 cm above the symphysis pubis. The 12 mm size is needed for a laparoscopic clip applier.

Dissection of the bladder from its anterior surrounding fatty tissue was accomplished with electrocautery. Dissection was carried laterally and along the dome. A balloon catheter filled the bladder during the dissection of the detrusor muscle and mucosa. Detrusor flaps were freed laterally so they could reach Cooper's ligament, where each side was tacked down with interrupted sutures.

The operation lasted 6.5 hours and had an estimated blood loss of 75 ml. The patient was discharged on postoperative day 2 with both catheters and ureteral stents in place. One catheter was left in place for 1 month before no leakage was confirmed on cystogram. Initially, the patient required intermittent self-catheterization and later voided by Valsalva technique every 3 hours. At 9-week and 6-month follow-up, the patient was dry in the day and night.[20]

Laser laparoscopic bladder autoaugmentation

Delayed bladder rupture after bladder autoaugmentation has been reported. One theory was that using a different energy source, such as a laser, would cause less thermal injury to the mucosa. It was hypothesized that electrocautery may cause a spark gap injury that may contribute to mucosal necrosis.

This technique was first described in a canine model. Using a transperitoneal approach, nine canines underwent a midline bladder seromyotomy. Initial follow-up urodynamics at 6 weeks showed a 45% increase in bladder capacity and a 67% increase in bladder compliance. However, the follow-up at 3 months was less impressive. Compared with the starting baseline, there was a 5.3% increase in bladder capacity and a 13.9% increase in compliance. Although the technique was easily feasible in canines, neither of these later results was statistically significant.[21]

Poppas et al then described a similar technique used in two pediatric patients. Both patients underwent a mechanical bowel preparation in preparation for a possible open enterocystoplasty if any difficulty with laparoscopy was encountered. Both patients had ventriculoperitoneal shunts and had intraoperative pressures measured continuously. Using an open technique, a 10 mm laparoscopic port was placed in an infraumbilical incision and 5 mm working ports were placed in the upper quadrants (one in the right and two in the left). A 532 nm potassium titanyl phosphete (KTP) laser was used through a 600 μm fiber. This was done through a 5 mm port. The laser was used to incise the peritoneum overlying the bladder. The detrusor muscle was then mobilized bluntly and the mucosa was easily visualized secondary to instilled methylene blue.

Each procedure lasted approximately 90 minutes. No intraoperative mucosal perforations occurred. Both patients began intermittent catheterization on postoperative day 1 and both patients were discharged on postoperative day 2. Initial results were favorable, with no leakage and decreased detrusor peak pressure. However, at 4-month follow-up, there was urinary leakage between catheterizations and detrusor pressures >40 cmH_2O. Ultimately, both patients underwent enterocystoplasty. At the time of that procedure, there was a thickened covering over the area of autoaugmentation. Pathology revealed mucosa with chronic inflammation but no muscular tissue.[22]

Although autoaugmentation is an ideal procedure for adaptation to a minimally invasive approach, long-term results have, in general, not been favorable. Nonetheless, this technique can be considered when the main goal is either improved compliance or decreased uninhibited contractions in a patient who already has adequate volume.

Laparoscopic enterocystoplasty

Enterocystoplasty remains a commonly used technique for increasing bladder capacity. Classically, this is performed through an open laparotomy. First described in a canine model in 1888, it was then demonstrated in a clinical report in 1899.[23] As time has progressed, modifications have been made to improve operative technique and postoperative outcomes.

In the past 10 years we have seen the introduction of laparoscopy to assist in enterocystoplasty. The initial attempts at a purely laparoscopic technique were hampered by long operative times and limited clinical outcomes.

Laparoscopic gastric augmentation

The first laparoscopic enterocystoplasty in an adult or child was a gastrocystoplasty that took place in 1994.[10] To begin, three 12 mm ports were placed. The camera port was placed through a supraumbilical incision. Two working ports were placed near the level of the umbilicus in the anterior axillary line. This access allowed manipulation within the pelvis as well as the upper abdomen (Figure 59.3).

The dissection began by separating the bladder from the anterior abdominal wall. This dissection was taken caudally to the level of the urethra. Next, the greater omentum was separated and the right epiploic vessels were divided from the greater curvature. This division was performed using small clips close to the wall of the stomach

A fourth 12 mm port was placed in the mid-epigastrium close to the pubic tubercle. A series of firings of a gastrointestinal stapler (Endo-GIA stapler, US Surgical Corporation, Norwalk, Connecticut) were used to resect a segment of the stomach (Figure 59.4). A 20 cm segment of stomach was isolated for the augmentation. This segment accounted for approximately one-third of the surface area of the stomach. The staple line of the stomach was oversewn with a 3–0 Vicryl suture in a running fashion. The bladder was then

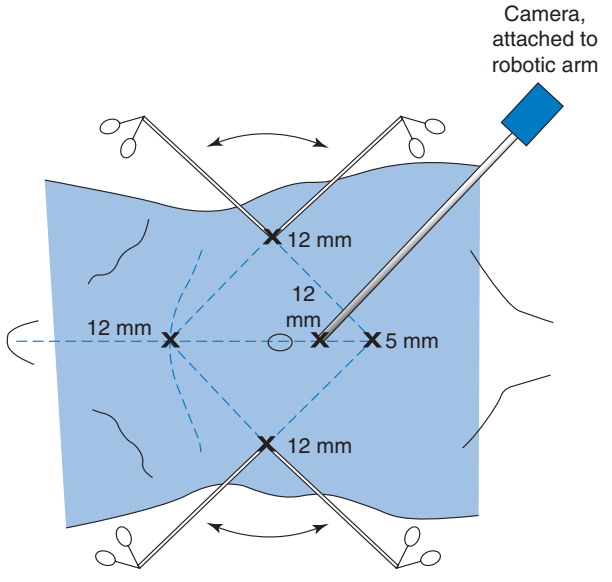

Figure 59.3 A camera is placed through the umbilicus. Two working ports are placed along the anterior axillary line. Positioning the working ports near the height of the umbilicus allows access into the upper abdomen and low in the pelvis. (Reproduced from Docimo et al,[24] with permission.)

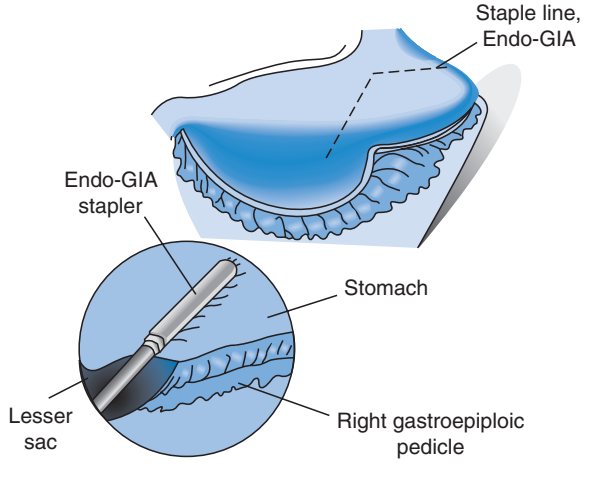

Figure 59.4 The gastric segment is isolated using multiple firing of an Endo-GIA stapler. (Reproduced from Docimo et al,[24] with permission.)

opened to the level of the urethra. The isolated gastric segment was sewn to the open bladder after the staple line had been removed: this was started posteriorly and then moved anteriorly. Similar to the gastric segment, the anastomosis of the augmentation was completed with a 3–0 Vicryl suture in a running fashion. To assist in the anastomosis, an Endo Stitch autosuturing device (Auto Suture Company, Norwalk, Connecticut) was used (see Figure 59.4.)

Due to incompetent bladder resistance, a modified Gittes bladder neck suspension was also performed. With the laparoscopic view, the bladder neck was visualized as it was suspended behind the posterior pubis. At the end of the procedure, a suprapubic catheter and an extravesical suction drain were placed. Operative time was close to 11 hours with no intraoperative complications.

Postoperatively, the patient was tolerating regular food on postoperative day 4. An external drain was required for 13 days until a urine leak sealed over. Because of social concerns, the patient was not discharged until the drain was removed. However, at the time of discharge, the patient resumed normal activities.

The early outcomes from this case report were favorable. The bladder capacity doubled from 150 ml to 315 ml. The patient was dry on intermittent catheterization every 4 hours.[10]

Laparoscopic ileal augmentation

There are limited reports of ileal enterocystoplasty using a completely laparoscopic approach. Meng et al[25] described this technique in a 31-year-old paraplegic female: five laparoscopic ports were used in a transperitoneal fashion. A gastrointestinal anastomotic stapler was used to divide the ileal segment and restore bowel continuity (Figure 59.5). The mesentery was incised using ultrasonic coagulating shears (Ethicon, Cincinnati, Ohio). Electrocautery was used to remove the stapled ends of the isolated segment and to open the segment on its antimesenteric side.

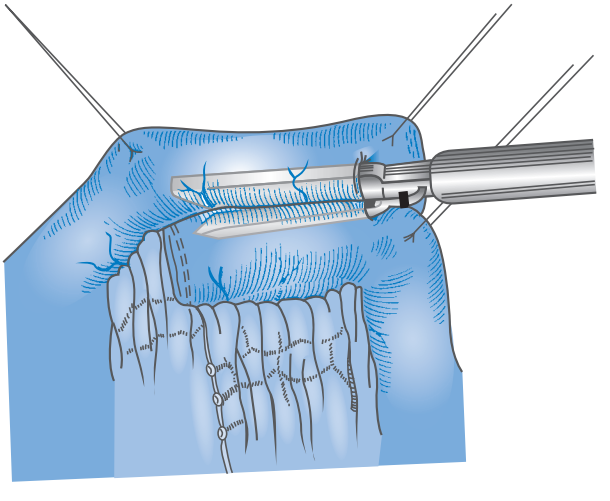

Figure 59.5 A gastrointestinal stapler can be used to divide the bowel segment. In addition, it may be used to perform the enteroenterostomy. (Reproduced from Elliott et al,[26] with permission.)

Running 3–0 polyglactin sutures were used to configure the bowel into a U-shape and to suture it to the opened bladder. At the end of the anastomosis, the bladder was irrigated and noted to have a watertight closure.

The operative time was 9 hours and there were no intraoperative complications. Estimated blood loss was 100 ml. Postoperatively, the patient had a urethral catheter and an external Blake drain. On postoperative day 3, the patient resumed oral intake and had the Blake drain removed. Initial results showed an increase in bladder capacity from 85 ml to 400 ml. The bowel was returned to the peritoneum and ports replaced to re-establish a pneumoperitoneum.[25]

Although cases have been reported, the published outcomes are limited. A patient who had undergone the same procedure had follow-up at 8 months and had a bladder capacity of 550 ml and was continent in between catheterizations. But again, long-term outcome data are limited.[26]

Small case series have been reported of laparoscopic enterocystoplasty using a combination of intracorporeal and extracorporeal techniques. The bowel segment used included ileum, sigmoid colon, and proximal colon.[27,28]

Technique

A transperitoneal approach is used with four laparoscopic ports: a 12 mm port at the umbilicus, two working ports (5 or 12 mm) at the lateral edge of the rectus muscle at the level of the umbilicus, and a 5 mm port at the left anterior superior iliac spine (Figure 59.6). If sigmoid colon is used, an additional 10 mm port may be placed medial to the right anterior superior iliac spine.

The isolated bowel segment has to reach the bladder neck without tension and have a definitive arterial arcade in its mesentery. A laparoscopic camera is used to highlight the vasculature within the mesentery and 5 mm laparoscopic bowel clamps are placed accordingly. The umbilical port is widened 2 cm, both circumferentially and inferiorly in the midline. The chosen segment is delivered outside of the abdomen. A total of 15–20 cm of bowel is needed. Using standard open methods, the segment is divided and the mesentery is closed (Figures 59.7 and 59.8). The bowel continuity is restored, keeping the isolated segment inferior to the mesentery of the remaining bowel. To minimize edema, the bowel segment is placed back into the peritoneum before continuing further manipulation.

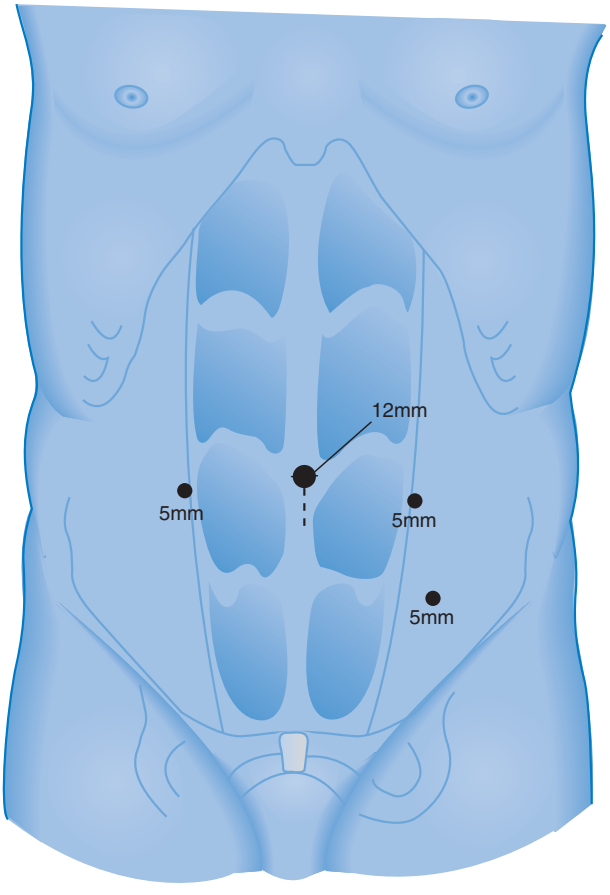

Figure 59.6 Laparoscopic enterocystoplasty port placement: a 12 mm port at the umbilicus, a 5 mm port next to the anterior superior iliac spine, and two 5 mm ports on the lateral edge of the rectus muscle at the level of the umbilicus. (Reproduced from Gill et al,[28] with permission.)

The isolated bowel segment is divided on its antimesenteric side and irrigated with saline. Small bowel and sigmoid are refashioned in a U-shape using 2–0 Vicryl in a side-to-side fashion (see Figure 59.8). If a catheterizable stoma is created, the terminal ileum is narrowed over a 16 Fr red rubber catheter using a gastrointestinal stapler (Endo-GIA stapler). This red rubber catheter is secured to the terminal end of ileum, which assists in intracorporeal manipulation and delivery to the umbilicus. The bowel is returned to the peritoneum and ports replaced to re-establish a pneumoperitoneum.

To facilitate the enterovesical anastomosis, the bladder is filled with saline and the patient placed in the Trendelenburg position. The peritoneum is incised from the medial border of the left medial umbilical ligament to the right medial umbilical ligament. A large cystotomy is created by making a curvi-

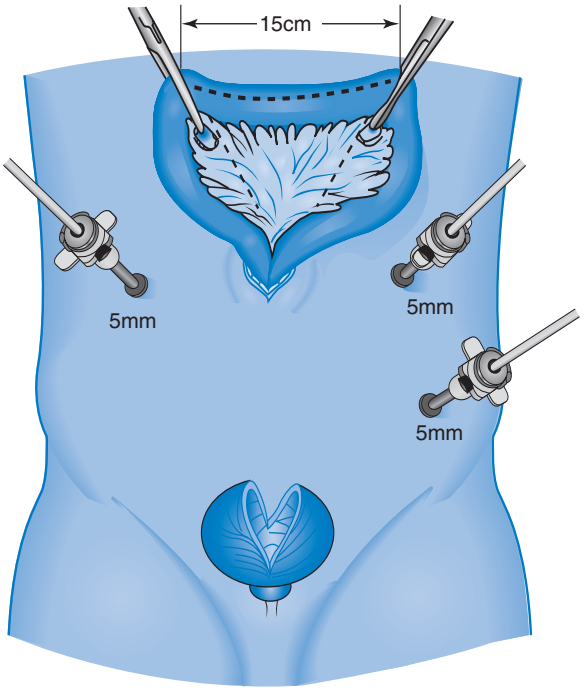

Figure 59.7 The umbilical incision is extended 2 cm circumferentially and inferiorly. Through this incision, the isolated bowel segment is delivered for resection and reanastomosis. (Reproduced from Gill et al,[28] with permission.)

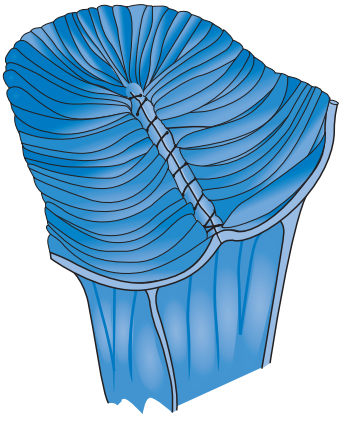

Figure 59.8 The bowel segment is refashioned in a U-shape before performing the anastomosis. (Reproduced from Rackley and Abdelmalak,[27] with permission.)

linear incision, which allows maximal disruption of the detrusor muscle (Figure 59.9). The anastomosis to the bladder starts posteriorly because starting at the anterior can inhibit visualization for the remaining anastomosis. A 5 mm laparoscopic needle driver is used to perform freehand intracorporeal suturing and knot tying. An assistant follows with a 5 mm grasper.

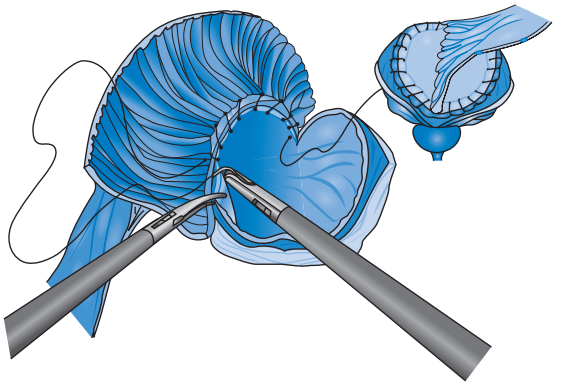

Figure 59.9 The enterovesical anastomosis is performed using a laparoscopic needle driver. Starting posteriorly, a continuous, full-thickness suture is used. (Reproduced from Gill et al,[28] with permission.)

An Endo Stitch device is used to facilitate this step (see Figure 59.9).

If a catheterizable stoma is required, the right colon and terminal ileum are utilized. These segments can be isolated after incising the peritoneum laterally and then mobilizing the segments through an extending umbilical incision. In order to manipulate the laparoscopic equipment in the lower ports, it is important that the patient be positioned in low lithotomy.[27]

Results

In the series by Gill et al, all patients had two Jackson–Pratt (JP) drains left in place. These were placed through the pre-existing port sites. Operating time ranged from 5.3 to 8 hours. Intracorporeal suturing took between 1.7 and 2.1 hours. Patients were discharged between postoperative days 2 and 5. A urethral catheter was left in place for 1 month and removed after a cystogram confirmed no leakage.[28]

The series by Rackley et al had an average operative time of 7 hours. Average time for laparoscopic suturing was 2.4 hours. The average blood loss was 175 ml. The majority of patients resumed oral intake 24 hours postoperatively. The average date of discharge was 5.7 days. The only complication noted was a rectus sheath hematoma secondary to port placement. This was recognized and corrected laparoscopically.[27]

Laparoscopic-assisted bladder reconstruction

The current state of the art in minimally invasive reconstruction is the laparoscopic-assisted approach.

The biggest concerns with a purely laparoscopic approach are the technical challenges of bowel manipulation, irrigation, and anastomosis. This can be intricate and time consuming. In addition to time, reconstructive urologists are concerned about the technical ability to match the outcomes of open procedures. The goal of laparoscopic-assisted surgery is to combine the morbidity and cosmetic benefits of laparoscopy with the technical precision of open reconstruction.[29]

By using laparoscopy, the required bowel segments can be isolated and mobilized quickly with small access ports. Once the bowel segment is freed, ureter or stomach harvested, and omentum mobilized, the more precise aspects of the surgery can be performed through a small lower abdominal incision. If a bladder augmentation is planned without any bladder neck reconstruction, ureteral reimplantation, or continent stoma, this can often be done simply with a lower abdominal incision and no laparoscopy is required.

The biggest benefit of laparoscopy is the ability to quickly mobilize the necessary bowel segments without the upper aspect of a large abdominal incision. Many of the pediatric patients requiring bladder reconstruction have an underlying neurologic disorder such as myelomeningocele. These patients often have an abnormally rotated cecum and appendix with position in the right upper quadrant.[30] Although challenging to reach through a lower abdominal incision, the high cecum can easily be reached with laparoscopy. In addition, patients with spina bifida may have severe lordosis, which can inhibit the mobilization of the cecum.[31] In addition, laparoscopy can easily allow lysis of adhesions that may have developed because of prior surgeries or long-term ventriculoperitoneal shunts. The presence of a shunt is not a contraindication to laparoscopic surgery.[15]

Once the needed segments are harvested, a lower midline or Pfannenstiel incision is used to mobilize the bladder and bladder neck and to assemble the anastomosis. The lower abdominal incision may incorporate one of the lower abdominal ports as well (Figure 59.10).

The technique allows similar dissection to the open technique, with smaller incisions and lower morbidity.[10,32]

Using laparoscopic assistance to create an appendicovesicostomy was first described in 1993.[32] Since that time, there have been other reports of successful laparoscopic bladder reconstructions with creation of continent stomas.[29,31,33,34] The only large reported series is from Docimo and colleagues.[33]

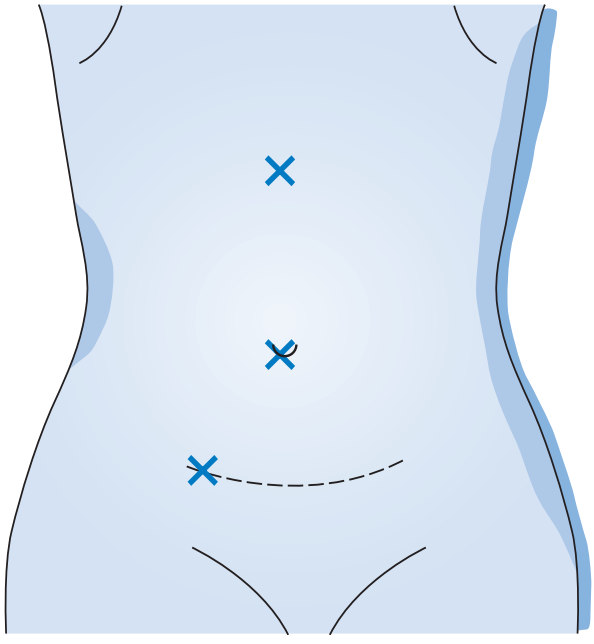

Figure 59.10 After harvesting the necessary bowel segments, the lower working port can be incorporated into a Pfannenstiel incision. (Reproduced from Hedican et al,[29] with permission.)

Technique

Preoperatively, the patient undergoes a mechanical and antibiotic bowel preparation. Intraoperatively, the patient is positioned in low lithotomy to perform a cystoscopy. If there is no active cystitis, the patient is repositioned supine. If a concominant nephrectomy or ureterocystoplasty is anticipated, the patient may be positioned in a modified flank position. The patient is padded with foam and gel pads to protect any pressure points. In addition, the patient is secured to the table to allow repositioning with steep Trendelenburg and lateral rotation as needed.

Intravenous antibiotics are given to cover Gram-positive and Gram-negative bacteria. After induction of general anesthesia, a nasogastric tube is placed. If possible, an epidural catheter is also placed.

The first step is to obtain peritoneal access. If a concealed umbilical stoma is anticipated, a U-shaped flap is created on the lower umbilicus.[11] For the purposes of achieving a straight stoma, the fascia inferior to the umbilicus is opened and the peritoneum entered under direct vision. A radially dilating trocar sleeve is inserted into the peritoneum, and dilated using the trocar insert. This should be 10 or 12 mm in size to allow easy passage of the stomal segment without creating too large a defect, which would risk parastomal herniation.

Figure 59.11 After incorporating the lower port into a Pfannenstiel incision, the visible scars are minimized. Here the umbilical port site was used for the continent stoma and the lower port healed within the Pfannenstiel scar. (Reproduced from Chung et al,[33] with permission.)

Figure 59.12 The majority of bowel manipulation can be done through a lower midline or Pfannenstiel incision. (Reproduced from Chung et al,[33] with permission.)

Placement of the working ports depends on the type of repair planned and the bowel segments needed. Most commonly, two working ports are used. A 3 or 5 mm epigastric port is placed between the umbilicus and the xyphoid. An additional port in the lower abdomen can be of variable size because it will be incorporated into the abdominal incision (Figure 59.11). If an additional stoma is created (i.e. ACE), another U-shaped incision is made in the right lower quadrant and a 10 mm port placed at this site.

Laparoscopy is for bowel manipulation, lysis of adhesions, performing nephrectomies, harvesting ureter, and harvesting omentum.

If appendix is needed, the right colon is mobilized until the appendix can reach the lower abdominal incision. Through the open incision, the appendix can be divided from the cecum. An alternative is to isolate and divide the appendix using an Endo-GIA stapler. If this approach is chosen, care must be taken to avoid disruption of the mesoappendix (Figure 59.12). If laparoscopic examination reveals an appendix in the deep pelvis, easily accessed through a Pfannenstiel incision, further laparoscopic dissection is not necessary.

After the laparoscopic portion of the procedure is completed, a 4–5 cm Pfannenstiel incision is made. This can incorporate the lower working port (see Figure 59.12). To minimize bowel manipulation, the peritoneum is left intact and any bladder work is completed first. This may include bladder neck division or reconstruction, ureteral reimplantation, and cystolitholapaxy. The next step is opening the bladder, implanting the continent stomal segment, and creating the anastomosis to the augment. All stomas are matured to the skin and any redundancy is addressed to allow easy catheterization. The bladder stoma is spatulated dorsally and then secured to the U-shaped flap. This helps conceal the stoma and reduce the chance of stenosis. The entry site of the stoma to the bladder is secured to the anterior abdominal wall to decrease the likelihood of eventual tortuosity and difficulty with catheterization.

Postoperatively, most patients are left with a nasogastric tube, suprapubic tube, and a 10 Fr stomal catheter. Drains are rarely used. The stomal catheter is secured to the skin with the balloon deflated to avoid excess tension on the continence mechanism.

Results

Laparoscopic-assisted bladder reconstruction allows patients to resume a normal diet faster and leave the hospital earlier. These outcomes exist without an increase in operative time or perioperative complications.[29,35]

The only large series of minimally invasive bladder reconstruction is the Pittsburgh series reported by the Docimo group in 2004. This series consisted of 31 patients with a mean age of 14 years: 29 of 31 patients had at least one stoma created; 10 patients had both a Mitrofanoff and an ACE stoma created;

19 patients had additional procedures performed (e.g. fascial sling, bladder neck reconstruction, revision of epispadias, ureteral reimplantation, and revision of orchidopexy).

Mean hospital stay was 6 days. Mean follow-up was 32 months. Of all stomas, 94.9% were continent of either urine or stool and easy to catheterize. Improved compliance and capacity were maintained at last follow-up. There were no late bowel obstructions or other sequelae of problematic adhesion formation. Stomal stenosis occurred in 5.1% of patients, 7.7% required stomal revision secondary to incontinence or difficulty with catheterization, and minor procedures were required in 25.6% of stomas.

Complications occurred in five patients, including ileus, partial small bowel obstruction, delayed bladder perforation, deep vein thrombosis, and wound infection.[33]

Conclusions

Minimally invasive bladder reconstruction has become our standard approach. The outcomes match or exceed those of open operations with recovery and cosmetic benefits. Long-term benefits of decreased intra-abdominal adhesions will be hard to measure, but may be the most important reason to continue to pursue these techniques. Further advances may allow purely laparoscopic techniques to achieve a more prominent role, but complex reconstruction will probably remain too time consuming for the near future. The ability of reconstructive surgeons to achieve consistent results depends on the precision of reconstructive techniques. Perhaps robotics and other advances will eventually allow performance of even complex operations with equivalent outcomes. For now, laparoscopic-assisted reconstruction is the only minimally invasive technique with well-documented outcomes, and should be considered the state of the art. One thing that is certain: in this era, there is no need for a large abdominal incision in the majority of children who require bladder reconstruction.

Genitourinary rhabdomyosarcoma and other bladder tumors

60

Paul A Merguerian, Lisa Cartwright, and Antoine E Khoury

Introduction

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma in children under 15 years of age. After neuroblastoma and Wilms' tumor, it is the third most common childhood extracranial solid tumor, and accounts for 60%[1] of all childhood sarcomas and 10–15% of all solid pediatric tumors. Approximately 25% of these tumors arise from the genitourinary (GU) tract and another 10% from pelvic or retroperitoneal sites.[2–4] Nearly 75% of genitourinary RMS cases are diagnosed before the age of 5 years, with a 3.3:1 male predominance. Since its discovery by Weber in 1854, the clinical and pathologic features of RMS have been studied extensively, thus permitting the development of uniform diagnostic criteria and prognostically relevant staging systems.[5]

RMS is by definition a sarcoma showing evidence of skeletal muscle differentiation and can occur in sites where skeletal muscle is not found, suggesting that it is a tumor of primitive mesenchymal skeletal muscle differentiation.[6] RMS has two large peaks of incidence: the first, which accounts for more than 50% of cases, occurs in the first decade and is mainly embryonal (ERMS) or botryoid RMS (BRMS); the second, which occurs during adolescence, consists of alveolar RMS (ARMS).[7]

The histopathologic variants of RMS (embryonal, botryoid, and alveolar) pursue different biologic courses. ERMS tends to occur in the head and neck and GU system and the majority of patients survive beyond 5 years. ARMS is often seen in the extremities and metastasizes early with only a small number of patients surviving beyond 5 years.[8]

The cure rate for patients with RMS has improved significantly over the past 25 years, from an estimated 25% in 1970 to 70% in 1995.[6,9,10] This improvement is credited to the use of increasingly effective multimodal, risk-adapted therapy, refinement in tumor grouping, better diagnostic imaging, and better supportive care. Emerging information on the numerical and structural abnormalities of tumor cell chromosomes and the development of probes that can be used to identify molecular genetic lesions has led to improved diagnostic methods and has afforded new insights into the pathogenesis of this tumor. Knowledge of the genetic features of these tumors will significantly improve the ability to identify patients at lower or higher risk of treatment failure, thus paving the way for advances in risk-based therapy.

Epidemiology

RMS may be associated with congenital anomalies, including the central nervous system, and, most frequently, the GU system. Interestingly, patients with RMS are noted to have fewer musculoskeletal anomalies.[1]

Neurofibromatosis is the most common syndrome in which RMS has been described. From the patients enrolled in the Intergroup Rhabdomyosarcoma Study IV (IRS IV), the incidence of neurofibromatosis was 0.5%. Of the five patients with neurofibromatosis three had relapses, two of whom died of progressive disease. Because of this finding, it is recommended that patients with neurofibromatosis and rhabdomyosarcoma be treated with intensive contemporary therapy protocols.[11] Costello syndrome is associated with an increased risk of solid tumors, the most common of which is RMS. Gripp et al recommended a screening protocol of abdominal/pelvic ultrasound every 3–6 months for up to 8–10 years for RMS and neuroblastoma.[12] Other congenital syndromes in which RMS is seen are Gorlin's basal cell nevus syndrome, Rubinstein–Taybi syndrome, trisomy 21 syndrome, Beckwith–Wiedemann syndrome (BWS), fetal alcohol syndrome, and Li–Fraumeni

syndrome. Whereas Wilms' tumor is the most common malignancy associated with BWS, in the first 7 years of life RMS, adrenocortical carcinoma and hepatoblastoma may be seen.

Li–Fraumeni syndrome is associated with a known *p53* mutation with autosomal dominant transmission. These patients are predisposed to multiple tumors, which often retain a normal *p53* allele, suggesting an alternate additional tumorgenic mechanism is involved in *p53* inactivation. Malkin et al evaluated two patients with multiple tumors in the presence of Li-Fraumeni syndrome who had a heterozygous germline *p53* mutation and found that they both were heterozygous for *p53* mutation, and tumors that they developed, which maintained *p53* heterozygosity, were noted on immunostaining to contain the DNA tumor virus SV40. The authors postulate that *p53* inactivation by viral proteins may contribute to tumor formation in these genetically susceptible patients.[13–15] Some concern has been raised for an increased risk of breast cancer in the mothers of children with soft tissue sarcomas; however, this has not been demonstrated by the International Rhabdomyosarcoma Study Groups (IRSG).[1]

Environmental factors associated with RMS include ionizing radiation and alklyating agents. The increased risk of secondary malignancies in those patients with neurofibromatosis and Li–Fraumeni syndromes after treatment with alkylating agents and radiation therapy for RMS draws a link between the likely dual causation of malignancy by genetics and environment. It is therefore desirable to limit the use of alkylating agents and radiotherapy in these particular populations.[1]

Molecular and cellular biology

Somatically acquired genetic changes underlie all forms of cancer; however, until recently, the genetic characteristics of RMS were largely unknown. With improved cytogenetic techniques, it is now clear that the chromosomes of this tumor contain both numerical and structural abnormalities.[16–18] Recent advances in the molecular and cell biology of RMS have helped in understanding the pathogenesis of this tumor and will aid in its diagnosis, staging, and management.

RMS appears to develop from a derangement in the final steps of myogenic differentiation. Genes of the *MyoD* family are crucial in the early differentiation of skeletal muscle precursors.[19,20] These genes express DNA-binding proteins that facilitate the production of myogenic proteins such as desmin, creatine kinase, and myosin. *MyoD* expression is higher in rhabdomyosarcoma cells. Activation of p38 MAP kinase, which is required for muscle differentiation, is absent in RMS cells.[21] Failing to differentiate completely, the rhabdomyosarcoma cells continue to produce forms of actin seen only transiently in normal-developing skeletal muscle cells.[22] *MyoD1*, a recently described myogenic regulatory protein, maps on chromosome 11p15.4 and is expressed during skeletal muscle development. Steroid receptor coactivator SRC-2 is necessary for skeletal muscle differentiation. RMS cell lines have demonstrated aberrant transcription factor SRC localization and expression.[23]

Myogenin is a myogenic regulatory protein whose expression determines differentiation of primitive mesenchymal cells into skeletal muscle. It is regulated by pathways involving p38, calcium–calmodulin-dependent protein kinase (CaMK), or calcineurin, and its expression may be down-regulated with terminal differentiation. The activation of myogenin by CaMK and calcineurin pathways fails in RMS cell lines.[24] Myf5 is an additional transcription factor which is useful in differentiating RMS from other sarcomas.[1]

MAGE, *BAGE*, and *GAGE* are active genes expressed in RMS which encode tumor-associated antigens and may have therapeutic potential in tumor immunotherapy.[25] The MDM2 protein binds p53 (tumor suppressor) and deactivates it. It may be seen frequently in RMS but not ERMS, and its splice variants are present in up to 82% of RMS tumors.[26–28] MDM2 increased resistance to vincristine, etoposide and doxorubicin, but not cisplatin in RMS cell lines.[29]

ARMS may be distinguished from ERMS and other tumors on the basis of structural abnormalities. Cytogenetic analysis of ARMS tumors revealed a translocation involving chromosomes 2 and 13, t(2;13)(q35;q14) in 70–80% of cases (Figure 60.1).[30–33] There have also been several reports of a

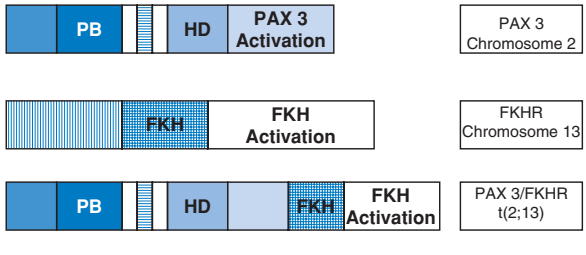

Figure 60.1 Structure of PAX3 on chromosome 2, the fork head in rhabdomyosarcoma (FKHR) on chromosome 13, and the fusion product PAX–FKHR of the t(2;13) in alveolar rhabdomyosarcoma. PB = paired box; HD = homeodomain.

t(1;13)(p36;q14) variant translocation,[32,34,35] and single reports of cases with other related alterations.[32,35,36] The t(2;13) and t(1;13) translocations have not been associated with any other tumor and appear to be specific markers for ARMS.

In a series of mapping experiments, the chromosome 2 locus disrupted by the t(2;13) was found to be *PAX3*, and translocation breakpoints were localized to the final intron of the *PAX3* gene.[37] This gene is a member of the paired box family and encodes a transcription factor with an *N*-terminal DNA-binding domain containing paired box and homeobox motifs. Its presumed function is that of transcriptional regulation strictly during embryogenesis, important in the development of mesenchymal precursors.[38] Northern analysis of ARMS tumors with 5′ PAX3 probes demonstrated a 7.2 kb transcript that is the product of the rearranged *PAX3* gene located on the derivative chromosome 13[der(13)].[37,39–41] Cloning of the corresponding cDNA revealed a fusion of exons 5′ to the t(2;13) breakpoint with a novel sequence from the 13q14 chromosomal region. A full length cDNA of the wild-type chromosome 13 gene was cloned and found to be a novel widely expressed member of the fork head transcription factor family.[42,43] This family is characterized by a conserved DNA-binding motif termed the 'fork head' domain. Based on homology to this family, the chromosome 13 gene was named FKHR for 'fork head in rhabdomyosarcoma'.[42] These combined findings indicate that the t(2;13) results in a chimeric transcript composed of 5′ PAX3 and 3′ FKHR exons (see Figure 60.1). The PAX3–FKHR fusion in ARMS is characterized by a rearrangement of chromosome 2 and 13, t(2;13)(q35;q14), in which the *PAX3* gene within band 2q35 is fused with the *FKHR* gene within band 13q14. Both of the PAX3 DNA-binding regions (the paired box and the homeodomain) are retained in the fusion gene, whereas the carboxyl-terminal sequences are replaced by the bisected fork head DNA-binding sequences of FKHR.[5,44] In PAX7–FKHR fusions, a chromosome 1 locus encoding PAX7,[43] another member of the paired box family, is rearranged and fused to FKHR in the t(1;13) conscript, consisting of 5′ PAX7 and 3′ FKHR regions, which is very similar structurally to the 5′PAX3– 3′FKHR transcript formed by the t(2;13) translocation.[45,46]

Assays of expression during embryogenesis demonstrate that PAX3 and PAX7 are expressed with specific temporal and spatial patterns in early skeletal muscle progenitors, the presumed origin of ARMS, and in the developing nervous system.[47,48] PAX3–FHKR fusion proteins have been identified to interfere with normal embryonic development prior to transformation.[49] Several putative target genes for PAX3 and PAX3–FHKR have been identified, including *Itm2A*, *Fath*, *FLT1*, *TGFA*, *BVES*, *EN2*, and *GLUT4*, which all may be involved with PAX3 regulation during embryogenesis and tumorigenesis.[50,51] In ARMS, studies indicate that the alteration of the *PAX3* gene by the t(2;13) results in a gain of function. These studies are consistent with the hypothesis that the t(2;13) activates the oncogenic potential of PAX3, by dysregulating or exaggerating its normal function in the myogenic lineage. Studies indicate that the PAX3–FKHR and PAX7–FKHR proteins affect the cellular activities of growth, differentiation, and apoptosis, and enhance cellular proliferation and invasion, with the potential to exert oncogenic effects through multiple pathways.[33,52,53]

PAX–FKHR fusions result in potent transcriptional activators.[54] FHKR may be overexpressed due to increased transcription on the PAX3–FKHR fusion protein and with in-vivo amplification of PAX7–FKHR. As opposed to FKHR, these fusion proteins are resistant to regulation by AKT, altering function and increasing expression.[33] The PAX7 *N*-terminus has repressor function which inhibits transactivation by its *C*-terminus and is only partially effective at inhibiting the C-terminus of PAX7–FKHR. This is similar to the mechanism for gain of function with PAX3–FKHR.[54] PAX3–FKHR is capable of inducing myogenin and MyoD. It is also associated with up-regulation of *Six1*, *Slug*, and *Igfbp5*, which are all genes associated with muscle development and noted to be up-regulated in ARMS.[54]

The matrix metalloproteinases (MMPs) are a family of enzymes that degrade extracellular matrix and are important in neoplastic cell invasion and metastasis. It has been shown that ARMS strongly expresses MMP-1, -2, and -9 compared with ERMS. These seem to contribute to the more aggressive nature of alveolar rhabdomyoblastic cells.[55]

PAX3–FHKR has become a potential target for ARMS therapy. Repression of *PAX3* target genes, using PAX3–KRAB fusion proteins in ARMS cell lines, has resulted in tumor repression in mice, and the engineered repressor approach targeting the genes deregulated by PAX3–FHKR may be useful to identify target genes critical for ARMS tumorigenesis.[56,57] Insulin-like growth factor-1 (IGF-1) has an important role in muscle development and in the etiology of ARMS. PAX3–FHKR has been shown to transactivate the IGF-1 receptor gene (*IGF-1R*) promoter in sarcoma cell lines with a higher potency than PAX3.[58]

Sorenson et al determined the PAX3–FKHR/PAX7–FKHR fusion status in 171 patients enrolled in IRS IV with reverse transcription polymerase chain reaction (RT-PCR). PAX3–FKHR and PAX7–FHKR were detected in 55% and 22% of the 78 patients with alveolar histology, respectively, and none with other than ARMS. Fusion status was a prognosticator for metastatic but not local disease between the two transcripts, with an estimated overall 4-year survival rate of 75% for PAX7–FKHR vs 8% for PAX3–FKHR. Failure, death, and bone marrow involvement were all significantly increased on multivariate analysis in patients with metastatic disease harboring PAX3–FKHR compared with PAX7–FKHR.[59] This corroborated results by Anderson et al, who had previously evaluated 91 RMS tumors with unequivocal evidence of the presence or absence of PAX3/PAX7–FKHR fusion transcripts: 37 had PAX3–FHKR, 8 had PAX7–FHKR, and 46 had neither. The authors found a statistically significant association between PAX3–FKHR and higher-stage disease and its absence and lower-stage disease (p = 0.06 when grouping stages 1 and 2 and stages 3 and 4). PAX7–FKHR transcript numbers were too small to reach statistical significance, but stage results were similar to the group without a translocation. PAX3–FHKR was in statistically significantly older children (p = 0.001, median 9 years old) than the other two groups (3 and 4 years for PAX7–FHKR and no translocation, respectively), whereas translocation status was not associated with disease site. Among 66 patients with non-metastatic disease, overall and event-free survival were significantly worse in the PAX3–FKHR group.[60] Collins et al found that, compared with PAX7–FKHR, PAX3–FKHR RMS demonstrated greater cell cycle dysregulation, related to both increased cell proliferation and apoptosis, and concluded that this contributes to the poorer prognosis in the PAX3–FHKR group.[61]

Evaluation of 23 ARMS tumors lacking PAX3–FHKR or PAX7–FHKR fusions identified seven cases with low expression, atypical presentation of standard fusions, or variant fusions with other genes, suggesting a genetic heterogeneity in this subset of RMS tumors.[30]

ERMS has not been associated with consistent chromosomal alterations. Ten percent of ERMS demonstrate EWS–ETS fusion anomalies that are sometimes seen simultaneously with PAX–FKHR fusions.[1] EWS/ETS is a chimeric protein identified in most Ewing's sarcoma. These are characterized by specific chromosomal translocations wherein the EWS (Ewing's sarcoma) gene on chromosome 22 is fused to one of the five members of the ETS gene family. The ETS family of transcriptional factors is so named because the first gene was uncovered in E26 avian retrovirus. Molecular genetic analyses have revealed frequent allelic loss on chromosome 11.[62] Loss of heterozygosity (LOH) at chromosome 11 is also seen in Wilms' tumor and hepatoblastoma. This genetic feature is not found in ARMS.[18] The smallest region of consistent allelic loss in ERMS cases has been localized to chromosomal region 11p15.5.[63] The deletion may be detected by cytogenic or loss of heterozygosity analysis.[38] Alterations in this chromosome region are also noted in BWS and Wilms' tumor.[64] Whereas ERMS over ARMS is more commonly associated with BWS, there is a report of three cases in the literature where ARMS without PAX–FHKR fusion was associated with BWS, with two of the cases having an 11p15 defect, suggesting that chromosome 11 alterations may play a role in this particular subset of ARMS as well as ERMS.[65]

Usually, the presence of a consistent region of allelic loss suggests the presence of a tumor suppressor gene that is inactivated in the associated malignancy. Studies have confirmed the presence of a tumor suppressor gene locus in the region previously demonstrated to show allelic loss in ERMS.[66,67] Comparing allelic loss pattern in ERMS tumors to allelic status of the patients' parents has revealed that ERMS tumors preferentially maintain the paternally inherited allele and lose the maternal allele.[17,18] The presence of the paternal allele suggests imprinting, the process by which individual genes from one parent are preferentially expressed over genes from the other. Even in close proximity to the genome, two genes can be oppositely imprinted, as is the case with the insulin-like growth factor-2 gene (*IGF-2*) vs *H19* and *CDKN1C* genes, which all map to chromosome 11p15.5. The *H19* gene product is an RNA molecule that is widely expressed during fetal development in association with cell differentiation but is apparently not translated into a protein product.[68] It controls the *IGF-2* gene, and is deactivated in several pediatric tumors, including Wilms' tumor and ERMS.[69] The *CDKN1C* gene is expressed during development in several tissues, including skeletal muscle, and encodes a cyclin-dependent kinase inhibitor that negatively regulates cell cycle progression by binding to and inhibiting the activity of several G1 cyclin/cyclin-dependent kinase complexes.[70] *H19* and *CDKN1C* are preferentially expressed from the maternally inherited allele and *IGF-2* is imprinted in the opposite

direction, so that the paternally inherited alleles are expressed preferentially.[68] Recently, another gene, *GOK*, has been identified at chromosome 11p15.5. *GOK* may act as a tumor-suppressor gene in RMS and rhabdoid tumors. It has been shown that *GOK* is not expressed in many RMS cell lines, which contrasts with high expression of *GOK* in skeletal muscle.[71] Therefore, down-regulation of *GOK* expression may also play a role in the pathogenesis of RMS. *STIM-1* is another gene which maps to 11p15.5 and is a candidate growth suppressor gene with the features of a regulatory cell surface phosphoprotein. In RMS cell lines, *STIM-1* overexpression has resulted in growth arrest.[72,73] Results of these allelic loss studies suggest that ERMS tumorigenesis frequently involves inactivation of an imprinted tumor suppressor by allelic loss of the maternal active allele and retention of the paternally inactive allele.

In a small study of RMS, CD44, a membrane glycoprotein involved in cell–substrate and cell–cell interactions, was identified in 11/20 favorable and 1/7 unfavorable histology RMS ($p = 0.07$). Of the 12 patients with CD44+ve tumors, 11 were alive and in first remission, significantly less than 5/15 patients with CD44–ve tumors ($p = 0.001$). In this small study, CD44 expression in RMS correlated directly with prognosis.[74]

The combined data indicate that RMS tumorigenesis involves a variety of genetic alterations within a chromosomal region encompassing several genes. Some alterations serve to increase the number of active *IGF-2* alleles, thereby overexpressing this fetal growth factor, whereas other alterations serve to mutate or inactivate expression of growth-suppressive loci such as *H19*, *CDKN1C*, *GOK*, and *STIM-1*.

Although the *PAX3/PAX7–FKHR* gene fusions and allelic loss at chromosome 11p15.5 are the consistent, and possible defining, genetic alterations in ARMS and ERMS, other alterations have also been detected. These alterations include both mutations that activate proto-oncogenes and mutations that inactivate tumor suppressor genes. These additional genetic changes indicate that ARMS and ERMS arise and evolve by a multistep process.

Studies of genomic amplification have shown differences between ARMS and ERMS. Using chromosome scanning techniques of comparative genomic hybridization, there are frequent examples of whole chromosome gains in ERMS involving chromosomes 2, 7, 8, 11, 12, 13, 17, 18, 19, and 20.[75,76] Examination of ARMS tumors reveals few examples of chromosomal gains but evidence of amplification in almost every sample tested.[76] In contrast, in a study of 23 ARMS and 22 ERMS cases, gains and losses of chromosomal regions were found to be equally distributed between ARMS and ERMS with the exception of 7/7 q and 11/11 q gains, which were chiefly seen in ERMS. Additionally, amplifications were identified in 26% of ARMS and 23% of ERMS, with nearly all of the ERMS subset demonstrating anaplastic features.[75] In 50% of ARMS, amplification of chromosomal region 12q13–15 was detected; this region contains numerous growth-related genes, including *MDM2*, *CDK4*, and *GLI*.[77–79] Also, *MYCN* gene amplification has been found in 10 of 40 ARMS cases and in no ERMS cases.[40,80–82] This particular amplification may prognosticate a poor outcome. Among 15 ARMS patients, lack of *MYCN* amplification was associated with 66% survival compared with 11% ($p < 0.05$) for those who had it.[74] The locus for IGF-IR, 15q25–26, has been shown to be one of the amplicons that may be present in these cell lines.[75]

Another group of proto-oncogenes that are genetically altered in RMS are members of the *Ras* gene family. Mutations of members of this family (*K-ras*, *N-ras*, and *H-ras*) have been detected in some ERMS tumors, whereas none were detected in ARMS tumors.[83–85] Of the tumor suppressor genes, alterations of the *p53* gene have been most extensively studied in RMS. Using immunohistochemical assays of *p53* expression that screen for tumors in which missense mutations increase the p53 protein half-life, p53 staining was detected in approximately 70% of RMS tumors.[86,87] Diller et al corroborated previous findings that *p53* germline mutations are seen with increased frequency in sporadic cases of RMS and that these alterations are almost uniquely seen in children <3 years of age.[88] The combined results of these studies indicate that germline and acquired *p53* mutations contribute to the development of both ERMS and ARMS.

Other known tumor suppressor loci have also been investigated in RMS. A genome-wide screen of 32 RMS cases revealed several regions of allelic loss in addition to the expected 11p15 region.[89] In at least 25% of cases the regions showing allelic loss were 6p, 11q, 14q, 16q, and 18p. The overall frequency of allelic loss was lower in ARMS tumors than in ERMS tumors, again supporting the view that different molecular mechanisms are involved in the development of these two RMS subtypes. The *DCC* gene, initially identified as a tumor suppressor gene in colorectal cancer, is noted to have a mutation in 6/10 RMS cell lines.[90]

IGF-2 is overexpressed in RMS cell lines and inhibited by IGF-binding protein 6 (IGFBP6), which is associated with myoblast quiescence. IGFBP6 expression is low in RMS cell lines, and studies have demonstrated that it induced a decrease in growth and increase in apoptosis in RMS cell lines that were partially reversed with the IGF-2.[91] Several growth factors in addition to IGF have been identified to play a role in RMS tumor biology. Transforming growth factor-β (TGF-β) is an inhibitor of myogenic differentiation and an autocrine product in RMS cell lines. Inhibiting the activation of latent TGF-β in these cell lines has induced growth arrest and myogenic differentiation, whereas its elimination induces arrest, but not differentiation, indicating that there is a critical concentration required for myogenesis and this concentration is much higher in human primary muscle cells than in RMS cell lines.[92] Both high- and low-affinity receptors for nerve growth factor (NGF) have been identified in RMS cell lines. NGF has been associated with decreased apoptosis without altering differentiation in these lines.[93]

In conclusion, molecular genetic studies of RMS support the premise that ARMS and ERMS represent distinct entities. These tumors are associated with specific molecular alterations, namely PAX3/PAX7–FKHR gene fusions in ARMS and 11p15.5 allelic loss in ERMS. The gene fusions in ARMS represent gain-of-function oncogenic mutations that generate potent transcriptional activators of target genes with PAX3/PAX7 binding sites. On the other hand, the 11p15 allelic loss in ERMS acts on an imprinted region to inactivate expression of putative tumor suppressor loci. Genomic hybridization techniques may be utilized to identify genomic gains and losses in ERMS. In addition, secondary genetic alterations of other genes occur in both ARMS and ERMS, indicating that these tumors arise in a multistep process. Both the primary and secondary events affect gene products that function in signal transduction and gene expression regulatory pathways, altering numerous key pathways in the cell to ultimately generate the phenotypic changes of growth autonomy, abnormal differentiation, and motility.[94] Molecular techniques identifying these changes will be useful in differentiating ERMS and ARMS from each other and other soft tissue sarcomas as well as detecting occult bone marrow and peripheral blood metastasis, and evaluating surgical margins, both at initial resection and with second-look procedures.

Pathology

The significant difference in survival between embryonal RMS and alveolar RMS makes it imperative for the pathologist to accurately diagnose variants of RMS so that the biologic course of the disease can be predicted and appropriate therapy initiated.

In 1995, a consensus classification of RMS was published[8] that was based on a review of a large number of tumors from IRS II by 16 international pathologists from eight pathology groups. This produced a classification that was both reproducible and could predict outcome by univariate analysis. A multivariate analysis of this new International Classification of Rhabdomyosarcoma (ICR) indicated that a survival model that included the ICR along with known prognostic factors of primary site, clinical group, and tumor size was significantly better at predicting survival than a model with only the known prognostic factors.[8] The ICR classification is shown in Table 60.1, along with the IRSG addition (anaplastic variant). The data presented in this table are from ICR-related publications and IRSG publications on specific RMS subtypes.[7,8,95–97]

Table 60.1 International classification of rhabdomysarcoma

Diagnosis	Histology	Incidence (%)	5-year survival (%)	Prognosis
Embryonal, botryoid	Favorable	6	95	Superior
Embryonal, spindle cell	Favorable	3	88	Superior
Embryonal, not otherwise specified (NOS)	Favorable	49	66	Intermediate
Alveolar, NOS, or solid variant	Unfavorable	31	53	Poor
Anaplasia, diffuse	Unfavorable	2	45	Poor
Undifferentiated sarcoma	Unfavorable	3	44	Poor

Total incidence is only 94%: remaining 6% are sarcomas (NOS category) that had insufficient or inadequate tissue to make a more specific diagnosis.

Embryonal rhabdomyosarcoma

These tumors have variable amounts of spindle and primitive round cells, which may be either tightly packed or loosely dispersed in a myxoid background. The rhabdomyoblast, the more mature embryonal component, is characterized by bright eosinophilic cytoplasm and may appear in a variety of unusual shapes, termed 'tadpole', 'racquet', or 'strap' cells.[8,98] Cross-striations are seen in 50–60% of cases. Embryonal RMS represents the most common genitourinary RMS variant. These tumors rarely metastasize and respond well to current therapy. On fine needle aspiration (FNA), the embryonal subtype is suggested in specimens with large tissue fragments containing abundant eosinophilic material and small, tightly packed cells with oval nuclei.[99] ERMS stains positively for myoglobin, desmin, and vimentin. Classic ERMS with a polypoid growth pattern was associated with a more favorable prognosis than a diffuse intramural (endophytic) growth pattern in 65 cases of bladder and vaginal RMS (92% vs 68% 10-year survival, $p = 0.02$).[95]

Botryoid embryonal rhabdomyosarcoma

The ICR criterion for diagnosis of botryoid embryonal RMS requires demonstration of a cambium (condensed layer of rhabdomyoblasts) tumor layer underlying an intact epithelium in at least one microscopic field (Figure 60.2). This microscopic criterion supersedes any gross demonstration of a 'grape-like' tumor mass. An extensive degree of rhabdomyoblastic differentiation can be evident both in the cambium layer and elsewhere in the tumor. The importance of diagnosing this subtype is evident given its superior prognosis, with a 95% 5-year survival. There remains debate as to whether BRMS is a distinct entity or a variant of ERMS, and biologic studies have not demonstrated a molecular distinction.[100]

Spindle cell embryonal rhabdomyosarcoma

The spindle cell variant of RMS also enjoys a superior prognosis, with an 88% 5-year survival rate. It has only been recognized in the literature since 1993.[101] This neoplasm has a fascicular, spindled 'leiomyomatous' growth pattern that can show a marked degree of rhabdomyoblastic differentiation. Some tumors show marked collagen deposition. This variant almost exclusively occurs in the paratesticular region, although it can rarely occur at other body sites. These tumors are immunopositive for titin, a marker for terminal differentiation.[102]

Alveolar (solid) rhabdomyosarcoma

A review comparing IRSG pathologic diagnosis with institutional diagnosis performed between 1984 and 1997 showed concordance in only 63% of cases. The high level of discordant diagnosis (37%) reflects the need for better recognition of the solid alveolar variant of this RMS subtype. The classic cleft-like spaces lined by rhabdomyoblasts (Figure 60.3) that are traditionally described[7,8] for alveolar RMS may merge with spaces filled with tumor cells that sit on thin fibrovascular septae. This latter solid variant is rarely present without the classic finding of cleft-like spaces and can be recognized with adequate tumor sampling. The key criterion is to recognize palisading of tumor cells

Figure 60.2 Botryoid embryonal rhabdomyosarcoma demonstrating the cambium (condensed layer of rhabdomyoblasts) tumor layer underlying an intact epithelium.

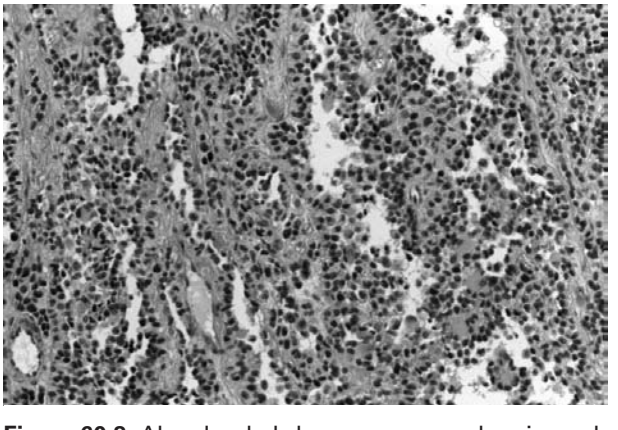

Figure 60.3 Alveolar rhabdomyosarcoma showing palisading of tumor cells with a coarse chromatin pattern about fibrovascular cores.

about fibrovascular cores. The tumor cells have a coarse chromatin pattern to their nuclei, with less-evident myogenesis than in embryonal RMS.[8] FNA biopsies of ARMS demonstrate predominantly two architectural patterns: either completely dissociated cells or many chance formations of cells. However this is non-specific, and any RMS diagnosis on FNA requires immunohistochemical confirmation.[99]

The prognosis for both the classic and solid variants is the same. Both carry a poor prognosis, with only a 53% 5-year survival rate. Improved concordance of review and institutional diagnosis is crucial for this malignancy, as they receive intensified therapy on current IRSG protocols.

Anaplastic rhabdomyosarcoma

This variant also has a high rate of discordance(62%).[7] Using the IRS I–III material, anaplastic RMS was defined using the following criteria:

- large, lobate hyperchromatic nuclei of at least three times the size of neighboring nuclei
- atypical multipolar mitotic figures.[7,96]

It is also defined further by its distribution as focal (group I), consisting of single or few anaplastic cells, or diffuse (group II), where anaplastic cells aggregate in clusters or form a continuous sheet.[7,96] The occurrence of anaplasia is independent of both RMS tumor site and histopathologic subtype, although it occurs preferentially in embryonal RMS. The overall incidence of anaplasia in IRS I–III was 3%, and it will be assessed as a new diagnostic feature of RMS in IRS V therapeutic trials.[7]

Undifferentiated sarcoma

This category, which also has a high rate of discordance (62%),[7] is included in the ICR classification only because its response to therapy is similar to that of RMS.[8]

These tumors are mainly composed of sheets of medium-packed cells with no discernible architectural structure except for delicate fibrovascular septae or a vague spindled-storiform pattern. Necrosis and inflammation are not prominent, cellularity is high with high mitotic activity [>10 mitoses per 10 high-power field(hpf)], and the nuclei are predominantly oval with prominent chromocenters and indistinct cytoplasm.[7,97] The tumors stain only with vimentin antisera (77%), if at all.

This entity is rare (3% of cases) and, like ARMS, occurs more often in males (62%), in patients ≥ 5 years old (65%), and is more common in the extremities (53%).[97] Five-year survival with localized disease is 72%, but with disseminated disease is only 44%.[7] Early identification of this histologic subtype, enabling prompt, intensified therapy, is an important component of the IRS V studies.

Ectomesenchymoma

A rare malignant neoplasm, consisting of RMS with a neural component, ectomesenchymoma (EM) is probably underdiagnosed and has a similar outcome to the RMS component of the tumors. Boue et al, in their report of 15 cases, noted that there were previously only 21 other cases reported in the literature. They noted that, of their 15 cases, only two had an originating institutional diagnosis of EM, with 12 diagnosed as RMS, and one diagnosed as undifferentiated sarcoma. Five of these cases were of external genital origin and six were pelvic/abdominal.[103]

Other diagnostic studies

Ancillary studies performed on histopathologic tissues are useful in confirming the diagnosis and in providing prognostic information on the course of the malignancy. A comprehensive study using commercially available and experimental antibodies was undertaken in the IRS IV study, which included 100 cases of RMS representing all subtypes.[7] The incidence of immunopositivity for the various antisera is summarized in Table 60.2. Around 20% of RMS cases required the use of immunohistochemistry to establish the final diagnosis.[7]

Table 60.2 Incidence of immunopositivity for antisera in rhabdomyosarcoma diagnostic studies

Antibody	Percentage
Polyclonal desmin	99
Monoclonal desmin	62
Muscle-specific actin	94
α-Smooth muscle actin	4
Myoglobin	78
Wide-spectrum keratin	7
Epithelial membrane antigen	2
S-100 protein	19
Neuron-specific enolase	6
Leukocyte common antigen	0
MIC-2	14
p53	16

Immunostaining

Myogenin is specific for rhabdomyoblastic differentiation and may help in the differentiation of small round cell tumors. It is strongly expressed in ARMS nuclei but demonstrates little or no staining in ERMS, where it has a variable staining pattern and intensity. The extent of myogenin staining in RMS is much greater than in non-RMS tumors, making it a useful marker.[104–107] In contrast to other studies, Cessna et al did note some rare non-RMS (7/107) focal nuclear reactivity to myogenin.[105] Pseudosarcomatous myofibroblastic tumors (PMTs) of the urogenital tract are rare benign tumors which may be mistaken for RMS. Myogenin is expressed in RMS but not PMTs and may be useful in differentiating these distinct clinical entities.[108]

MyoD1 expression is a distinguishing characteristic of RMS. It is now possible, through RT-PCR assay to evaluate expression of *MyoD1* mRNA. This has been found to be highly sensitive and specific in detecting minimal residual disease, as well as bone marrow and peripheral blood stem cell involvement, regardless of histologic subtype.[109] This is in contrast to a report by Gattenloehner et al, who described that *MyoD1* mRNA could be amplified from many other tissues and childhood tumors ex vivo.[110] Cessna et al reported that while all RMS stained for *MyoD1*, there was diagnostic difficulty on paraffin-embedded specimens studied due to cytoplasmic and non-specific background staining of non-myoid tissues.[105]

Polyclonal antidesmin (P-DES) antibody was positive in all but one rhabdomyosarcoma (99%). Monoclonal antidesmin (M-DES) antibody was negative in many of the same tumors (38%). Antimuscle-specific actin (MSA) antibody was positive in 94% of the RMS. Antimyoglobin (MYO) antibody was positive in 78% and was negative mostly in the less differentiated tumors. Anti-α smooth muscle actin (SMA) antibody reacted positively only in a minority (4%) of embryonal RMS.[7]

The current approach at the IRSG Pathology Center in cases where the diagnosis of RMS is in question is to screen the case with immunostaining for three antibodies: P-DES, MSA, and MIC-2; the latter helps to rule out the diagnosis of an extraosseous Ewing's sarcoma or primitive neuroectodermal tumor.[111] Around 14% of RMS stain positive to MIC-2 antisera, but this is only a weak granular intracytoplasmic immunopositivity, whereas Ewing's sarcoma and primitive neuroectodermal tumors show discreet plasma membrane staining.[111] Antibodies to the various myogenic transcription factors (MyoD1, etc.) are not tested because of their noted negativity with paraffin sections.[112]

Monoclonal antibody to p53 protein was also studied in pediatric RMS.[113] Positive immunostaining is seen in only 16% of RMS specimens.[7,114] On the other hand, immunopositivity at the grade 3–4 level (6% of RMS) was significantly associated with occurrence of any anaplasia in alveolar RMS and diffuse anaplasia in embryonal RMS, independent of fusion gene status.[115] The potential linkage of p53 abnormalities with anaplasia in RMS will be further studied in the IRS V study.

Molecular studies

Tobar et al analyzed RMS samples from nine patients (two ERMS, four ARMS, three undifferentiated sarcoma) with RT-PCR to identify the PAX3–FKHR transcript (Table 60.3). As expected, all patients diagnosed with ARMS demonstrated the chimeric transcript. However, positivity in one patient diagnosed with ERMS (with LOH at 11p15.5) and two diagnosed with undifferentiated sarcoma prompted histologic review. In the ERMS patient and one of the undifferentiated sarcoma patients, areas consistent with ARMS were identified on histologic review and patients were reclassified as ARMS, whereas the second undifferentiated sarcoma patient's diagnosis was substantiated.[38] RT-PCR for PAX3–FKHR and PAX7–FKHR on tumor tissue, bone marrow, and body fluids obtained at initial presentation and relapse in 13 ARMS patients was found to be sensitive and specific in identifying residual disease and micrometastases. Rate of detection of micrometastases in this study of three pediatric sarcomas using RT-PCR was 95% compared with 70% for morphologic methods. In three of the ARMS patients, micrometastases were

Table 60.3 Rhabdomyosarcoma immunodifferentiation

ERMS	ARMS	Poorly differentiated RMS

	α-1-actin	
	t(2;13)(q35;q14)	

From Tobar et al.[38]

identified with RT-PCR alone and no patient diagnosed with localized disease was found to have micrometastases on RT-PCR evaluation of bone marrow. The significance of molecularly detectable disease is unclear.[116]

In IRS V the emphasis will be on the incidence of t(1;13) and t(2;13) and their fusion genes in RMS.[7] RT-PCR methodology will be employed in detecting fusion genes in frozen and archived tissue.[117] The t(1;13) (PAX7) translocation may predict a different clinical phenotype and longer event-free survival and predilection for younger patients and extremity tumors than the t(2;13) (PAX3) translocation.[7,38]

As determined by flow cytometry, approximately two-thirds of alveolar tumors have near-tetraploid DNA content. The remaining cases are usually diploid.[118] Interestingly, near-tetraploidy is almost never observed in embryonal RMS.[5] LoH for closely linked foci of chromosome 11p5.5 is seen in embryonal RMS.

Post-treatment pathologic studies

The most difficult assessment by pathologists is the prognostic significance of residual rhabdomyoblasts in post-therapeutic RMS tissue specimens. Studies support the concept that post-therapeutic cytodifferentiation occurs more frequently in botryoid or embryonal RMS.[119–121] In botryoid RMS, cytodifferentiation and decreased proliferation activity were associated with favorable outcome. Unchanged or increased post-therapeutic proliferation activity suggested aggressive biologic potential in embryonal or alveolar RMS.

Smith et al reported on the post-treatment cytodifferentiation and clinical outcome from 19/31 IRS IV cases which were adequate for evaluation. None of the 10 cases with extensive cytodifferentiation (two BRMS, eight ERMS) failed, whereas among the five cases with moderate cytodifferentiation, only the two ARMS patients failed, and all four patients (one ERMS, three ARMS) with mild or no cytodifferentiation failed. The authors concluded that post-treatment cytodifferentiation is more common in both ERMS and BRMS than in ARMS, and postulated that this difference is due to different mechanisms of cellular response to therapy. They also noted that sparse persistent tumor cells in ARMS/BRMS did not appear to affect outcome.[121] Myoglobin is specific for terminally differentiated myocytes, and as such is a useful marker for differentiated tissue in organs such as bladder and prostate, which normally do not contain skeletal muscle. As the expression of myogenin and MyoD is down-regulated with terminal differentiation, they are less helpful to identify differentiated cells.[100] In another study, sequential evaluation of six patients with pelvic (four bladder/prostate, two vulvovaginal) RMS who had persistent well-differentiated rhabdomyoblasts without mitotic activity during and after the completion of therapy demonstrated rhabdomyoblast persistence, but decrease in number with time. All six patients were alive, with no evidence of disease from 37 to 233 months after the completion of therapy. The authors conclude that, while the biologic nature of these cells is not known, their presence is not an indication for further therapy.[122]

These phenomena will be further studied in IRS V.

Staging of rhabdomyosarcoma

Both the surgically based clinical grouping system employed in IRS I, II, and III, and the site-based TNM staging system have been used.[123–125]

Table 60.4 Clinical group staging system for rhabdomyosarcoma

Clinical	Group	Extent of disease
I	A	Localized tumor, confined to site of origin, completely resected
I	B	Localized tumor, infiltrating beyond site of origin, completely resected
II	A	Localized tumor, gross total resection, microscopic residual disease
II	B	Locally extensive tumor (spread to regional lymph nodes), completely resected
II	C	Locally extensive tumor (spread to regional lymph nodes), gross total resection, but microscopic residual disease
III	A	Localized or locally extensive tumor, gross residual disease after biopsy only
III	B	Localized or locally extensive tumor, gross residual disease after major resection (>50% debulking)
IV		Any size primary tumor, with or without regional lymph node involvement, with distant metastases, without respect to surgical approach to primary tumor

Table 60.5 Clinical grouping system for rhabdomyosarcoma

Clinical Group	Extent of disease
I	*Localized, completely resected* A Confined to site of origin B Infiltration beyond site of origin
II	*Micro residual or regional spread* A Localized with micro positive margins, grossly resected B Regional disease with complete resection, most distal node negative C Regional disease resected with micro residual or most distal resected nodes involved
III	*Gross residual* A Biopsy only B Gross/major primary resection (>50%)
IV	*Distant metastasis at diagnosis* (lung, liver, BM, bone, brain, distant muscle or + cytology CSF, pleural fluid, peritoneal fluid)

BM = bone marrow; CSF = cerebrospinal fluid.

The clinical grouping system (CGS) (Tables 60.4 and 60.5) is a surgicopathologic staging system based on whether surgical resection has been accomplished, with modifiers related to clinical and pathologic findings.[123,124]

The CGS is used to plan radiation therapy and relies on the pathologic findings determining if the tumor is confined to the primary site, with or without local invasion, and if the surgical resection is complete with tumor-free margins.

The TNM staging system (Table 60.6) takes into account tumor location, size, clinical lymph node involvement, and the presence or absence of metastases. It is used to plan therapy and is highly predictive of outcome.[123–125]

Per IRS V protocol, representative portions of the tumor should be submitted for light microscopy or fixed for electron microscopy, placed in tissue culture medium for potential chromosome studies, and frozen and stored for molecular studies.[7] When a tumor is resected, evaluation of the margins is mandatory. Recording the three-dimensional tumor size is of utmost importance as it influences staging and outcome. The distance of the tumor from the nearest resection margins is also important for staging. The pathologist has an important role in the proper staging/grouping of RMS as well as its proper histopathologic classification. Also, rapid pathology review is important for patients diagnosed with ARMS or undifferentiated sarcoma who receive additional cytotoxic therapy and radiation based on the IRS V therapeutic trials.[126] Figure 60.4 outlines the treatment algorithm for IRS V low-risk genitourinary sarcoma at diagnosis.

Presentation: bladder/prostate

- Urinary tract obstruction, hematuria, abdominal mass.
- Typically >5 cm and invasive at presentation.

Table 60.6 TNM staging of childhood genitourinary rhabdomyosarcoma

Stage	Sites	T invasiveness	T size	Regional nodes	Metastases
I	Genitourinary (non-bladder/prostate)	T1 or T2	a or b	N0, N1 or NX	M0
II	Bladder/prostate	T1 or T2	a	N0 or NX	M0
III	Bladder/prostate	T1 or T2	a	N1	M0
		T1 or T2	b	N0, N1 or NX	M0
IV	All	T1 or T2	a or b	N0 or N1	M1

T tumor: T1 = confined to anatomic site of origin; T2 = extension.
Size: a = <5 cm in diameter; b = >5 cm in diameter.
Regional nodes: N0 = not clinically involved; N1 = clinically involved; NX = clinical status unknown.
Metastases: M0 = no distant metastasis; M1 = distant metastasis present.

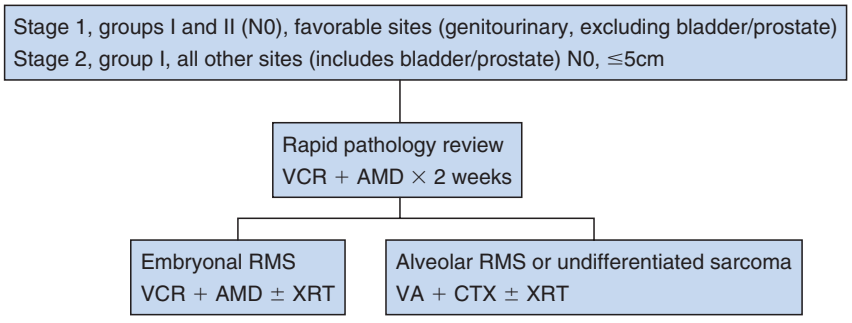

Figure 60.4 Treatment algorithm for low-risk genitourinary sarcoma in IRS V. RMS = rhabdomyosarcoma; VCR = vincristine; AMD = actinomycin D, CTX = cytoxan; XRT = radiotherapy.

A rare neonatal RMS presentation has been described, with several cases reported in the literature. It presents in the neonatal period, frequently of alveolar subtype associated with multiple cutaneous metastases, lacking characteristic RMS translocations, and has been fatal with current therapy.[21,127] In general, cutaneous metastasis of non-hematopoietic neoplasms is rare; however on review of this entity, RMS was noted to be the most common pediatric neoplasm to metastasize to the skin.[128]

Diagnostic evaluation

Imaging

The first diagnostic procedure performed in patients who present with an abdominal or pelvic mass and/or symptoms of urinary obstruction is to perform a pelvic and renal ultrasound. This will usually show a solid tumor, which may be hyperechoic or hypoechoic, and will also evaluate the status of the bladder, the postvoid residual, and the upper tracts. Bladder BRMS may appear as a polypoid intraluminal mass resembling a cluster of grapes, which is characteristic but not pathognomonic of this entity.[129]

The remainder of the radiographic evaluation is to determine the extent of the local and regional disease as well as to identify metastatic foci. Magnetic resonance imaging (MRI) is replacing computed tomography (CT) as the examination of choice for accurate presurgical assessment of the extent and volume of disease. An accurate pretreatment tumor volume is necessary to plan later for adequate radiation treatment, if necessary. The extent of the tumor around the bladder and prostate can be determined by MRI T2-weighted images, with sagittal views demonstrating urethral tumor extent[130] (Figures 60.5–60.8). RMS has intermediate signal intensity on T1-

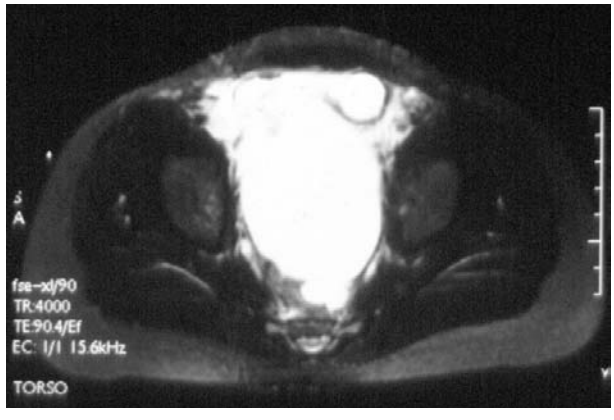

Figure 60.5 Magnetic resonance imaging scan finding in a 4-year-old male with embryonal group III rhabdomyosarcoma. On T2-weighted images the extent of the tumor is well visualized.

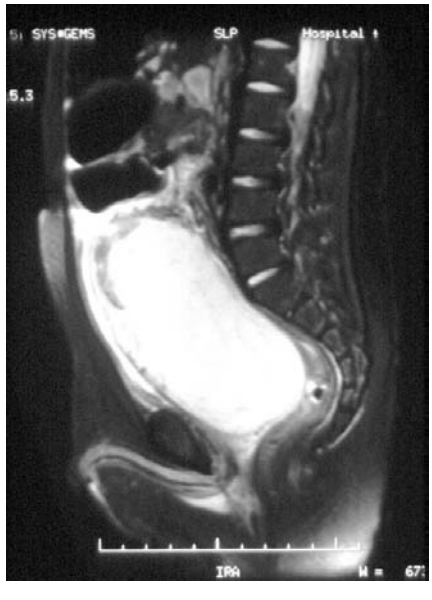

Figure 60.6 Magnetic resonance imaging scan in a 4-year-old child with embryonal group III rhabdomyosarcoma. In this sagittal view, the extent of the tumor into the membranous urethra is well delineated.

Figure 60.7 Magnetic resonance imaging scan in a 6-year-old child with embryonal group III rhabdomyosarcoma. This sagittal view on T2-weighted image shows the extent of the tumor distally in the membranous urethra.

Figure 60.8 Magnetic resonance imaging scan in a 5-year-old child with embryonal group III rhabdomyosarcoma after 16 weeks chemotherapy. The tumor is visualized extending into the bladder and its extent into the urethra is also well seen.

weighted images and intermediate to high signal intensity on T2-weighted images with significant enhancement with gadolinium diethylenetriamine penta-acetic acid (Gd DTPA). ARMS demonstrates a lobular appearance on post-contrast images. Although these characteristics are non-specific and indistinguishable from other soft tissue sarcomas, MRI is useful for staging and therapeutic response assessment in RMS.[129]

Metastases occur most commonly to the lungs, bone, and lymph nodes followed by bone marrow and liver. Prostatic primaries are more likely than bladder primaries to metastasize to the lungs or bone marrow.[129] Metastatic assessment may be achieved by a CT scan of the chest, an MRI or CT of the abdomen and pelvis, bone marrow aspiration, and, if indicated, a bone scan. A CT scan may identify inguinal or retroperitoneal nodes as well as pulmonary metastases. The absence of ascites does not exclude peritoneal involvement.[131] Bone metastases in RMS are identified on imaging as ill-defined lytic lesions.[129]

In a retrospective review of 301 consecutive patients from the UK Children's Cancer Study Group, only one asymptomatic patient had evidence of metastasis on bone scan in the absence of other identifiable metastatic disease. Based on these findings, McHugh et al suggest that a routine bone scan may not be justified in patients without symptoms attributable to bone metastases (back or limb pain, limp, or hypercalcemia) or other demonstrable metastatic disease, but may be reserved for older patients or those with high-risk RMS, bone pain, alveolar histology, or poor prognostic sites outside of the head and neck.[132] These findings and recommendations were further supported by Jager et al in their study of 109 soft tissue sarcoma patients.[133] Bone marrow aspirate and biopsy are mandatory for IRS protocols, and bone marrow involvement at diagnosis is a poor prognosticator, with <10% survival. Any bone medullary defects noted on MRI require biopsy, even in the presence of a normal bone scan.[1] Routine CT or MRI of the head to evaluate for metastatic RMS of extracranial origin, required for the IRS IV protocol, is now recommended only for clinically symptomatic patients or those with paraspinal tumors.[134]

Biopsy

Tissue diagnosis of RMS is confirmed by biopsy. Specimens can be obtained either cystoscopically or with a needle biopsy. During endoscopic biopsy, it is preferable to utilize a cold-cup biopsy forceps or cold knife to avoid coagulation-induced histologic artifacts. An ultrasound-guided needle biopsy through the perineum or the extraperitroneal suprapubic route may also be used. Vaginal tumors are diagnosed and biopsied endoscopically; the extent of distortion and/or infiltration of the bladder by the tumor can also be assessed by cystoscopy. Uterine tumors can be biopsied either at the time of vaginoscopy or by performing a cervical dilatation and curettage.

Confer with the pathologist to ensure that ample tissue is obtained in order to identify the histologic

subgroups of RMS and allow adequate grading to direct therapy. Needle biopsies that are performed to establish the diagnosis of RMS must include a sufficient number of cores.

Brahmi et al effectively differentiated RMS from other malignant round blue cell tumors, including Ewing's sarcoma, neuroblastoma, non-Hodgkin's lymphoma, peripheral neuroectodermal tumor, and Wilms' tumor, but not from retinoblastoma on FNA, using nuclear image morphometry.[135]

Suprapubic catheter drainage should not be used in children with RMS who present in urinary retention, to avoid the risk of tumor spread along the suprapubic track. A urethral Foley catheter can usually be used, and can be removed after chemotherapy reduces the tumor and the child is able to void.

Treatment

The outcome of children with RMS has improved dramatically over the past 30 years. Despite more frequently presenting with larger, invasive tumors and positive lymph nodes, children of ethnic minorities have enjoyed similar 5-year failure-free survivals as white children on IRS protocols in the period 1984–1997.[136] In the 1960s when therapy was local in the form of surgery and irradiation, only around one-third of all patients survived.[137] The subgroup of patients with tumors in selected primary sites such as the bladder or the orbit was treated with radical surgery, with 70% survival.[138,139] During the 1960s combined chemotherapy was initiated, with vincristine, dactinomycin, and cyclophosphamide (VAC) yielding promising results.[140,141] These early encouraging results, combined with the heterogeneity and rarity of RMS, prompted implementation in 1972 of the first national cooperative trial.

The IRS committee has reported the results of four consecutive trials, encompassing 3680 patients: IRS I (1972–1978, n = 686), IRS II (1978–1984, n = 999), IRS III (1984–1991, n = 1062),[6,9,10] and IRS IV (1991–1997, n = 883).[142] The results of the fifth consecutive trial IRS V have not been published yet. The estimated 5-year overall survival rates steadily and significantly increased in each of the first three trials: 55% in IRS I, 63% in IRS II, and 71% in IRS III, whereas the fourth trial only showed benefit over prior studies in specific subgroups of intermediate-risk ERMS, with an overall 3-year survival of 86%.[142]

In IRS I, treatment assignment was based on the postsurgical extent of disease, with no stratification for specific risk subgroups. The IRS II study recognized the prognostic significance of certain risk factors (clinical group, site, and histology), and stratified patients accordingly. Patients with primary tumors in 'special pelvic' sites (bladder, prostate, vagina, and uterus) received VAC chemotherapy. The IRS III further stratified patients into nine distinct risk subgroups according to extent of disease, primary tumor site, and histology. IRS IV evaluated new upfront window chemotherapy regimens and the effectiveness of hyperfractionated radiation therapy compared with conventional radiation.[142] IRS V, now also named the Soft Tissue Sarcoma (STS) studies of the Children's Oncology Group, has three primary protocols that are based on the risk of disease recurrence with the overall aims of reducing cyclophosphamide and radiation in low-risk groups, evaluating new regimens for unfavorable disease, and applying molecular studies for occult metastasis. The low-risk protocol will target localized embryonal and botryoid histology patients and will evaluate the efficacy of treating node-negative, favorable-site (GU non-bladder/prostate) clinical group I or II, and unfavorable-site clinical group I ≤ 5 cm with vincristine and actinomycin D, reserving the three-drug VAC regimen for favorable sites with gross residual or positive nodes and unfavorable sites with tumor >5 cm, microscopic residual, or positive nodes. It is also evaluating the efficacy of reduced radiation doses in microscopic residual low-risk disease. The intermediate-risk protocol will compare VAC to VAC alternating with vincristine, topotecan, and cyclophosphamide as the chemotherapeutic regimen in conjunction with radiotherapy and surgery for localized ARMS stages 1–3, ERMS stage 2 or 3 with gross residual, or patients <10 years old with stage 4 ERMS. The high-risk protocol is a phase II trial of irinotecan followed by VAC and radiation, with responders receiving additional irinotecan for stage 4 patients with ARMS as well as patients >10 years of age with ERMS.

Clinical group I

This group consists of children whose tumors were completely resected and who were expected to have an excellent prognosis.[6] In the IRS I trial it was concluded that the 5-year overall and disease-free survival did not change with the addition of radiotherapy to VAC chemotherapy. Therefore, radiotherapy was omitted in children with clinical group I tumors.[9] In this subset of patients, the IRS II study showed that vincristine and dactinomycin chemotherapy (VA) was

equivalent to VAC chemotherapy. The IRS III study showed that the 5-year progression-free survival (PFS) and survival for those treated with VA for 1 year was similar to VAC for 2 years or VA for 2 years.[6] IRS IV treatment protocols, with an increased cyclophosphamide/ifosfamide intensity over IRS III, demonstrated improved 3-year failure-free survival (FFS) in group I and II unfavorable site ERMS from 71% to 86%.[143] Thus, patients with completely resected embryonal histology tumors at favorable sites (GU non-bladder prostate) can be treated safely and effectively with two drugs (VA) for 1 year. Those with bladder/prostate group I should receive cyclophosphamide, potentially at an intensified dose, and those with alveolar or undifferentiated histology should receive radiotherapy in addition to VAC.[143]

Clinical group II

Children in this category usually received postoperative radiotherapy at various time points during treatment, resulting in a local control rate of 90%.[6,9,10] Based on findings of IRS I and IRS II studies, VA with radiotherapy remains the therapeutic standard for children with clinical group II disease who present with a favorable histology tumor in a favorable site. IRS III compared VA + adriamycin and radiotherapy to VA only + radiotherapy. Even though there seemed to be an advantage to adding adriamycin, this was not statistically significant.[6] The Cooperative Soft Tissue Sarcoma Study Group (CWS) reviewed the benefits of radiotherapy for group II patients over four trials in the period 1981–1998. In this study of 203 group II patients, 110 received radiotherapy and 93 did not. Local control rates were 83% with and 65% without radiotherapy ($p < 0.004$), whereas the difference in overall survival was not statistically significant (84% vs 77%). In these studies the distribution of patients with unfavorable histology or sites was significantly higher in the groups that received radiotherapy than in those that did not, and despite this difference, the trends were for better outcome in the groups that received radiotherapy. This group was not able to identify a subset of group II patients in whom radiotherapy may be spared.[144] In IRS IV, which evaluated higher-dose cyclophosphamide as well as ifosfamide and etoposide, the intensified cyclophosphamide therapy from IRS III to IRS IV provided similar survival for patients with local or regional tumors in all IRS IV treatment groups, with a lower overall toxic death rate in IRS IV (1%). However, IRS IV was associated with improved overall survival and FFS than IRS III for the subgroup of patients with intermediate-risk (stage II/III, group 1/2) embryonal RMS (93% vs 76% 3-year FFS).[142]

As part of the Italian Cooperative Study RMS-88, 25 patients with microscopic residual RMS after primary excision were reviewed. Microscopic residuals were difficult to manage because of the lack of a measurable target. Primary re-excision with chemotherapy was the treatment of choice for children <3 years old who could not receive radiation. It was not effective for tumors >5 cm where adequate radiotherapy and chemotherapy were found to be effective.[145]

Clinical group III

This is the largest group of patients enrolled in IRS I, II, and III.[9,10,146] In IRS I, all group III patients were randomized to receive either VAC chemotherapy and radiation, or VAC with doxorubicin (VADRC–VAC) and radiation. Addition of doxorubicin failed to improve the 5-year overall survival.[9] In IRS II, patients were randomized to receive intensified VAC or VADRCV–VA therapy. Prognosis was not different between those two regimens, but the intensified treatments were superior in inducing complete responses and prolonged survival compared with IRS-I.[10] In IRS III, patients were randomized to receive either pulsed VAC or VADRC–VAC–cisplatin or VADRC–VAC–cisplatin–VP16 and radiotherapy. At 5 years, the overall survival rate was the same for all three regimens.[6] Several patients among these study arms received alternate induction chemotherapy with one of three drug pairs (doxorubicin–dacarbazine, dactinomycin–VP16, or dactinomycin–dacarbazine) and second-look surgery.[6,146] Outcome of these children was improved compared with that of patients who were treated in IRS II. In IRS IV, regimens including ifosfamide and etoposide and higher cyclophosphamide doses than in IRS III resulted in similar outcomes for group III patients among the IRS IV treatment groups and between IRS III and IRS IV. The standard remains VAC and radiation therapy for these patients.[142] However, whereas unfavorable-site group III patients demonstrated no improvement in survival on IRS IV compared with IRS III, the subset of group III or resectable node-positive ERMS with a GU non-bladder/prostate primary improved from 72% to 92% 3-year FFS.[143]

Clinical group IV

With the exception of a subset of intermediate-risk patients (<10 years old, embryonal), the 5-year survival

for patients with metastatic disease continues to be poor, in spite of intensified therapy and new drug combinations. The combined-agent regimens in the first three IRS studies led to 5-year overall survival and PFS rates of below 30%.[6,9,10]

In a pilot study for IRS IV, doxorubicin and ifosfamide were used in an upfront window prior to VAC for metastatic RMS, resulting in an ultimate complete response rate of 53% and one-third survival, similar to prior regimens. Factors in this study contributing to a better prognosis included age <10 years old, embryonal histology, a GU primary, lack of nodal disease, and absence of bone or bone marrow metastasis.[147] IRS IV evaluated the effectiveness of an upfront window of ifosfamide and etoposide (IE) compared with vincristine and melphalan (VM) for metastatic presentations. This initial therapy was followed by VAC, surgery, and radiotherapy and then a repeat of VM or IE in initial responders. Whereas initial response in both groups was high, overall survival was better in the IE group, with 3-year FFS and overall survival of 33 and 55% in the IE group compared with 19 and 27% for the VM group, respectively.[148] Retrospective multivariate analysis of 137 group IV patients enrolled in IRS IV identified the presence of two or fewer metastatic sites as a predictor of survival. The subgroup with embryonal histology and two or fewer metastatic sites demonstrated a 3-year FFS of 40% and overall survival of 47%, compared with 25% and 39% for all patients studied. The authors suggest that this subgroup, whose survival approaches that of selected patients with nonmetastatic disease, might not be appropriate candidates for consideration in highly toxic or unproven antitumor investigational regimens.[149]

Topotecan in an upfront window prior to VAC and continued for responders, in 48 patients with metastatic RMS, resulted in a 46% overall response rate with an acceptable toxicity profile; in particular, efficacy was greater against ARMS than ERMS (65% vs 28% response, $p = 0.08$).[150]

IRS V is investigating new drugs such as irinotecan and topotecan.[126] It is also exploring the role of surgery after induction chemotherapy (12 weeks for most group III patients) as a strategy to reduce local failure risk. The decision for resection is determined by chemotherapy response, and whether form and function can be preserved. If such surgery is performed, postoperative radiotherapy is required, with doses determined by resection margin status: gross residual 50.4 Gy; microscopic residual 41.4 Gy; and clear margins 36 Gy.[151]

The European Collaborative Studies MMT4–89 and MMT4–91 failed to demonstrate a statistically significant improvement in 3-year event-free survival comparing consolidative megatherapy (high-dose chemotherapy and stem cell rescue) and standard chemotherapy (30% vs 19% of 53 and 44 patients) in the treatment of metastatic disease.[152] The lack of benefit of this modality was further verified by Weigel et al, who completed a meta-analysis of 389 metastatic RMS patients treated with high-dose chemotherapy and stem cell rescue; this treatment conferred no survival advantage for stage IV patients compared with IRS II and III.[153]

A novel treatment strategy for these patients includes immunotherapy. Research at the National Cancer Institute has demonstrated that blocking the IGF-1 receptor using the antibody α-IR-3 can inhibit RMS cell proliferation.[154]

Special pelvic tumors

Early on in the IRS studies, it became apparent that certain pelvic tumors (bladder, prostate, vagina, and uterus) responded better to therapy than other sites. The 5-year overall survival rate in this group of patients was 74%. However, this outcome was achieved at the expense of numerous bladder extirpations for patients with GU tumors, and only 23% of the patients had functional bladders 3 years after therapy.[155] In IRS II, the treatment strategy changed to primary chemotherapy with 4 months of VAC followed by delayed radiation and/or surgery. This treatment approach failed to improve the bladder salvage rate, with a 3-year bladder retention rate of only 25% and a survival rate similar to IRS I.[156,157] In IRS III, patients in clinical group III received an either intensified VADRC–VAC regimen + cisplatin to induce a complete response. Second-look surgery was recommended at 20 weeks. Alternate induction therapy with dactinomycin alone or dactinomycin and VP16 was initiated if tumor remained. The 3-year bladder preservation rate (60%), 5-year PFS estimate (74 ± 5%) and overall survival (83 ± 4) were strikingly superior to those of IRS I and IRS II.[6,9,10]

The extent of surgical intervention in RMS of the bladder, vagina, and prostate remains controversial. In a series of 15 patients with tumors confined to one of these three organs, Fisch et al have shown that, after chemotherapy, radical operative intervention with multiple biopsies at the resection margins permits complete tumor resection with excellent long-term results.[158] This radical operative approach is in

contrast to the IRS protocol. The main advantage of this treatment protocol is that radiotherapy – which is often used in conjunction with organ-sparing surgery, and can be associated with severe complications, including radiation-induced cystitis and impaired growth of the pelvic bone – is avoided.[3] Fichtner and Hohenfellner reported a 10% rate of radiation-induced cystitis when radiation was used alone and 30% when it was used in conjunction with chemotherapy.[159]

Bladder/prostate

Prior to multiagent chemotherapy, bladder/prostate RMS was treated with radical cystectomy or pelvic exenteration. Encouraging results with primary chemotherapy have prompted a paradigm shift toward organ preservation when possible without negatively impacting long-term survival.

Heyn et al reviewed the outcome of 28 patients with group III bladder RMS. All received 20 weeks of multiagent chemotherapy and 4 weeks of radiotherapy. Of these, 13 underwent cystectomy. Cystectomy specimens demonstrated diminished tumor cells with varying degrees of maturation. They concluded that primary bladder RMS is very responsive to chemotherapy and radiotherapy, and that these tumors show further maturation following treatment, thus allowing preservation of larger proportions of bladders with residual disease.[119] Similarly, Lobe et al examined the role of conservative surgery in localized prostatic RMS and have shown a high cure rate with relatively good bladder salvage rate without aggressive early surgery.[160]

Arndt et al reported the results from the IRS IV study. They reviewed the records of 88 patients with non-metastatic bladder/prostate RMS. Tumors commonly arose in the bladder (70%) and had favorable histology (80% embryonal or botryoid). Of these tumors, 69% were >5 cm in diameter, 84% were group III, and 56% were invasive T2 tumors. The survival rate at 6 years was 82%, and event-free survival at 6 years was 77%. Of all the patients entered in the study, 40% (36/88) survived event free, with apparently normal functioning bladders. The authors state that more precise long-term evaluation of bladder and sexual function will be required using such tools as urodynamic studies and validated patient surveys.[161]

In an outcome analysis of 13 patients with lower urinary tract RMS at the Hospital for Sick Children in Toronto, the authors proposed a strategy of induction chemotherapy followed by surgical excision and reconstruction without radiotherapy, which provided a high cure rate without the late sequelae of pelvic radiotherapy.[162] The survival rate in this small group of patients was 80%. They suggested reserving radiotherapy for residual and metastatic disease and for patients with unresectable disease and those with microscopic disease. Their approach included performing re-excision should microscopic disease be found in the final pathology report.

Arndt et al reviewed bladder function retention with a bladder preservation approach in patients with non-metastatic bladder or prostate RMS enrolled in IRS IV.[161] Of 90 patients, 88 had sufficient information for review, with most tumors in the bladder, large, favorable histology, unresectable, and invasive. All received alkylating-based chemotherapy, and 74 received radiation. As one of the goals of the protocol was organ preservation, initial radical resection was not recommended. Patients underwent initial biopsy with initial complete resection only if organ preservation was possible, with extirpation reserved for biopsy-proven residual after completion of therapy, or progression of disease and early treatment failure after chemotherapy and radiotherapy, Overall and event-free survival rates at a median follow-up of 6.1 years were 82% and 77%, respectively. Events included three second malignancies, one toxic death, and 18 relapses (14 (78%) deaths with relapse). Bladder preservation without relapse was achieved in 55 patients, 40% of whom had normal bladder function defined as lack of incontinence, dribbling, hydronephrosis, or enuresis after age 10 years at a median follow-up of 9 years. The authors advocated conservative delayed surgery in this group of patients and recognized the need for continued long-term evaluation of bladder function in these patients as radiation treatment may have late effects.

Female genital tract

From 1972 to 1996, with the advent of effective chemotherapeutic regimens, the rate of surgical tumor resection for vaginal/uterine RMS decreased from 100% to 13%. Management with chemotherapy and restrictive surgery has demonstrated excellent long-term survival and frequent uterine preservation. Arndt et al reviewed the 151 patients with RMS of the female genital tract out of the 4272 enrolled in IRS I–IV with RMS. Overall 5-year survival was 82%. Chemotherapy was primarily VAC based. Local control was surgery alone in 42%, surgery and radiotherapy in 19%, biopsy and radiotherapy in 12%, and

biopsy without radiotherapy in 21% (no local therapy). Many patients with primary vaginal tumors received delayed radiotherapy or had it omitted with excellent outcome. Hysterectomy rates decreased from 48% in IRS I–II to 22% in IRS III–IV, with an increase in radiotherapy from 23% in IRS II to 45% in IRS IV. There was no significant difference in survival over the course of the four trials for patients with localized embryonal/botryoid tumors. Prognostic factors included improved prognosis for age 1–9 years, embryonal histology, N0 disease, non-invasive tumors, and the use of IRS III or IV treatment protocols. Patients outside of the 1–9 year age range particularly benefited from the intensified treatment of IRS III or IV (5-year survival 67% IRS I–II vs 90% IRS III–IV); 43% of deaths of patients with group I–III tumors were from toxicity. Unlike RMS at other sites, in this subgroup of patients, 67% of those who developed recurrent disease were salvaged with multimodal treatment, including chemotherapy, surgery, and radiotherapy if not previously received. The authors recommend continued use of primary chemotherapy of VA for group I or II embryonal RMS and VAC for group III disease, with individualized local treatment plans based on tumor site and histology. Non-embryonal female genital tract RMS should receive intensified chemotherapy, as they are of intermediate recurrence risk. Delayed radiotherapy is recommended for selected patients, such as those with positive margins after chemotherapy and local surgery, those with vulvar embryonal group II or III tumors, and all those with embryonal lesions who are lymph node positive.[163]

Unfavorable histology clinical groups I and II tumors

The poor outcome for children with clinical group I alveolar tumors was recognized in IRS I.[9] All these children therefore received intensive VAC chemotherapy in IRS II. This treatment modification increased the 3-year disease-free survival rate from 43% to 69%.[10] In IRS III, therapy was further intensified with the use of a VADRC–VAC–cisplatin-containing regimen. The 5-year PFS (71 ± 6%) and overall survival (80 ± 6) rates were significantly improved over those for comparable patients treated on IRS II protocols.[6]

Despite using an intensified chemotherapy regimen in IRS III compared with the first two studies, patients with unfavorable histology (alveolar or undifferentiated) who did not receive radiotherapy fared worse than those who received radiotherapy in this study or historically. Pooled data from IRS I, II, and III on all undifferentiated and alveolar RMS demonstrated that radiotherapy was associated with improved FFS (73 vs 44%, 10 years; $p = 0.03$), with fewer local, regional, and distant relapses.[54] In a review of IRS I, II, and III group 1 patients, Wolden et al identified that tumors >5 cm and alveolar histology were associated with poorer FFS. GU primary site conferred both an overall survival and FFS advantage for embryonal RMS but not for alveolar RMS or undifferentiated sarcoma.[164] IRS IV found no improved survival in alveolar histology compared with IRS III.[142]

Local therapy: results of multi-institutional trials

Although RMS is a chemosensitive tumor, drugs alone cannot cure most children who have this disease. Surgical resection alone or in combination with irradiation is necessary for local control of the tumor, which is essential as nearly half of those children who die of this tumor fail at the primary site.

Radiotherapy

Radiotherapy has been used to eradicate residual microscopic or macroscopic tumor cells following surgery or chemotherapy. In response to the results of several trials, radiotherapy doses now vary according to the patient age, tumor site, and amount of residual tumor.[165]

Intensified chemotherapy and second-look surgery have decreased the use of radiotherapy and extensive primary surgery for patients with vaginal and vulvar RMS.[166] In addition, the use of early radiotherapy, aggressive chemotherapy, and second-look surgery has dramatically decreased the use of radical surgery to treat children with genitourinary RMS.[6,166]

Currently, microscopic residual disease is treated with 40 Gy of radiation to the tumor bed and a 2 cm margin. In IRS IV, radiotherapy of completely resected tumors with unfavorable features (large size, unfavorable site, nodal involvement) was mandated, with gross residual disease requiring higher doses of 45–55 Gy, depending on the site and size of the tumor.[5,44]

Further, to increase local control and decrease the acute and late adverse effects of radiotherapy, IRS IV evaluated hyperfractionated radiotherapy in patients with unresectable or metastatic disease. A total of 559 patients with group III RMS were enrolled, of which

490 were eligible for randomization. Of these 239 were randomized to hyperfractionated radiation therapy and 251 to conventionally fractionated radiotherapy. There was no statistical difference in overall survival or FFS between the two radiation treatment methods, and no difference between the two treatment groups when analyzed for age, gender, tumor size, invasiveness, nodal status, histology, or primary site. The recommendation from the analysis is that the standard of care for group III RMS remains chemotherapy and conventionally fractionated radiation therapy.[149]

Surgery

Surgical approaches to the treatment of RMS have also been influenced by the multi-institutional studies. Nodal involvement is very common among patients with GU tumors; therefore, nodal sampling should be considered at the time of initial staging.[124,167] If performed within 35 days of the primary procedure, surgical re-excision may benefit patients with microscopic positive residual tumor; however, such re-excision may be difficult with the lack of a measurable target.[145,162,168]

Summary

IRS III trials in patients with group III special pelvic primary tumors (bladder, prostate, vagina, and uterus) clearly demonstrated that these patients benefited from the more complex therapy. Addition of doxorubicin (ADR) and cisplatin (CDDP), with or without second-look surgery, or dactinomycin (AMD) + VP16 to VAC improved outcome as compared with the results with VAC with or without second-look surgery in IRS II (83% vs 72% 5-year survival rate). Of the 90 patients who achieved complete response (CR), 29% (26/90) were rendered tumor free by second-look surgery. They also concluded that the introduction of radiotherapy in patients with tumors in the bladder neck/trigone or prostate may have had a favorable impact on outcome. Finally, there was a more than doubling of the bladder salvage rate, which was attributed to the more intensive therapy used in IRS III.

Figure 60.4 summarizes the protocol for low-risk genitourinary RMS in the present IRS trial.

Chemotherapeutic agents

Doxorubicin

IRS I, II, and III randomized group III and IV tumor patients to VAC with or without doxorubicin with similar radiotherapy. No benefit to doxorubicin was detected.

Cisplatin and etoposide

IRS III evaluated VAC vs VAC–doxorubicin + cisplatin vs VAC–doxorubicin–cisplatin + etoposide, with all patients receiving radiotherapy. There was no benefit of any of the additional agents over VAC alone.

Ifosfamide

Severe acute renal tubular toxicity was noted for ifosfamide when combined with carboplatin in children with sarcomas compared with ifosfamide alone or with cisplatin, whereas combination use with cisplatin was associated with delayed renal tubular toxicity.[169] Skinner et al identified risk factors associated with nephrotoxicity from ifosfamide in 148 young sarcoma patients. Reduction of risk for nephrotoxicity was noted with doses <84 g/m,^{2} whereas doses >119 g/m^2 were associated with a very high risk of severe toxicity.[170]

Melphalan

Melphalan is active in previously untreated RMS and was combined with vincristine in IRS IV in comparison with ifosfamide–etoposide and ifosfamide–doxorubicin (DOX) for metastatic disease in an upfront window. Despite high response rates, the melphalan group required more dose reduction of cyclophosphamide and had higher rates of secondary malignancy and inferior overall survival.[126,148]

Topotecan

Chastagner et al reported that topotecan potentiates the radiation response of two different human RMS tumors xenografted into nude mice. Five days of concomitant topotecan and radiotherapy had a synergistic therapeutic effect, with the efficiency of the combined regimen resulting in similar effect at a radiation dose of 20 Gy to the 40 Gy of radiation alone.[171] Topotecan administered to 40 patients with stage 4 RMS resulted in a 45% complete and partial response rate.[126] Fifteen patients with recurrent or refractory RMS were treated with a combination of topotecan and cyclophosphamide, with 10 achieving a partial or complete response.[172]

Investigational

Differentiation therapy is a novel approach for cancer treatment in which the principle is to transform

malignant cells into mature cells and decrease side effects of classical chemotherapy such as drug resistance and cytotoxicity. This technique has shown in-vitro effectiveness using GR-891 and QF-3602, 5-fluorouracil acyclonucleoside derivatives, against RMS cell lines, by inducing terminal myogenic differentiation with no cytotoxicity, increased adhesion capability, and no induction of *MDR1*, a gene that induces multidrug resistance.[173,174]

Antiangiogenesis therapy is a novel treatment approach of great research interest. The angiogenesis stimulators, vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and interleukin-8 (IL-8), have all been identified as products of ERMS, and effective antiangiogenic therapies may require multiple drugs to target several angiogenic factors.[175] Landuyt et al induced tumor necrosis in subcutaneous RMS in rats using the angiogenesis inhibitor TNP-470, with both tumor volume and drug dose affecting treatment outcome and therapy found to be potentially useful in treating progressive tumor growth and large tumors.[176] Antibodies to VEGF have been shown to decrease growth of RMS cell lines; however, there is up-regulation of host VEGF in response to hypoxia, indicating a need to completely block VEGF for maximum tumor inhibition.[177] VEGF and VEGF receptor 2 (fetal liver kinase 1 (Flk-1)) play a role in tumor angiogenesis. Dc101, an anti-Flk-1 antibody, in conjunction with doxorubicin demonstrated greater antitumor activity in RMS cell lines xenografted in immunodeficient mice than doxorubicin alone.[178]

An alternative method of targeting tumor-specific vascularization is antivascular therapy, which would target inadequate and ill-structured tumor vasculature. Combretastatin A4 phosphate is an antivascular drug that when administered systemically to rats induced growth delay in solid RMS with a greater effectiveness with larger tumor volume.[179] As opposed to small or medium tumors, large tumors had a better response with the addition of radiotherapy to combretastatin A4 phosphate. The addition of the antiangiogenesis drug TNP-470 demonstrated no added therapeutic effect.[180]

Late effects of therapy

Because of the improved long-term survival and the use of intensified chemotherapeutic regimens, several serious and potentially life-threatening therapy-related complications have emerged. In IRS IV pilot studies, the incorporation of ifosfamide into front-line therapeutic protocols for children with unresectable tumors was associated with a 14% incidence of renal toxicity. Factors that contributed to that toxicity included high doses of ifosfamide (>72 g/m^2), age younger than 3 years, and pre-existing renal abnormalities such as hydronephrosis.[181,182] Toxicities for the final IRS IV trial included >90% myelosuppression, 55% severe infections, and only 2% severe renal toxicity. Toxic deaths were highest in the VAC regimen in patients with pre-existing renal abnormalities (3/56), with rates for other regimens <1% (neutropenia with septicemia = 6, metabolic = 1, and other = 1).[142]

Of the 109 patients with bladder and prostate tumors who were treated in IRS I and II, 29% developed post-therapy hematuria, 29% showed evidence of delayed pubertal development, and 10% had growth retardation.[183]

The occurrence of second malignant neoplasms is one of the most devastating sequelae of successful contemporary therapy. Of the 1770 patients enrolled in IRS I and II, 22 developed second malignant neoplasms (10-year cumulative incidence rate of 1.7%). The most common malignancies were bone sarcomas (n = 11) and acute non-lymphoblastic leukemia (n = 5). The median time to development of these neoplasms was 7 and 4 years, respectively.[184] In the IRS III trial, acute myeloid leukemia occurred in 5 of the 1062 patients enrolled. All of the patients received the alkylating agent cyclophosphamide, and four received etoposide. The median time to development of acute myeloid leukemia was 39 months; median follow-up was 3.7 years.[185] IRS IV had 10 second malignancies in the initial report (myelodysplastic syndrome/acute myeloid leukemia = 4, acute lymphoid leukemia = 1, lymphoblastic lymphoma = 1, osteogenic sarcoma = 1, leiomyosarcoma = 1, undifferentiated sarcoma = 1, and primitive neuroectodermal tumor = 1), for a 3-year cumulative risk in locoregional disease on IRS IV of 2%.[142] A large review of secondary malignancies in long-term survivors of childhood RMS was performed by Scaradavou et al.[186] They reported on 130 patients, with a median follow-up of 9 years. Seven patients (5.4%) developed secondary malignancies, including three with acute non-lymphoblastic leukemia and four with solid tumors. This study identified an increased risk of secondary neoplasms in patients receiving the chemotherapeutic agents carmustine and doxorubicin. They did not find radiotherapy to be a significant risk factor in contrast to the findings from the Late Effect Study Group, which reported an increased incidence of secondary neo-

plasms within prior radiation fields. Additionally, there are case reports in the literature of other secondary malignancies after RMS treatment, including adenocarcinoma of the colon associated with radiation colitis 13 years after treatment for bladder RMS, bladder transitional cell carcinoma 8 years after cyclophosphamide for ERMS, and Hodgkin's disease after childhood RMS therapy.[187]

Residual disease

Residual disease after treatment is a risk factor for local recurrence. Differentiation of residual tumor from fibrosis can be very difficult on CT and MRI. Positron emission tomography (PET) scanning with fluorodeoxyglucose (FDG), which has been found to have a high uptake in many different tumors, may help with this differentiation in the future. These techniques may also be useful in screening for metastatic disease.[132]

Recurrence

Review of IRS I–III for group 1 patients found 86/439 patients relapsed, with median follow-up of 12.9 years for IRS I, 9.1 years for IRS II, and 4.6 years for IRS III. Relapses in these patients occurred within 1 year in 48% and 3 years in 93% of patients, while two patients relapsed as late as 10 years after diagnosis.[164] In IRS III, the estimated 5-year cumulative incidence of local failure was 19%, regional nodal was 2%, and distant recurrence was 11%. Lymph node involvement at diagnosis was the single factor most predictive of increased total local failure risk (5-year cumulative incidence of 32%), compared with children with negative nodes or unknown node status (16%). The 5-year FFS and overall survival rates were 70% and 78%, respectively.[151]

IRS IV had a 3-year estimated cumulative incidence of local, regional, and distant failures of 10%, 4%, and 7%, respectively.[142] Retrospective analysis of survival for 605 patients after relapse in IRS III and IV revealed that 5-year survival depended significantly on histology (64% of botryoid, 26% of embryonal, and 5% of alveolar). Within the embryonal group, stage and group at presentation affected probability of relapse survival (52% stage 1/group I; 12% stage 4/group IV), but the type of relapse was only influential in initial stage 1/group 1 disease, with local relapse survival 72% and distant 30%. Relapse in alveolar RMS was associated with better survival after an initial group 1 tumor compared with other initial presentations despite location of recurrence (40% vs 3%).[188]

From the IRS trials III, IV, pilot and IV, the 10-year late event (disease recurrence, second malignant neoplasm, or death from other causes) rate was estimated at 9%. The estimated cumulative incidence of the specific subtypes of failures at 5 and 10 years were 2.4% and 2.7% for recurrence, 1.9% and 2.4% for second malignant neoplasms, and 0.8% and 3.5% for death as a first event, respectively. Patients with both advanced disease (group III/IV) and large primary tumors at diagnosis (>5 cm) were at the highest risk for late events. The probability of a late event in that high-risk group of patients was 19%.[189] Relapse in ARMS continues to have a dismal clinical outcome, prompting ongoing evaluation of novel therapies. Dagher et al evaluated the effectiveness and toxicity of a peptide pulsed vaccination targeting the breakpoint region of fusion proteins administered concomitantly with continuous IL-2 infusion. Treatment did not alter the poor outcome for all 16 translocation positive Ewing sarcoma and ARMS patients who continued to have progressive disease after immunization. All patients in this trial were significantly immunocompromised and had large bulky tumors.[190]

Conclusion

The advances in understanding the biologic and genetic features of RMS, as well as the development and scheduling of new drugs, have improved the survival of these children. However, several challenges still remain. These include the refinement of risk-directed therapy based on the understanding of newly recognized biologic and clinical features. The use of newly developed hematopoietic growth factors will allow dose intensification, which may offer improvement in children with metastatic or recurrent disease. Finally, genetic abnormalities such as translocation (PAX3–FKHR and PAX7–FKHR) in alveolar tumors may provide molecular targets for future therapies.

Other pelvic tumors

Transitional cell carcinomas

Bladder tumors rarely occur in the first two decades of life and are commonly of mesodermal origin. These are low-grade transitional cell carcinomas that seldom recur.[191–197] Some of these tumors occur secondary to cyclophosphamide therapy.[146,198–201] In more than 90% the lesions are solitary. Pathologically, 80% of

these tumors are grade I or papilloma, 20% are grade I–II tumors, and only 3% are invasive through the lamina propria. The recurrence rate is low (2–5%).

Presenting symptoms include gross hematuria in 80% of the patients, irritative voiding symptoms or recurrent urinary tract infections in 15%, and microscopic hematuria in 8% of patients.[202]

The initial diagnosis can be made by ultrasound, which in some series was found to be 100% sensitive. Intravenous pyelography and CT scans may not be able to detect small tumors. Cytologic evaluation is of limited value, as most of these tumors are low-grade transitional cell carcinoma.[191,202]

Cystoscopy allows definitive diagnosis, staging, and treatment of these tumors. Its role in surveillance remains ill defined, particularly because it requires general anesthesia and because the risk of recurrence is low.

Nephrogenic adenoma of the bladder

This rare, benign lesion of the bladder occurs as an epithelial response to infection or trauma. It presents as a papillary lesion resembling a low-grade, low-stage transitional cell carcinoma.[203–206] There is a significant predominance of girls to boys (5:1). The medical history in all cases is remarkable for previous bladder surgery or inflammation. This benign lesion is believed to represent urothelial transformation in response to trauma or inflammation.[203]

Most children present with unspecific symptoms of gross hematuria, dysuria, and bladder instability. Final diagnosis is established after cystoscopy and histopathologic review of a tumor biopsy specimen. Tumor recurrence develops in 80% of the children, with a latency period of 4 years. Therapy consists of transurethral resection, long-term antibiotic therapy, and periodic cystoscopy.[203–206]

Leiomyosarcoma

These tumors are rare in the pediatric age group and account for <2% of all soft tissue sarcomas; their diagnostic features and biologic behavior appear similar to those in adults. The most important features in assessing malignant potential are tumor size and mitotic counts. Local excision usually provides adequate therapy.[207–210]

Urachal adenocarcinoma

This very rare tumor accounts for only 0.17–0.34% of all bladder neoplasms. It usually occurs in adults, but there are several reported cases in children. This mucin-producing or colloid adenocarcinoma arises from the juxtavesical segment of the urachus and invades the bladder. The presenting symptoms are hematuria and bladder irritative symptoms. The primary treatment is surgical resection. The prognosis is poor because its location predisposes to extensive local spread before detection and diagnosis.[211,212]

Adenocarcinoma of the extrophied bladder

This tumor occurs more frequently in adults than in children. It occurs in patients who have not had bladder reconstruction and is rarely found in a reconstructed bladder.[213–223]

Pathologically, the epithelial lining of the bladder is replaced with colonic epithelium. The histochemistry comprises cells containing colon-specific mucin and carcinoembryonic antigen. In many of these tumors dysplasia of the colonic epithelium is found, with an area of colonic exophytic adenocarcinoma.

Mesonephric adenocarcinoma of the female genital tract

This rare and highly malignant tumor can occur at any age. Approximately 30% of such tumors occur in children. Evidence that these tumors originate from the mesonephric (wolffian) rests includes their tubular structure and their occurrence along the tract of the mesonephric duct or its remnants (vagina, cervix, uterus, and salpinx). The clinical, gross pathologic, and radiographic presentations of vaginal mesonephric carcinomas may be indistinguishable from those of ERMS. The presenting symptoms are vaginal bleeding or a vaginal mass. Radiographic features are similar to RMS and include grape-like clusters of tumor nodules within the vagina. Treatment includes radical excision, radiotherapy, or both.[224–226]

Clear cell adenocarcinoma of the vagina or cervix

Maternal diethylstilbestrol (DES) prior to 18 weeks' gestation has been strongly implicated in the etiology of this tumor. The age of the DES-exposed patients has varied from 7 to 34 years old, with the highest frequency from 14 to 22 years old. The risk among the exposed is in the order of 1 in 1000.[227–229]

The rarity of this tumor among exposed women suggests that DES is not a complete carcinogen but that some other factors are also involved in the pathogenesis of clear cell adenocarcinoma of the vagina and cervix.[229–236]

Cavernous hemangiomas of the bladder

This hamartoma is a rare benign tumor of the bladder that usually presents with macroscopic hematuria. In about 30% of cases, the bladder tumor is associated with angiomatous lesions in other parts of the body. The diagnosis may be suspected on ultrasound examination but it is generally made at cystoscopy.[237–240] Blood-pool scintigraphy using technetium 99m (^{99m}TC) human serum albumin combined with DTPA usually reveals an area of increased activity in the bladder.[241] Biopsy and transurethral resection must be avoided because of the risk of hemorrhage. Laser treatment of hemangiomas has been reported and should be the initial management.[241] Should laser coagulation fail, partial cystectomy appears to be the most effective method of treatment.[239,242]

Exstrophy and epispadias

61

Linda A Baker and Richard W Grady

Introduction

The exstrophic diseases, referred to collectively as the exstrophy–epispadias complex,[1] are considered a spectrum of embryologic malformations related by certain principal anatomic features. This complex includes:

- Epispadias – the urethra is a partial or complete open plate on the dorsal surface of the phallus.
- Classic bladder exstrophy – the bladder is an open plate on the low abdominal wall and the urethra is epispadic.
- Cloacal exstrophy – the bladder and the ileocecal junction of the bowel are an open plate on the low abdominal wall associated with other malformations.
- Exstrophy variants – partial manifestations are seen of the above malformations.

Formal historical descriptions of exstrophy date back to at least 1597 with Sherk Von Grafenberg's description of this congenital defect; possible depictions of exstrophy also exist on Assyrian tablets from 2000 BC. Chaussier first coined the term 'exstrophie' to describe this defect in 1780 following detailed descriptions of it by Mowat in 1748. Because exstrophy can be a non-lethal defect, its natural history is known and has been well described. Since the 19th century, various efforts to manage exstrophy have been described. Because exstrophic conditions are rare, these approaches were empiric and often unsuccessful. Until the 20th century, no effective surgical remedy was available to consistently ameliorate the morbidity associated with bladder exstrophy.

As we enter a second century of surgical care of the child affected by bladder exstrophy, epispadias, or cloacal exstrophy, a review of this history is a triumphant story for pediatric urology and pediatric surgery alike. These birth defects represent some of the most complex that pediatric urologists manage Although great strides in management have been made, many challenges still exist.

Anatomic pathology

Bladder exstrophy

Brock and O'Neill described exstrophy as 'if one blade of a pair of scissors were passed through the urethra of a normal person; the other blade were used to cut through the skin, abdominal wall, anterior wall of the bladder and urethra, and the symphysis pubis; and the cut edges were then folded laterally as if the pages of a book were being opened.'[2] (Figure 61.1)

Anatomic features of exstrophy include the presence of a layer of urothelium on the anterior abdominal wall representing the bladder and urethra. At birth, the urothelium is usually normal in appearance. However, ectopic bowel mucosa or polypoid lesions consistent with cystitis cystica and/or glandularis may be present. If left untreated and without meticulous protection after birth, the exposed urothelium will undergo squamous metaplasia in response to acute and chronic inflammation. Other inflammatory changes such as cystitis cystica and/or glandularis will also be seen.[3] When left chronically exposed to the environment, the areas of squamous metaplasia often undergo malignant degeneration to adenocarcinoma or squamous cell carcinoma.[4,5]

Associated anomalies

Classic exstrophy and epispadias have a relatively low incidence of associated anomalies. In contrast, patients with cloacal exstrophy have associated anomalies more often than not.[6,7] These anomalies can

Figure 61.1 Newborn boy with classic bladder exstrophy. Note evidence of anterior placement of the bladder and epispadic urethra.

affect the upper urinary tract, intestines, skeletal system, and neurologic system.

Kidneys and upper urinary tract

Renal anomalies can occur with bladder exstrophy but they are not characteristic. Associated renal abnormalities include cystic dysplasia, ureteropelvic junction (UPJ) obstruction, pelvic kidney, megaureter, renal hypoplasia, and horseshoe kidney.[8] In contrast, vesicoureteral reflux (VUR) occurs almost universally after exstrophy closure owing to the lateral placement of the ureters on the bladder plate in association with the lateral and inferior approach of the ureters into the bladder.

Genitalia

In males the penis is broad and shortened because the corpora cavernosa are splayed laterally, attached to the separated pubic bones. The penis is deflected dorsally and may have true intrinsic dorsal chordee

Figure 61.2 Newborn boy with classic bladder exstrophy. The phallus is pulled downward. The white arrow indicates the posterior urethra and location of verumontanum.

(Figure 61.2). Because of the varying degree of diastasis associated with exstrophy, the penis appears variably foreshortened. Further, magnetic resonance imaging (MRI) evaluation of the penile length of adult male exstrophy and epispadias patients reveals that the total corporeal length is significantly shorter than in a control population. This corporeal shortening apparently results from a foreshortened anterior segment (distal to the pelvic attachment); the posterior corporeal segment is unaffected in exstrophy patients (Figure 61.3).[9] It seems that in most cases, the length of the penis and the size of the exstrophic bladder plate are inversely related.

The short urethral plate also creates the appearance of the glans penis lying in close approximation to the prostatic utricle. The ejaculatory ducts empty at the prostatic utricle exposed on the urethral plate. The vas and ejaculatory ducts are probably unaffected in classic exstrophy unless iatrogenically damaged.[10] Innervation to the penis is also preserved. The cavernosal nerves are located on the lateral aspects of the corporeal bodies. In the normal situation, these nerves can be found on the dorsal aspect of the penis after they traverse the posterolateral aspects of the prostate and the membranous urethra.[11] The prostate is also incompletely formed in exstrophy.[12,13] The scrotum is usually not affected, although most exstrophy patients have an increased distance between the base of the penile shaft and the scrotum and a broadening of the scrotum dependent on the degree of diastasis. The testes may be undescended. Because of the underlying bladder neck anomalies, exstrophic males may have impaired fertility. A particular problem is retrograde

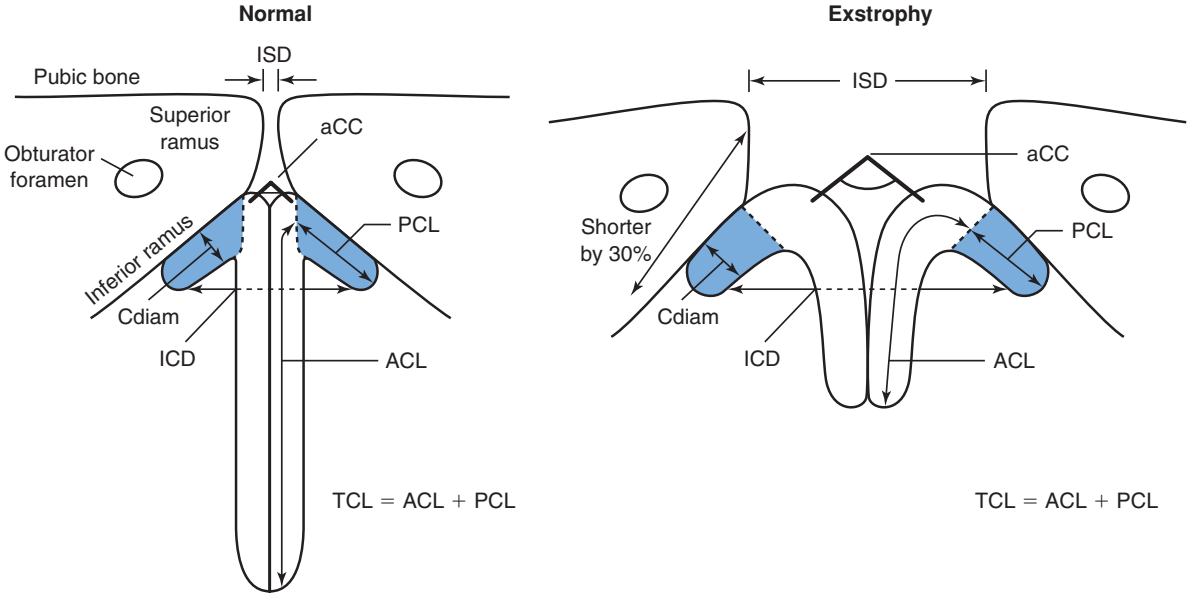

Figure 61.3 Penile and pelvic measurements in normal men and patients with exstrophy. ISD, intersymphyseal distance; aCC, corpora cavernosa subtended angle; Cdiam, corpus cavernosum diameter; PCL, posterior corporeal length; ICD, intercorporeal distance; ACL, anterior corporeal length; TCL, total corporeal length.[9]

ejaculation if the bladder neck cannot close completely following bladder reconstruction.[14–16]

In the female with bladder exstrophy or female epispadias (Figure 61.4), the mons pubis is absent. In association with a bifid clitoris, the anterior labia are laterally displaced although they fuse in the midline posteriorly. The vagina and introitus are also displaced anteriorly from their usual position. The vaginal opening may be stenotic in these patients but we have not found this to be a characteristic feature. Stenosis can result from improper primary closure. Internal female genital structures (uterus, cervix, fallopian tubes, and ovaries) are unaffected in classic exstrophy. Uterine prolapse as a result of deficient pelvic floor support can occur in the older exstrophy patient and poses particular problems with pregnancy.[17] Early primary bladder reconstruction with pelvic closure may decrease this risk. Uterine suspension procedures such as sacrocolpopexy can be employed in these situations as well.

Figure 61.4 Female epispadias in a 5-year-old. Chronic perineal skin changes are due to lifelong frank urinary incontinence. Note the depressed mons pubis, bifid clitoris, outwardly rotated labia minora, and open gaping urethral meatus just above the vaginal introitus.

Anorectal and intestinal abnormalities

The anus is often located anteriorly in the exstrophy complex. Surgical procedures involving these patients should preserve the anal sphincter mechanism. However, a few exstrophic patients will have insufficient anal continence due to the underlying abnormalities of the pelvic floor support structures including the levator ani and puborectalis muscles. Anal sphincter weakness impacts not only fecal continence but also limits the use of ureterosigmoidostomy and its variants; i.e. rectal bladder, ileocecal ureterosigmoidostomy, etc. In untreated patients rectal prolapse can also occur owing to insufficient pelvic floor support.

Figure 61.5 Plain abdominal radiograph demonstrating pubic diastasis in a patient with bladder exstrophy.

This is usually definitively treated with formal exstrophy repair that corrects the lack of anterior pelvic support. In the interim, most rectal prolapse is intermittent and reducible.[1]

Skeletal abnormalities

Diastasis of the pubic symphysis occurs as part of the exstrophy complex (Figure 61.5). This results from outward rotation of the innominate bones along both sacroiliac joints. Outward rotation of the pubic rami at the iliac and ischial junctions is also seen. Sponseller et al have quantified the differences in the pelvic anatomy of patients with exstrophy, noting (1) a 12° external rotation of the innominate bones on the sagittal axis, (2) retroversion of the acetabula, (3) increased distance between the triradiate cartilage, (4) 18° external rotation and shortening (by 30%) of the anterior segment of the iliac bone, and (5) external rotation of the posterior segment of ileum (Figure 61.6).[18] These pelvic bone abnormalities contribute to splaying of the penis noted with exstrophy and epispadias and cause the penis to appear foreshortened. Gait abnormalities in these children arise as a consequence of these bone abnormalities. Many of these children learn to ambulate with a wide waddling gait. This gait abnormality resolves as the children grow. Orthopedic procedures to reapproximate the pubis symphysis do not appear to offer any long-term benefits to these patients from an orthopedic viewpoint. Osteotomies to reapproximate the pubis symphysis do, however, increase the chance of successful primary bladder closure in selected patients and may have a significant role in securing continence and support of the pelvic diaphragm.[19,20]

Fascial abnormalities

Fascial abnormalities include the rectus fascial defect associated with the exposed bladder. Inferiorly, the pelvic floor support structures are also compromised. At the inferior portion of the fascial defect, these patients possess an anteriorly located intersymphyseal ligament or band representing the attenuated urogenital diaphragm. The rectus muscles diverge laterally with the widened pubis symphysis. This abdominal defect is most severe in cloacal exstrophy.

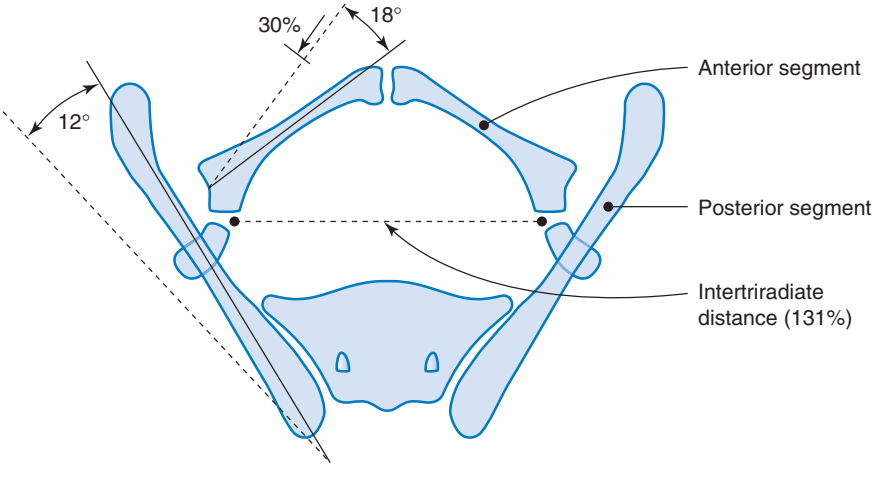

Figure 61.6 The anatomy of the normal bony pelvis is seen in transverse view. Superimposed are the deviations observed in the pelvis of classic bladder exstrophy patients. In the posterior segment, each half is externally rotated 12°. The acetabulae are retroverted, yielding an increased intertriradiate distance. In the anterior segment, each half is externally rotated 18° and is on average 30% shorter.[18]

Figure 61.7 Evidence of an inguinal hernia in this newborn male with bladder exstrophy, as demonstrated by the inguinal bulge.

Figure 61.8 Newborn male with cloacal exstrophy. The omphalocele is small. The terminal ileum is intussusepted and is the long 'trunk' to the patient's left. Each hemipenis is small, the left being smaller than the right.

Inguinal hernias are commonly associated with exstrophy in both male and female patients[21,22] (Figure 61.7). The majority of these hernias occur indirectly. They probably occur as a consequence of the enlarged internal and external inguinal rings noted in these patients in conjunction with compromised fascial support and lack of obliquity of the inguinal canal.[23] In a review of patients from Toronto Sick Children's Hospital, 56% of classic male exstrophy patients and 15% of classic female exstrophy patients developed inguinal hernias over a 10-year period. The authors recommended these hernias be repaired at the time of primary bladder closure to prevent incarcerated hernias, which could affect up to 50% of these patients in the first 2 years of life.[24] Reinforcement of the transversalis and internal oblique fascia during hernia repair decreases the incidence of later direct inguinal hernias. Umbilical hernias also uniformly occur with exstrophy and are repaired at the time of the primary repair.

An omphalocele can also be found in association with classic bladder exstrophy, although this is rare.[25]

Neurologic system

Spinal cord abnormalities are the exception rather than the rule in bladder exstrophy. Occult spina bifida and even myelomeningocele can be seen in combination with bladder exstrophy, but this is a rare occurrence.[26]

Cloacal exstrophy

The bladder plate associated with cloacal exstrophy is divided in half by the hindgut plate; the hindgut plate represents the deformation in the development of the colon that occurs with cloacal exstrophy. Ileum enters and intussuscepts into the middle of the hindgut, creating the 'trunk of an elephant's face' appearance with appendiceal appendages located laterally to give the impression of 'tusks on the face of the elephant'[27] (Figure 61.8).

With cloacal exstrophy, the bladder neck (internal urethral sphincter) and external urethral sphincter are not fully developed owing to the failed development of the bladder and urethral remnant located on the anterior and dorsal surfaces of the body wall and penis, respectively. However, because the innervation to these structures is usually intact, anatomic closure theoretically offers the possibility of achieving urinary continence.[17,28,29] The urethral plate is characteristically short as well.

Associated anomalies

Kidneys and upper urinary tract

Renal anomalies are much more common with cloacal exstrophy. They include anomalies of location such as pelvic kidneys or crossed fused ectopia. Horseshoe kidneys, renal agenesis, and UPJ obstruction may also occur.[17]

Genitalia

In cloacal exstrophy the penis is often separated into two hemiphalluses owing to the wide pubic diastasis

(see Figure 61.8). This can make subsequent reconstructive efforts technically more challenging if a male phenotype is preserved. Cryptorchidism is the rule with cloacal exstrophy.

For girls, in addition to the genital pathology described above with bladder exstrophy, uterus didelphys and other fusion anomalies of the müllerian duct structures are seen in up to two-thirds of cloacal exstrophy patients. Vaginal agenesis occurs in one-third of girls with cloacal exstrophy.

Anorectal and intestinal abnormalities

Associated intestinal abnormalities specific to cloacal exstrophy include imperforate anus, foreshortening of the midgut, bowel duplication, malrotation, intestinal atresia, and Meckel's diverticulum.[17] These are in addition to the exstrophy of hindgut, ileal intussusception, and exposed appendices that are considered part of the primary pathology of cloacal exstrophy.

Skeletal abnormalities

In addition to the features seen with bladder exstrophy, patients with cloacal exstrophy can have other skeletal abnormalities. Skeletal anomalies are seen in as many as 50% of patients with cloacal exstrophy. Anomalies include congenital hip dislocation, talipes equinovarus, and a variety of limb deficiencies.[18]

Fascial abnormalities

The fascial anomalies associated with cloacal exstrophy include those described above for bladder exstrophy. Further, omphaloceles often occur in association with cloacal exstrophy.[30,31] These can be closed during the initial bladder closure if they are small. If the omphalocele is large, it may require closure as a primary procedure with the reapproximated bladder halves acting as a silo to decompress intra-abdominal pressure. Alternatively, omphaloceles may be treated with antiseptic paint to promote skin overgrowth. Our preference is to proceed with a staged surgical omphalocele correction, with primary reconstruction of the bladder at a later date if the infant is a surgical candidate. In our experience, intra-abdominal pressure following omphalocele closure determines whether we may proceed with primary bladder closure at the same time as the omphalocele repair or whether these operations must be staged. Aggressive one-stage closure of a cloacal exstrophy can lead to organ ischemia from increased intra-abdominal pressure. Rupture of an omphalocele clearly requires immediate attention in these patients and would take precedence over other considerations. Fortunately, this occurs rarely.

Neurologic abnormalities

Neurologic involvement of the lower spinal cord in the cloacal exstrophy population is reported to occur in 50–100% of patients.[31–33] Most patients have lumbar or sacral cord involvement, but thoracic-level myelodysplasia has been reported.[31] Management of cloacal exstrophy in these situations must be coordinated with neurosurgical plans to close the neural tube defect.

Epispadias

Epispadias can be considered the least severe form of exstrophy. It does not involve the body of the bladder. However, the urethra is represented as a plate of tissue located dorsally on the penis (Figure 61.9). The genital anomalies described above are noted with epispadias. These include lateral splaying of the penis and dorsal chordee in boys. In affected girls, the clitoris is bifid, the perineal body is broadened, and the vagina is anterior to its orthotopic or typical position (see Figure 61.4). Widening of the pubic diastasis occurs as well. Importantly, the bladder neck is also frequently involved – it is often wide and incompetent. This directly affects the continence mechanism of these children and impacts the ability to achieve urinary continence. In boys with epispadias, primary continence is possible if the epispadias is located distally and the bladder neck is normally formed. In girls, however, continence is invariably affected to some degree because of the associated urethral and bladder

Figure 61.9 Penopubic epispadias in a 3-month-old male. Skin demarcation is due to chronic urine contact dermatitis in this patient.

neck ectasia. Because the features of epispadias are shared with bladder exstrophy, clinicians consider these anomalies as part of a spectrum of the exstrophy–epispadias complex.

Exstrophy variants

In the exstrophy–epispadias complex, variations in bladder plate size and compliance are commonplace but no system to quantify these differences is currently in use. Phallic size and degree of phallic separation also vary from patient to patient. However, despite these variations the underlying features of this disease are consistent for classic forms of the exstrophy complex.

Variants from these findings have also been recognized. Patients with atypical physical findings are referred to as exstrophy variant patients. These patients have some but not all of the typical features of bladder or cloacal exstrophy as well as other features not typically associated with bladder exstrophy. These include covered exstrophy and superior vesical fissure. Patients with exstrophy variants may have anatomically normal genitalia despite their bladder and colon anomalies.

Bladder exstrophy variants include patients whose anatomic features resemble classic exstrophy in regard to the fascial and/or symphyseal defects but who do not have any significant anomaly associated with the urinary tract. These patients are considered to have pseudoexstrophy.[34,35] If these patients also have an isolated ectopic bowel segment in association with these findings they are referred to as covered exstrophy variants.[36] Patients with superior vesical fissure also have the muscular and skeletal defects associated with bladder exstrophy, but only the upper portion of the bladder is affected, so that the urethra is intact and the genitalia are less significantly affected than with classic exstrophy.[37] Duplicate exstrophy may occur. Patients with this variation have a superior vesical fissure associated with normal fascial abdominal wall development, so that components of the bladder remain ectopic such as urothelial elements. These patients can have genital anomalies consistent with classic exstrophy as well, but this association is variable.[38–41]

Cloacal exstrophy variants also exist. These patients possess some of the features of cloacal exstophy such as an exposed hindgut plate and bladder plate but may not have the typical genital involvement.[42–44] Hypospadias has been described in association with cloacal exstrophy as well as normal genitalia in both male and female patients. Some have been reported with intact anal innervation, permitting a Peña procedure.[45] These patients may also have other atypical features such as accessory appendages or limb malformation. These findings, in association with prenatal ultrasound examinations that document twin gestations early in some pregnancies, suggest that aborted conjoined twinning may be the underlying cause of cloacal exstrophy variation in some case[46–48] (Figure 61.10).

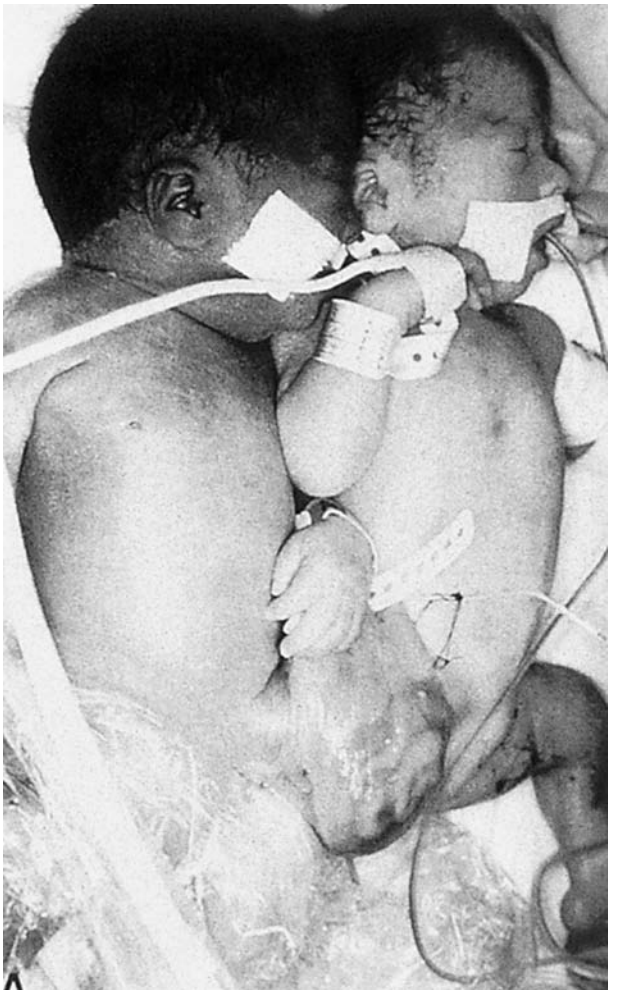

Figure 61.10 Conjoined twins connected by a membranous omphalocele sac containing a shared segment of distal ileum, cecum, and colon draining to a common exstrophic cloaca; an example of an exstrophy variant.

Embryology

Normal bladder development

Normal bladder development results in an organ that functions to store and evacuate urine. This process,

known as bladder cycling, requires the bladder to store urine at low intravesical pressures during filling while maintaining continence at the level of the bladder neck. Subsequent evacuation of urine from the bladder requires a coordinated contraction of the detrusor in conjunction with relaxation of the bladder outlet. Both normal storage and emptying require intact innervation of the bladder, sphincter mechanisms, and urethra.[49]

During embryogenesis, components of the urinary system such as the ureteral buds first appear during the 4th week of gestation. At this time the bladder has not completely formed from the anterior urogenital sinus. Before the bladder is completely formed, mesenchyme grows inward toward the midline between the bilaminar (ectoderm and endoderm) layers of the cloacal membrane. This mesenchyme later differentiates into the abdominal wall musculature and fascia. Subsequent to this, the urorectal septum separates the bladder from rectum by growing downward between them. Abnormalities in the appearance, timing, and function of the cloacal membrane are implicated in the creation of exstrophy. In this fashion, the urinary bladder arises during the 8th week of fetal development when the ventral portion of the urogenital sinus begins to expand.[49] With bladder filling, the mesenchymal tissue surrounding this structure differentiates into smooth muscle, which will eventually become the detrusor muscle. Ingrowth of neuronal tissue into this smooth muscle to form motor units is critical to the development of a functional bladder.[50] Embryogenesis of the pelvic floor is also important in normal fetal bladder development and function; the pelvic floor acts as a dynamic support for the bladder, which aids in both continence and volitional voiding.[51]

Theories of pathogenesis of exstrophy

Improvements in our understanding of embryogenesis have led to some insight into the cause of exstrophy. In the premodern era, trauma to the unborn child or ulceration of the abdominal wall and bladder between the 2nd and 3rd months of life was felt to be the underlying cause of exstrophy. Current theories implicate an error in embryogenesis rather than an event of arrested development, since the developing human embryo does not normally pass through a stage that corresponds to exstrophy.[52] Animal models suggest that exstrophy results from pathophysiologic events involving the cloacal membrane. This membrane serves to separate the coelomic cavity from the amniotic space in early development. The cloacal membrane can first be identified during development at 2–3 weeks of gestation. By the 4th week of development, it forms the ventral wall of the urogenital sinus, with the unfused primordia of the genital tubercles sitting cephalad and lateral to it. With further development, the primordia grow and fuse in the midline, and mesoderm grows toward the midline, creating an infraumbilical abdominal wall. Simultaneous to this process, the urorectal septum develops medially and caudally to separate the cloaca into the urogenital sinus and rectum.[49]

In 1962, Marshall proposed that exstrophy was caused by persistence of this cloacal membrane during fetal development based on autopsy studies of fetuses with bladder exstrophy done earlier in the century.[53] Persistence of the membrane would create a wedge effect that would keep the medially encroaching mesoderm from fusing in the midline.[52] To further study this hypothesis, Muecke subsequently created an animal model of cloacal exstrophy using the developing chick embryo. By placing a plastic graft in the region of the tail bud, he created cloacal exstrophy in these animals and concluded that exstrophy was due to persistence of the cloacal membrane, as Marshall had originally postulated.[52]

Other experimental models implicate the cloacal membrane in the pathophysiology of exstrophy as well. Thomalla and co-workers developed a model of cloacal exstrophy in the developing chick embryo by using a CO_2 laser to create an early dehiscence in the tail bud caudal to the omphalomesenteric vessels. Their results suggest that exstrophy may be caused by failure of the mesodermal ingrowth between the ectoderm and endoderm of the cloacal membrane, which later ruptures to produce exstrophy. They hypothesize that such an event could be caused by early hypoxemic infarction in the region of the tail bud, with subsequent cellular loss of the mesoderm, and herniation of the developing bladder or cloaca.[54] This type of ischemic injury has been implicated as the cause of gastroschisis and could explain the spectrum of exstrophy–epispadias complex.[55]

Other proposed theories for exstrophy include caudal displacement of the paired primordia of the genital tubercles. Exstrophy occurs by this mechanism when the primordia of the genital tubercles fuse caudal to their usual location relative to where the urorectal fold divides the cloaca into the urogenital sinus and rectum.[56] This theory readily explains the spectrum of variation seen in the exstrophy–epispadias complex. However, it fails to explain the higher

incidence of exstrophy compared with epispadias; one would anticipate a higher incidence of epispadias if caudal displacement were the underlying cause of exstrophy–epispadias because it would represent the most minimal example of this phenomenon.[2]

In 2005, a new maldevelopment theory was put forth for cloacal exstrophy based on a suramin-exposed chick model.[57] When these chick embryos were examined at 1 or 2 days after pericardial injection of suramin, ~8% were noted to have a midline infraumbilical opening into the cloaca and allantois, abnormal leg bud abduction, hypoplastic tail and allantois, broad infraumbilical pelvic region, and large aneurysmal dilation of the paired dorsal aortae at the level of the leg buds. The aortic dilation is transient, resolving on the 2nd and 3rd days after drug exposure, but leaving maldevelopment. These authors implicate the aneurysmal paired dorsal aorta as the primary defects leading to cloacal exstrophy in this animal model.

The chick model to study bladder exstrophy has inherent limitations. Chicks normally possess a cloaca, which precludes the creation of a bladder exstrophy vs a cloacal exstrophy. Other animal models to study bladder exstrophy have been difficult to create. Slaughenhoupt and colleagues created an exstrophy model using fetal sheep. A significant increase in the ratio of collagen-to-smooth muscle was noted in exstrophic vs normal control bladders ($p < 0.05$). There was no significant difference in the ratios of types I and III collagen in the two groups of sheep bladders. These histologic changes are similar in part to changes seen in human bladder exstrophy tissue.[58,59] The underlying cause of human exstrophy remains in question.

Incidence and genetics

Bladder exstrophy occurs at a rate of 1 in 10 000 live births to 1 in 50 000 live births.[60,61] This anomaly has long been recognized to occur more commonly in males than females, with a ratio of 3–6:1 reported in the literature.[62,63] Cloacal exstrophy occurs even more rarely, with an incidence of 1 in 200 000 to 1 in 400 000 live births,[64] but is higher in stillborns, at 1 in 10 000 to 1 in 50 000.[65]

Genetic factors involved in exstrophy remain incompletely defined. Because of the associated physical anomalies with this condition, patients with bladder exstrophy often have to overcome significant obstacles to reproduce. Men may need to resort to assisted reproductive techniques (such as intracytoplasmic sperm injection[66]) because their seminal emissions drain from their ejaculatory ducts located at the base of their bladder plate, if at all. Further, sexual intercourse due to the accompanying deformity of the phallus can be difficult for some of these patients, although the majority have the capacity for satisfactory sexual relations. In the 1800s the prevailing thought declared males with bladder exstrophy as completely impotent because of the associated deformities of the penis.[67] Women with exstrophy were (and still are) prone to uterine prolapse and miscarriage. In the mid-19th century, few reported cases of women with bladder exstrophy successfully conceiving are documented. Difficulty with conception and pregnancy are still a problem today despite in vitro fertilization and careful obstetric care.[68,69]

These issues combined may explain, in part, why familial patterns of inheritance of exstrophy–epispadias complex are noted infrequently. To date, 37 familial cases of bladder exstrophy have been reported.[70] Five cases of an affected parent–child pair have been reported.[70–72] Another 18 cases with bladder exstrophy have been reported in twin pairs.[70] In 1984, a survey of pediatric urologists and surgeons reported nine cases related to 2500 index cases of bladder exstrophy; this same series also reported on cases of twins, and noted discordance in both fraternal as well as identical twinships.[71] In a study population of greater than 6 million births with 208 reported cases of exstrophy, no case had a family history for this anomaly.[73] Current recommendations on counseling about risk of recurrence in a sibling of a patient with exstrophy cite an estimate of about 1%[74] and a 1:70 chance of transmission to the progeny of an affected parent.[72] A Florida population-based study found multiple births had a 46% increased risk of birth defects, with bladder exstrophy being the fifth highest adjusted relative risk.[75]

A genetic basis is further supported by several reports of karyotypic anomalies. Of 39 cases karyotyped at Johns Hopkins, two patients with exstrophy–epispadias complex had anomalies, including 47XYY and a balanced translocation 46XY,t(8;9)(p11.2;q13).[74] A candidate gene on 9q13, contactin associated protein-like 3 (CNTNAP3), was evaluated, but a causal relationship could not be proven in bladder exstrophy.[76] A recent report of cloacal exstrophy with a de-novo unbalanced translocation yielding monosomy from 9q34.1-qter[77] may indicate this as a potential genetic locus. Given the multi-organ maldevelopment in cloacal exstrophy, it is not surprising

that aneuploidies such as 47XXX,[78] 45XO/46XX, or 47XX,+21 have been found.[79,80] Based on these findings, the exstrophy–epispadias complex appears to be multifactorial, with a strong genetic predisposition for susceptibility. Collaborative efforts are underway to further investigate the causes of exstrophy–epispadias complex. If environmental factors play a role, they have not yet been identified.

Antenatal diagnosis

Prenatal detection of bladder exstrophy is possible. Ultrasonography can reliably detect exstrophy before the 20th week of gestation[81–89] (Figure 61.11). Absence of bladder filling in the presence of normal kidneys and in association with a low-set umbilical cord suggests the diagnosis. Sonographic examination may also reveal a semisolid mass protruding from the abdominal wall in association with the findings above.[90,91] Gearhart and co-workers reviewed the antenatal ultrasonographic studies of 25 women who delivered live infants with exstrophy and found:

- an absent bladder in 71% of the studies
- a lower abdominal protrusion in 47% of the studies
- an anteriorly displaced scrotum with a small phallus in 57% of the male fetuses
- a low-set umbilical cord in 29% of the studies
- an abnormal iliac crest widening in 18%.[85]

Amniotic fluid levels are normal since urine production is normal for these fetuses. Prenatal diagnosis is valuable in the management of bladder exstrophy because it allows optimal perinatal management of these infants at a center equipped to treat this unusual anomaly. Unfortunately, many affected fetuses are not detected antenatally.[92]

Antenatal diagnosis also allows the parents the opportunity to discuss termination of the pregnancy. It is our opinion that such a discussion should include a pediatric urologist experienced in the treatment of bladder exstrophy. The overall prognosis of these children is excellent if they are treated at medical centers with physicians experienced in the treatment of this disorder. Unfortunately, because of the rarity of bladder exstrophy, healthcare providers who lack insight and knowledge of this disorder often counsel prospective parents of these patients. For example, in one article, the authors state '… the point of termination (of

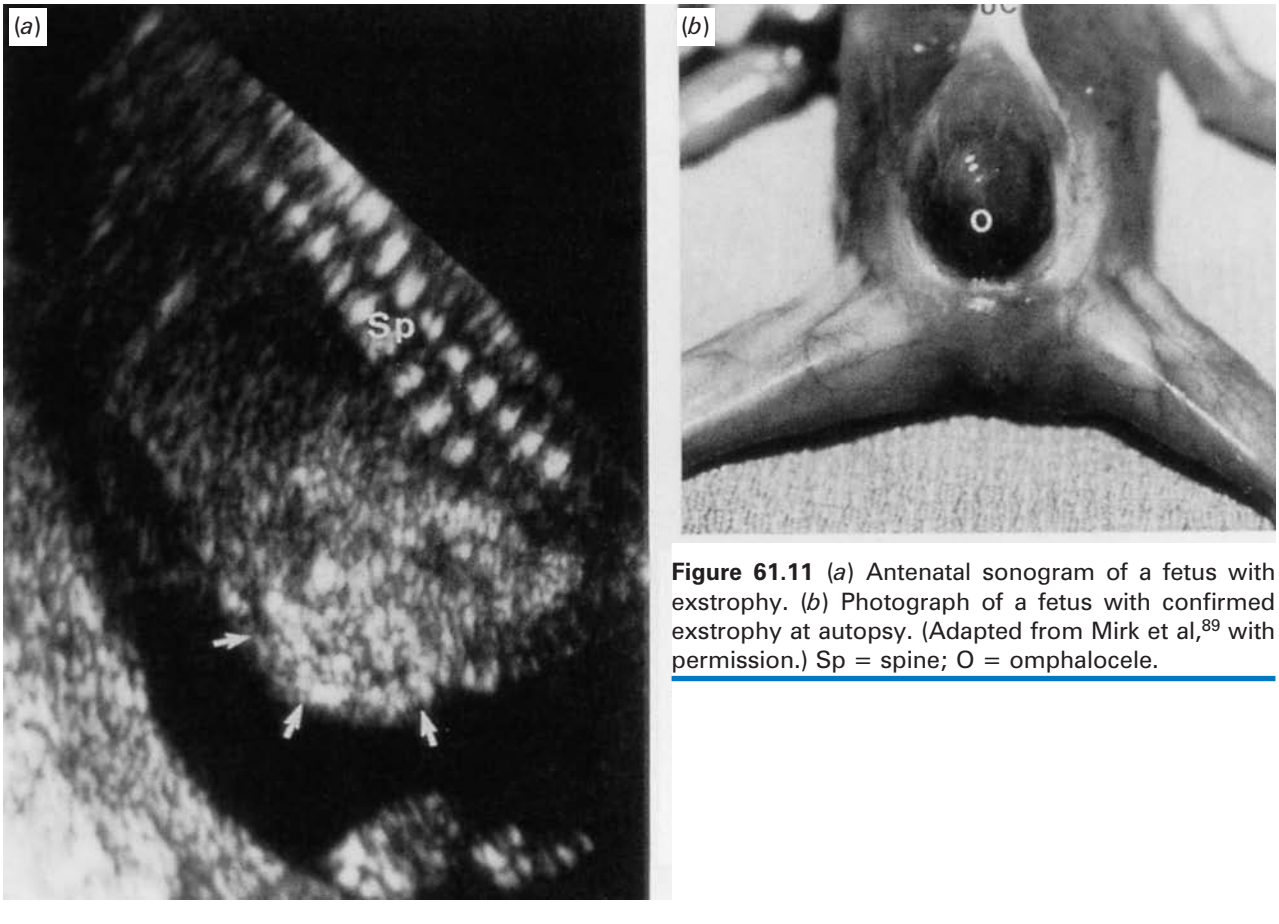

Figure 61.11 (*a*) Antenatal sonogram of a fetus with exstrophy. (*b*) Photograph of a fetus with confirmed exstrophy at autopsy. (Adapted from Mirk et al,[89] with permission.) Sp = spine; O = omphalocele.

the pregnancy) may be underlined by the poor long term results in boys, who mostly end up with severe sexual dysfunction.'[72] Such recommendations are based on an outdated understanding of bladder exstrophy. We believe that recommending abortion for exstrophy would be akin to recommending therapeutic termination in a child diagnosed antenatally with a cleft lip/palate or ventricular septal defect. Unfortunately, the counseling of these families by healthcare providers who are unaware of the true prognosis of patients with bladder exstrophy has led to an increase in the abortion rate of these fetuses, who have a treatable condition with a satisfactory long-term outcome and life expectancy when appropriately managed.[84]

Treatment philosophies

Goals of reconstruction of exstrophy–epispadias

In the treatment of exstrophy, objectives for reconstruction can be placed broadly in the following categories:

Principal objectives:
- urinary continence
- volitional voiding
- low-pressure urine storage
- preservation of kidney function
- functionally and cosmetically acceptable external genitalia.

Secondary objectives:
- avoid urinary tract infections (UTIs)
- reduce risk of urinary calculi
- minimize the risk for malignancy associated with the urinary tract
- integrity of the abdominal wall fascia
- integrity of the pelvic floor.

Successful achievement of these goals remains challenging. Numerous operations have been devised for the treatment of bladder exstrophy, testing the ingenuity of the physicians and the resilience of the patients themselves. The objectives have expanded since the first operations were proposed and attempted in the 1800s. These objectives address the primary pathology and problems associated with exstrophy and its management. These problems include:

Primary pathophysiology (untreated):
- urinary incontinence
- UTI/renal scarring
- urinary calculi
- bladder malignancy
- pelvic floor prolapse
- inguinal herniation
- inadequate phallus and ejaculatory dysfunction in males, with subsequent sexual, social, and psychological sequelae.

Potential complications (associated with management of exstrophy):
- malignancy (related to the use of intestine in bladder reconstruction)
- UTI
- urinary tract obstruction
- inadequate bladder emptying
- urinary incontinence
- uterine prolapse
- severe penile shortening with dorsal chordee
- ejaculatory dysfunction
- urinary calculi
- renal scarring
- abdominal wall hernia
- epididymo-orchitis.

Natural history of exstrophy

Bladder exstrophy–epispadias complex is not a lethal anomaly; reports exist of untreated patients with classic bladder exstrophy living into their eighth decade.[5] Far from debilitated, these children are often quite intelligent, with many achieving postgraduate education degrees. In contrast, until recently, patients born with cloacal exstrophy died shortly after birth from electrolyte abnormalities and malnutrition. Because bladder exstrophy is a serious anomaly, the morbidity these patients experienced was often severe and included the problems noted above. Patients left untreated covered the exposed bladder with a variety of undergarments, including liniment-soaked rags, cotton, and wool bolsters, etc. The surrounding skin around the exstrophic bladder was often inflamed and broken down from urine contact dermatitis and secondary infection. These patients were often social pariahs because of the odor and hygiene problems. Up to the 20th century, many considered bladder exstrophy irreparable, as evidenced by these comments by Gross in 1876:[67]

> Exstrophy of the bladder, unless the patient is willing to assume the (often mortal) risk of an autoplastic operation, is utterly irremediable; all

that can be done is to palliate the patient's suffering by attention to cleanliness, and by the use of a closely-fitting flexible gutta-percha shield, furnished with a gum-elastic bottle for receiving urine… When this cannot be obtained, the part must be kept constantly covered with a thick, soft compress, renewed as often as it becomes wet and disagreeable. The skin around may be protected, if necessary, with pomatum, simple cerate, or zinc treatment.

Early attempts at surgical reconstruction

The morbidity of exstrophy led surgeons to begin empiric approaches to the operative correction of this anomaly. Surgeons in the 19th century attempted urinary reconstructive or diversion procedures to treat these patients. Initial efforts were directed at partial reconstruction of the abdominal wall to allow the application of a urinary receptacle to collect urine. The first successful record of this form of repair is attributed to Dr Pancoast in 1859. He used skin flaps from the abdominal wall:

> In the treatment of exstrophy of the bladder the principal objects aimed at are either to establish a channel for the conveyance of the urine to the rectum or perineum, or to cover its exposed and sensitive mucus membrane with flaps of skin, thereby protecting it from contact of the clothing, and preventing excoriation of the surrounding parts, as well as facilitating the adjustment of an apparatus for receiving the urine.[67]
>
> A flap is taken from one side of the abdomen or groin, dissected up, and turned over like the leaf of a book so that the epidermis comes into contact with the mucous membrane. A second flap is then taken from the groin on the opposite side and its raw surface applied to the raw surface of the former flap … thus a thick bridge is formed over the cleft.[93]

Dr John Wood and Maury also described variations on the use of skin flaps to reconstruct the abdominal wall.[67,94] Wood used a full-thickness skin graft from the abdominal wall followed by a lateral, pyriform flap from each groin held in place with hare-lip pins, wire sutures, and broad straps of adhesive plaster which were removed 6–8 days after surgery (Figure 61.12). In contrast, Maury created perineal and scrotal skin flaps to repair bladder exstrophy. These procedures represented early attempts at anatomic closure but did not address the functional reconstruction of these bladders – namely to achieve satisfactory storage and emptying of urine. Van Buren and Keyes aptly stated the common sentiment of the time:

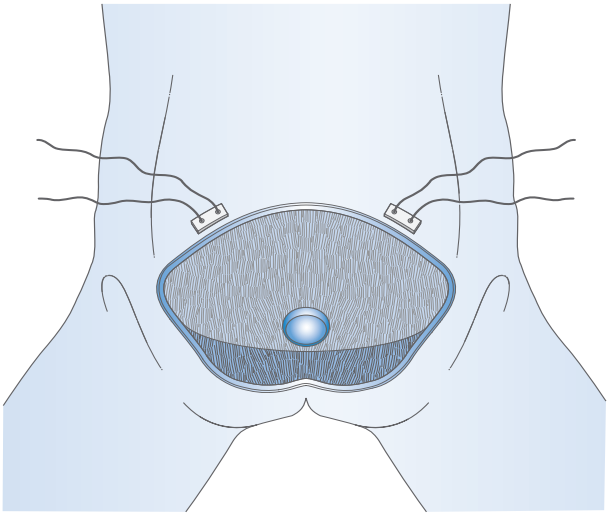

Figure 61.12 Early operation for bladder exstrophy, as proposed by Maury in the mid-19th century.

> The most that can be promised by operative interference is to leave behind a fistula, more or less large, over which a urinal must be constantly worn. The patient's virility is not returned to him, nor is his condition very materially bettered. A less dangerous and equally efficacious mode of treatment seems to be to adapt a suitable urinal to the parts as they are left by Nature, such a one as shall shield them from injury, and keep the patient dry and clean.[95]

Others, such as Simon, approached the surgical treatment by attempting urinary diversion in these patients through the creation of a ureteral sigmoid fistula. Results were poor; one patient died of peritonitis in the immediate postoperative period and the other died of renal failure secondary to chronic pyelonephritis.[67]

These early efforts suffered from lack of understanding of the physiology of the urinary tract and bladder and subsequently how these operations would affect urine storage and emptying, kidney function, electrolyte homeostasis, the propensity for UTI or calculus formation, fertility, and sexual function. Complications from these operations as noted above were often life threatening. The fact that patients were willing to assume the risk of surgical death demonstrates the impact this anomaly had on their lives.

The modern era – operative procedures in the management of exstrophy

A host of operations for exstrophy have been proposed and attempted, which may be broadly characterized into two approaches:

- in the first approach, operations are designed to remove the exstrophic bladder and replace it with a form of urinary diversion.
- in the second approach, the operations are anatomically oriented and designed to reconstruct the bladder either in multiple stages or in a single stage.

Surgeon preference, patient anatomy, previous surgical procedures, availability of tertiary care facilities, and access to medical care all play a role in which operative procedure is chosen for a particular patient. Even in the 21st century, no standard of care exists for this patient population. However, because of the complexity of care involved and the rarity of this congenital defect, specialists with an interest in the exstrophy–epispadias complex usually manage these patients most effectively.[96]

Perioperative care of the patient with exstrophy

Preoperative care

With rapid referrals and, in some cases, prenatal diagnoses, neonates with bladder exstrophy should be evaluated for surgical reconstruction promptly. To prevent trauma to the exposed bladder plate after delivery, the umbilical cord should be ligated with silk suture rather than a plastic or metal clamp. An ideal protective covering for the exstrophic bladder is a hydrated gel dressing such as Vigilon, if available. If a hydrated dressing is unavailable, covering the exposed bladder with plastic wrap (Saran Wrap), especially for transportation, is an acceptable alternative. These protect the bladder plate effectively and allow handling of the infant with minimal risk of trauma to the bladder. In some circumstances, Vigilon has been used for over 2 months with minimal inflammation of the bladder noted at the time of repair. The dressing should be replaced daily and the bladder irrigated with normal saline with each diaper change. Others advocate the use of a humidified air incubator with no dressing at all to minimize bladder trauma.[24] Often, the keratinized skin around the bladder plate becomes inflamed from the chronic urine exposure; barrier creams (zinc oxide) help prevent this.

Some exstrophic bladders are extremely small, acontractile, and non-distensibile.[97] Although bladder cycling is known to stimulate bladder growth, in some cases an early attempt at closure will only result in upper tract deterioration. Although this is a subjective decision, delay of closure may give more time for bladder plate growth. Two reports have also indicated that exstrophy closure in the premature infant should be discouraged owing to higher complication rates.[98,99]

Routine use of intravenous antibiotic therapy in the pre- and postoperative period decreases the chance for bacterial infection; however, candidal infection may supersede. A baseline sonogram should be obtained to assess the kidneys preoperatively for later comparisons. A preoperative KUB (kidney, ureter, and bladder) X-ray can delineate the extent of pubic symphysis diastasis. A spinal sonographic examination should also be obtained if sacral dimpling or other signs of spina bifida occulta are noted on physical examination in the child under the age of 6 months. After this age, MRI will be necessary to image the spinal cord. Orthopedic consultation is advisable to plan osteotomies if needed and neurosurgical consultation is required for children with spinal anomalies.

Operative considerations

Most children with epispadias and bladder exstrophy have no additional anesthetic risk factors, but cloacal exstrophy patients often have comorbidities. Cloacal exstrophy patients with short gut will probably require long-term central venous access at the time of surgery. Exstrophy closure is performed using general inhalation anesthesia, avoiding nitrous oxide to minimize bowel and peritoneal distention and maximize surgical exposure. The use of a nasogastric tube to minimize abdominal distention is controversial.[100,101] Regional anesthesia can be achieved by a one-time caudal block to reduce the inhaled anaesthetic requirement during the operation or, in the older child, via a continuous infusion epidural.

General comments on osteotomies

Trendelenberg first recognized the importance of osteotomies in exstrophy closure at the start of the 20th century. Osteotomies optimize pubic symphysis apposition, diminish tension on the closure, and optimize anatomic placement of the bladder, bladder neck, and urethra in the pelvis. They also improve the

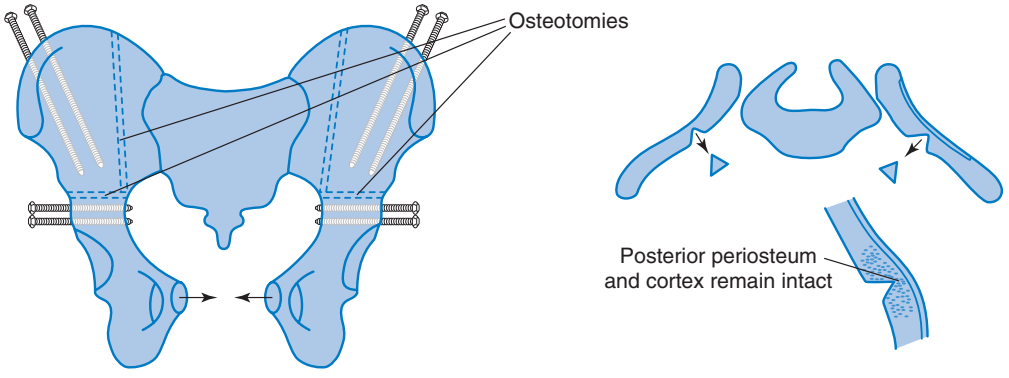

Figure 61.13 Osteotomy sites for combined vertical iliac and transverse innominate osteotomies showing the placement of intrafragmentary pins.[103]

reapproximation of the corporeal and clitoral bodies. Finally, osteotomies may decrease the chance for later uterine prolapse because the anterior closure brings the pelvic diaphragm into a more normal anatomic position to offer more support.

The need for osteotomy is best determined under general anesthesia. Candidates for osteotomy include infants more than 72 hours old, newborns with a wide pubic diastasis, newborns with cloacal exstrophy, and patients who have had a previously failed closure. Osteotomies are usually performed at the same setting as bladder closure to help secure the closure.

Osteotomies may be performed by an anterior or posterior approach or a combination of approaches. Posterior iliac osteotomies are performed with the patient in a prone position, after which the patient is then repositioned for the bladder closure. However, increased blood loss and occasional malunion of the ileum has caused this approach to fall out of favor. Anterior iliac osteotomies offer the advantage of a single position and sterile field preparation (see Figures 61.37 and 61.38). Anterior diagonal iliac osteotomies have been preferred by the Seattle group. Compared with posterior iliac osteotomies, an anterior approach has also been shown to result in less blood loss and better apposition and mobility of the pubic rami. The group at Johns Hopkins uses bilateral combined anterior innominate and vertical iliac osteotomies (Figure 61.13) because of superior initial and long-term results compared with anterior iliac osteotomies alone.[102,103] Both osteotomies may be performed through the same anterior skin incision on each side, and with minimal blood loss, and 4% complication rate[102,104] (Figure 61.14). McKenna et al have also described the use of a diagonal mid-iliac osteotomy performed through the same incision as the exstrophy closure.[105] Division of the superior pubic ramus has also been described; it is not as effective as the other methods described but may be used in the newborn period.[106,107]

Postoperative considerations

Several methods have been used to maintain pelvic ring closure and prevent external hip rotation following bladder closure without osteotomies. Although most agree that mummy wrapping is unreliable and should not be used,[101] high-volume exstrophy centers debate over the best method. The two most commonly employed methods in the newborn period are modified Bryant's traction for 4 weeks[1] (Figure 61.15) and spica casting for 3 weeks[100] (Figure 61.16). If osteotomies are performed, they are secured with interfragmentary pins and external fixation with light Buck's traction for 2–4 weeks (Figure 61.15). Some fit the newborn with a 'sled' to be used when the child

Figure 61.16 Use of a spica cast following complete primary repair for exstrophy to reduce tension on the closure by preventing hip abduction in the postoperative period.

Figure 61.17 Patient seen with an external fixator and in modified Buck's traction. (Photo courtesy of John Gearhart.)

is out of traction for feeding and bathing in these situations. Traction does make performing daily activities and routine care difficult, but spica casting can permit more mobility of the infant pelvis.

Low-dose antibiotic prophylaxis should be prescribed, since VUR is nearly universal. This is continued until VUR is corrected or resolves spontaneously.

Postoperative factors recognized to increase the success of the initial reconstruction[108] include:

- use of osteotomies (in selected cases) or newborn closure (<24–48 hours)
- postoperative immobilization
- use of postoperative antibiotics
- ureteral stenting catheters
- adequate postoperative pain management
- avoidance of abdominal distention
- adequate nutritional support
- secure fixation of urinary drainage catheters.

Exstrophy closure: anatomic reconstruction

The first efforts at anatomic reconstruction of the exstrophic bladder are usually attributed to Trendelenberg.[109] In 1881, he described an exstrophy closure that emphasized the importance of pubic reapproximation in front of the reconstructed bladder to achieve continence and prevent dehiscence. This effort ultimately proved unsuccessful. Because of discouraging results such as this, bladder reconstruction in exstrophy was largely abandoned and replaced by urinary diversion, most notably ureterosigmoidostomy, in the early part of the 20th century.

Not all attempts at bladder reconstruction for exstrophy were abandoned. Various surgeons reported occasional successful attempts at bladder reconstruction during this time. However, these results were uncommon and difficult to reproduce. For example, Young reported the first successful primary bladder closure in 1942. He achieved urinary continence after reconstruction in a young girl.[110] Primary reconstructive efforts by others remained inconsistent and largely unsuccessful during this period. Since Young's successful report in 1942, other investigators have intermittently achieved a satisfactory result with a one-stage reconstructive effort to repair the exstrophied bladder. Ansell reported on a one-stage closure in 1971 with a successful outcome in a newborn female.[111] Ansell was also one of the early advocates for primary closure of bladder exstrophy in

the newborn period, and reported 28 cases closed in this fashion.[112] Montagnani described a one-stage functional bladder reconstruction in two female babies aged 8 and 13 months. His bladder reconstruction procedure included innominate osteotomy, bladder closure, an antireflux procedure, and narrowing of the bladder outlet followed by pubic reapproximation. Continence was achieved in one of the two patients. The second patient required further bladder neck reconstruction (BNR) to achieve continence.[113] Fuchs et al also achieved urinary continence in 8 of 15 patients who were also repaired in a single-stage effort.[114] However, several large series of patients who underwent single-stage reconstruction in the 1960s and 1970s reported continence rates of only 10–30%.[115–120] Renal damage was as high as 90% in these series, generally because of bladder outlet obstruction.[115]

Because of these complications and the low rate of urinary continence, reconstructive surgical efforts were subsequently directed toward planned staged bladder reconstruction, an approach pioneered and advocated by Jeffs, Chisholm, and Ansell in the 1970s and further refined by Gearhart and others as the modern staged repair of exstrophy (MSRE).[19,112,121,122] Recent advances in single-stage reconstruction for neonatal and older exstrophy have been advocated by Fuchs et al,[114] Kelly,[123] and others; as such, the complete primary repair for exstrophy (CPRE) by Mitchell has gained favor.[114,123,124]

All approaches aim to reconstruct and achieve anatomic and functional normalcy with minimal surgical morbidity. In the subsequent section, the two currently favored surgical techniques, the CPRE and the MSRE, are detailed. In reality, closure of the female with bladder exstrophy is not significantly different in the CPRE and MSRE methods; the end result is closure of the bladder, urethra, and abdominal wall. In contrast, closure of the male with bladder exstrophy is quite different in the CPRE and MSRE. The CPRE closes and repositions the bladder and entire urethra at one stage. In contrast, the MSRE closes and repositions the bladder and posterior urethra at the first stage, with the remainder of the urethra closed at a later stage.

Complete primary repair for exstrophy

In the late 1980s, an anatomic approach to exstrophy repair that combined simultaneous bladder closure, bladder neck remodeling, and epispadias repair was initiated by Mitchell.[124] This operation evolved out of a technique developed for the treatment of epispadias – the complete penile disassembly technique.[125]

Complete primary reconstruction of the exstrophied bladder is best done in the newborn period. Primary reconstruction in the newborn period is technically easier than when done in an older child. It also offers theoretical advantages, as it may maximize the opportunity for 'normal' bladder development and the potential for urinary continence. The bony pelvis remains pliable in the newborn period, so that osteotomies may be avoided in some cases – usually if closure can be performed within the first 72 hours of life.

Clinical experience with patients with posterior urethral valves (PUV) suggests that early restoration of non-obstructive emptying and filling of the bladder allows the bladder to regain some or all of its normal physiologic and developmental potential.[126] This, in turn, implies that the bladder progresses through developmental milestones that occur in the first few months of life and which may be irreversibly lost if missed. Precedence for this form of organ development is noted in the brain with the acquisition of language and visual perception. Finally, early primary bladder reconstruction creates a more normal-appearing baby that fosters improved bonding between the parents and infant.

In the complete primary repair or Mitchell technique,[124] the bladder, bladder neck, and urethra are moved posteriorly within the pelvis. This movement positions the proximal urethra within the pelvic diaphragm in an anatomically more normal position to maximize the effect of the pelvic muscles and support structures in the achievement of urinary continence. Posterior movement of the bladder neck and urethra also facilitates reapproximation of the pubic symphysis, which in turn helps prevent anterior migration of the urethra and bladder neck and provides a more anatomically normal muscular pelvic diaphragm.

Total penile disassembly reduces anterior tension on the urethra because it is separated from its attachments to the underlying corporeal bodies. These attachments otherwise pull the urethral plate anteriorly, preventing posterior placement of the proximal urethra and bladder neck in the pelvis. Tension reduction theoretically decreases the risk of bladder dehiscence and also temporarily reduces the dorsal tension on the corporeal bodies that may contribute to dorsal chordee in males. Combining the epispadias repair with primary closure allows for the most important aspect of primary closure – division of the intersym-

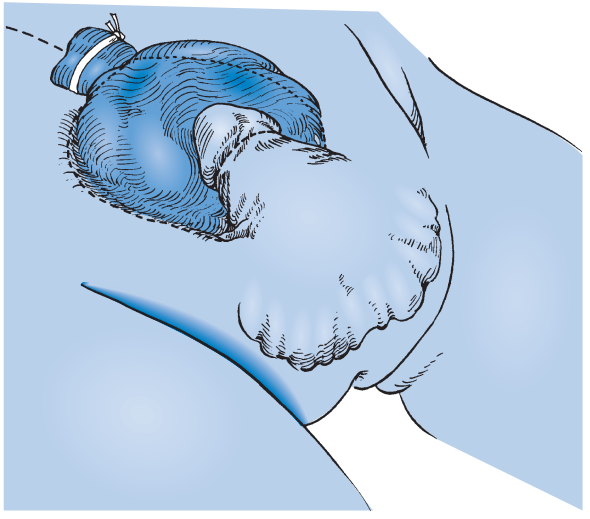

Figure 61.18 Initial lines of dissection for male complete primary exstrophy repair technique – ventral perspective.

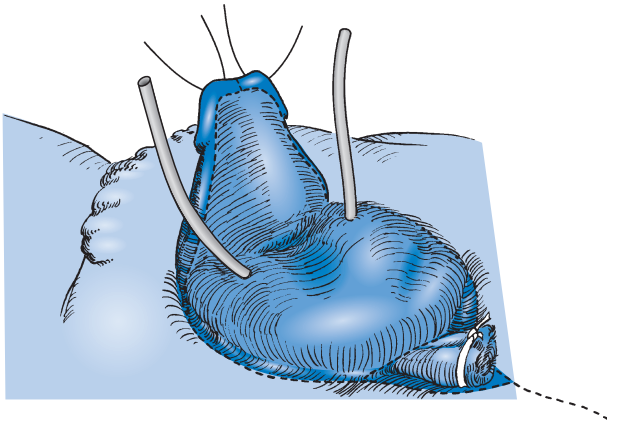

Figure 61.19 Initial lines of dissection for male complete primary exstrophy repair – dorsal perspective. Lines at the bladder neck indicate approximate tailoring that may be needed to exclude dysplastic tissue in this area.

physeal ligament or band located posterior to the urethra in these patients. Advocates of CPRE feel that division of this ligament and deep dissection is optimized when the urethra is separated from the corpora cavernosa.

Neonatal closure employing this technique optimizes the chance for early bladder cycling and consequent normal bladder development. It may also obviate the need for a multistaged repair of the exstrophied bladder, including further BNR, bladder augmentation, and penile reconstructive surgery.

Male CPRE technique

The surgical technique of CPRE and the Mitchell complete penile disassembly technique for epispadias follow the same principles and thus are discussed simultaneously. After standard preparation of the surgical field, 3.5 Fr umbilical artery catheters are placed into both ureters and secured with 5.0 chromic sutures. A marking pen outlines the planned lines of dissection (Figures 61.18 and 61.19). Initial dissection begins superiorly and proceeds inferiorly to separate the bladder plate from the adjacent skin and fascia using fine-tip electrocautery (Colorado tip). The umbilical cord usually needs to be mobilized on its vessels in a cephalad direction such that the resulting umbilicus will be at the level of a line drawn between the two iliac crests. The relocated umbilicus will also be the cutaneous site for bringing out the suprapubic tube. The dissection in classic exstrophy patients is extraperitoneally.

To aid in dissection, traction sutures are placed into each hemiglans of the penis. These sutures are placed at the beginning of the operation and are initially oriented transversely in the hemiglans. The sutures will rotate to a parallel vertical orientation as the corporeal bodies rotate medially following dissection of the corporeal bodies and the urethral wedge (urethral plate + underlying corpora spongiosa) from each other.

To begin the penile dissection, a circumcising incision is made along the ventral aspect of the penis. This should precede dissection of the urethral wedge from the corporeal bodies because it is easier to identify Buck's fascia ventrally. The initial plane of dissection is developed just above Buck's fascia. Buck's fascia stops at the corpora spongiosum during the dissection. So, as the dissection progresses medially, the plane shifts subtly from above Buck's fascia to just above the tunica albuginea. Dorsally, methylene blue or brilliant green helps differentiate urothelium from squamous epithelium. Injection of the surrounding tissues with 0.25% lidocaine and 1:200 000 U/ml epinephrine also improves hemostasis, which assists the dissection. The margins of the dorsal urethra are usually obvious. The surgeon must take care not to narrow the urethral wedge as this will be tubularized later. Urethral wedge dissection is carried proximally to the bladder neck. Careful lateral dissection of the penile shaft skin and dartos fascia from the corporeal bodies is paramount; the lateral dissection of the penis is always superficial to Buck's fascia because the neurovascular bundles are located laterally in the epispadic penis. Medially, under the urethral wedge, the

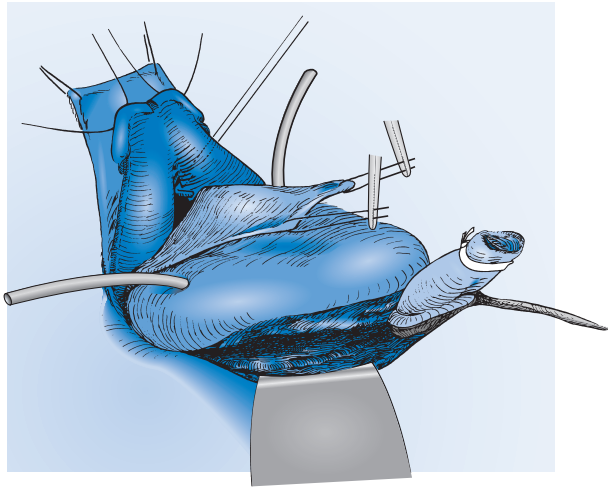

Figure 61.20 Disassembly of the urethral wedge (urethral plate with underlying corpora spongiosa) from corporeal bodies. The plane of dissection should remain on the corporeal bodies to allow the corpora spongiosa to remain with the urethra.

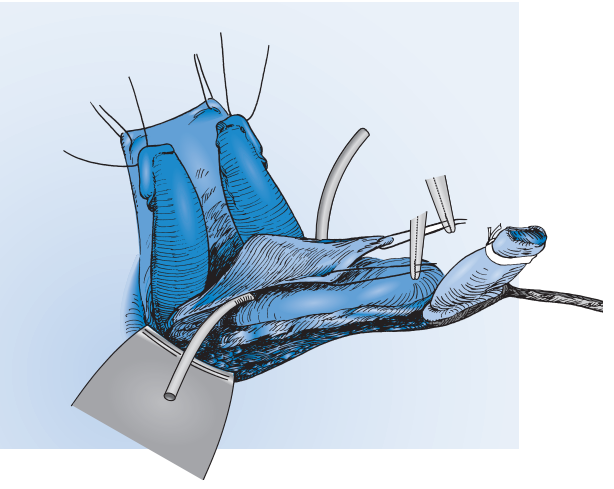

Figure 61.21 Distal separation of the corporeal bodies and urethral wedge. This maneuver may not always be required. Complete separation allows maximal exposure to the pelvis and optimizes the dissection and posterior positioning of the bladder, bladder neck, and urethra in the pelvis.

dissection plane is on the tunica albuginea of the corpora cavernosa.

The penis is surgically disassembled into three components – the right and left corporeal bodies, with their respective hemiglans, and the urethral wedge (urothelium with underlying corpora spongiosa).[125] This is done primarily to provide exposure to the intersymphyseal band and to allow adequate proximal dissection. It is easiest to initiate the dissection proximally and ventrally, on the underside of the corpora cavernosa (Figure 61.20). The plane of dissection should be carried out at the level of the tunica albuginea on the corpora. After a plane is established between the urethral wedge and the corporeal bodies, this dissection is carried distally to separate the three components from each other (Figure 61.21). This maximizes the degree of freedom for the best repair. The corporeal bodies may be completely separated from each other, since they exist on a separate blood supply. It is important to keep the underlying corpora spongiosa with the urethral plate; the blood supply to the urethral plate is based on this corporeal tissue, which should appear wedge-shaped after its dissection from the adjacent corpora cavernosa. The urethral–corporal spongiosal component will later be tubularized and placed ventral to the corporeal bodies. Paraexstrophy skin flaps should not be used for urethral lengthening, because this maneuver may devascularize the distal urethra. Because the bladder and urethra are moved posteriorly into the pelvis as a unit, division of the urethral wedge should never be necessary. However, in some cases, a male patient will be left with a hypospadias that will require later surgical reconstruction (short distal urethra).

Proximal dissection of the urethral wedge from the corporeal cavernosa bodies facilitates exposure of the intersymphyseal ligament, which must be incised. The dissection may be carried into the pelvis following the planes along the medial aspects of the corporeal bodies (Figure 61.22). Deep incision of the intersymphyseal ligaments posterior and lateral to each side of the urethral wedge is absolutely necessary to allow the bladder to achieve a posterior position in the pelvis

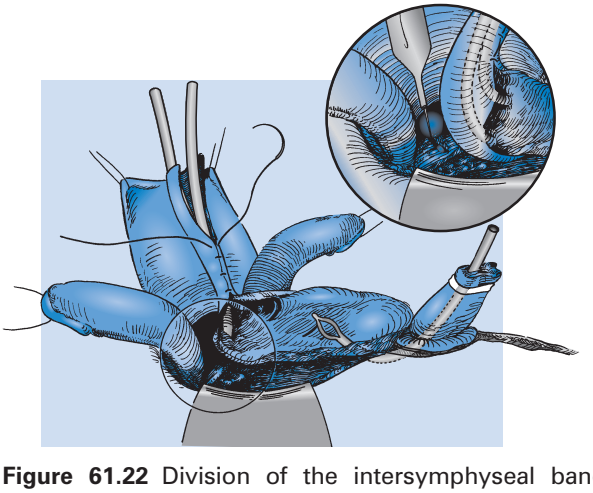

Figure 61.22 Division of the intersymphyseal band (condensation of anterior pelvic fascia) and deep pelvic dissection. The inset demonstrates division of the intersymphyseal band. Division of this band allows posterior placement of the bladder without tension.

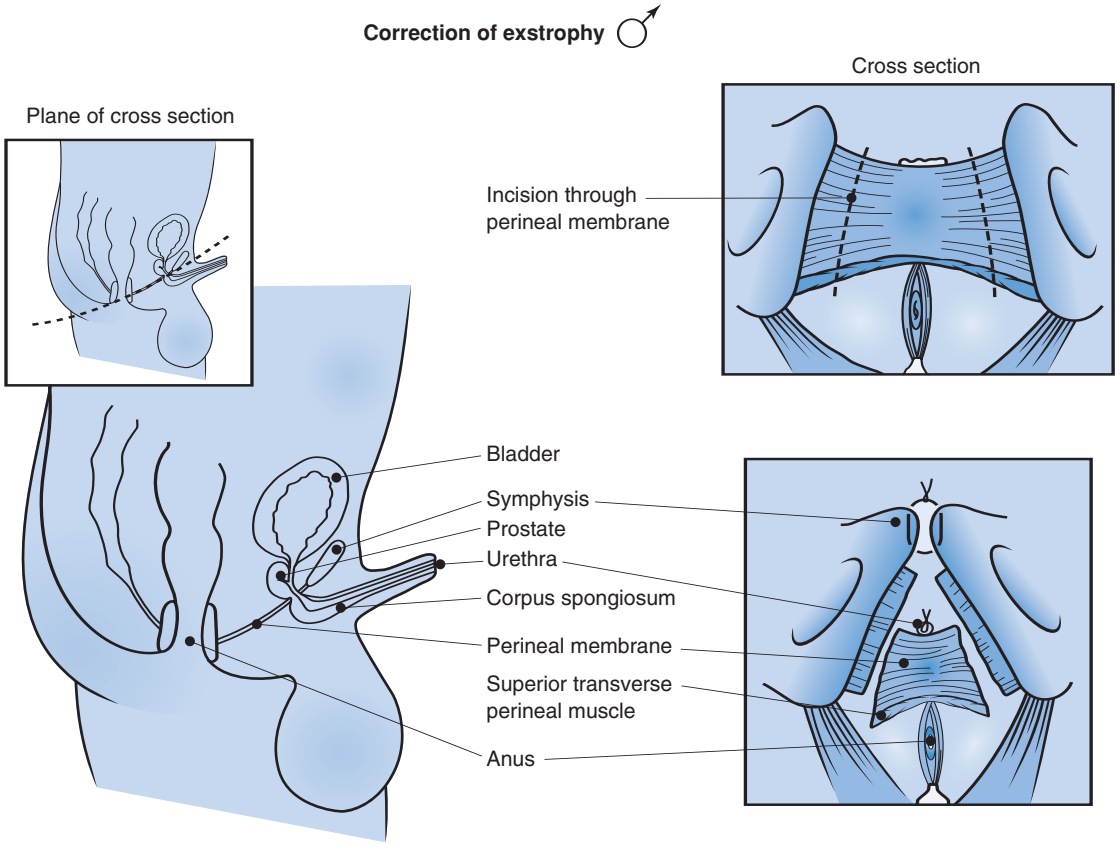

Figure 61.23 This cross section represents an idealized positioning of the urethra and bladder neck in the pelvis.

(Figure 61.23). This dissection should be carried until the pelvic floor musculature becomes visible (i.e. the intersymphyseal ligament is completely incised). Computed tomography (CT) of the pelvis demonstrates that these ligaments lie posterior to the bladder neck and urethra. Failure to adequately dissect the bladder and urethral wedge from surrounding structures will create anterior tension along the urethral plate and prevent posterior movement of the bladder in the pelvis.

Once the bladder and urethral wedge are adequately dissected from the surrounding tissues, the majority of the procedure is done and the closure is straightforward and anatomic. The importance of recognizing the proper location of the bladder neck is key: in boys, proximal to the verumontanum; in girls, just distal to the trigone. Prior to reapproximating the bladder, a suprapubic tube is placed and brought out through the umbilicus. The primary closure of the bladder is achieved using a three-layer closure with monofilament absorbable suture (i.e. Monocryl and Vicryl). The urethra is tubularized using a two-layer running closure with monofilament and Vicryl suture as well (Figure 61.24). The tubularized urethra is

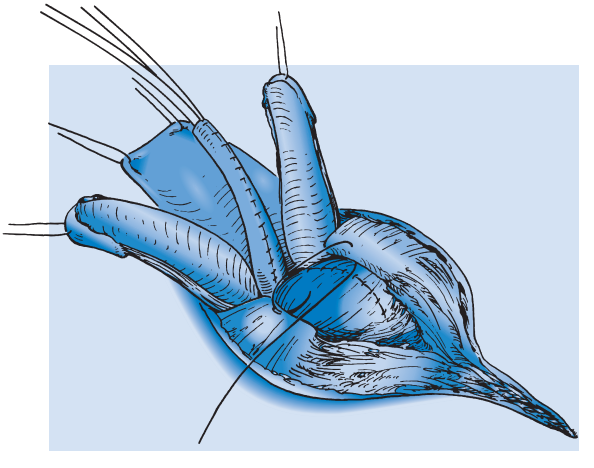

Figure 61.24 The bladder and urethra are closed in two layers using absorbable suture. The ureteral catheters are brought out throught the urethral closure. The suprapubic tube may be brought out through the umbilicus.

then placed ventral to the corpora in an anatomically normal position.

Then the pubic symphysis is reapproximated using 0–0 polydiaxonone interrupted figure-of-eight

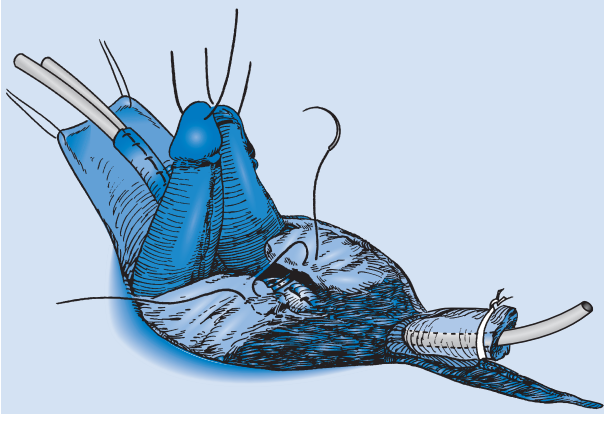

Figure 61.25 Reapproximation of pubis symphysis using absorbable suture. Note medial rotation of glans that occurs after dissection.

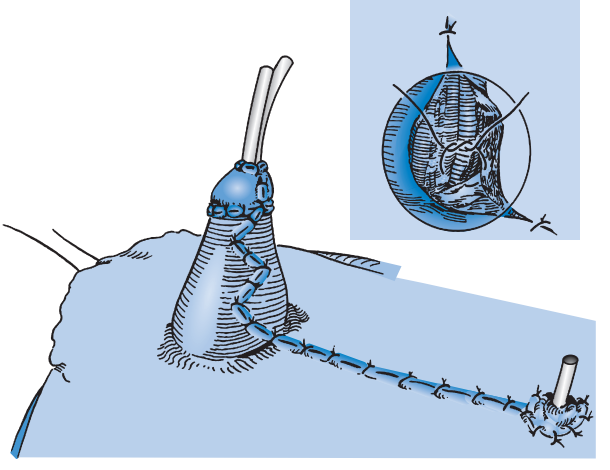

Figure 61.26 Skin reapproximation can be challenging. Tacking sutures placed between the dermal tissue and the corporeal bodies can assist in anchoring the penile shaft skin to the base of the penis. Z-plasty incisions can also be useful to approximate the shaft skin ventrally.

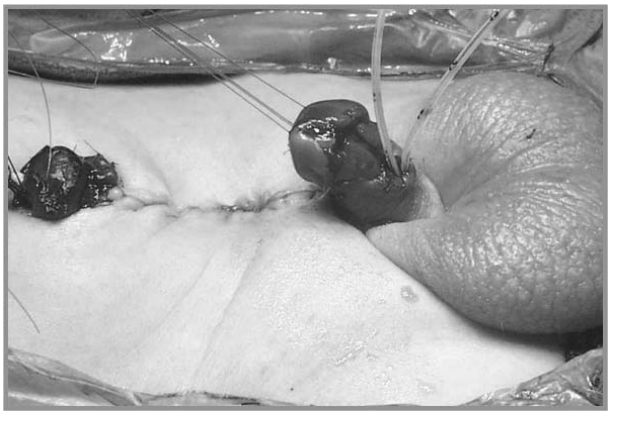

Figure 61.27 Hypospadias occurs in this situation because the urethra is too short after the bladder has been positioned posteriorly in the pelvis.

sutures. Knots are anterior to prevent suture erosion into the bladder neck (Figure 61.25). Rectus fascia is reapproximated using a running 2–0 polydiaxonone suture. Penile shaft skin is reconfigured using either a primary dorsal closure or reversed Byars flaps if needed to provide dorsal skin coverage. Skin covering the abdominal wall is reapproximated using a two-layer running closure of absorbable monofilament suture.

The corporeal bodies will tend to rotate medially with closure when the lateral margins of Buck's fascia of each corpora cavernosa are approximated. This rotation will assist in correcting the dorsal deflection and can be readily appreciated by observing the vertical lie of the previously horizontally placed glans traction sutures. Occasionally, significant discrepancies in the dorsal and ventral lengths of the corpora will require dermal graft insertion. However, this is rarely needed in the newborn closure. The corpora are reapproximated with fine interrupted suture along their dorsal aspect.

The urethra can then be brought up to each hemiglans ventrally to create an orthotopic meatus (Figure 61.26). The glans is reconfigured using interrupted mattress sutures of polydiaxonone suture (i.e. PDS) followed by horizontal mattress sutures of 7–0 monofilament suture (i.e. Maxon) to reapproximate the glans epithelium. The neourethra is matured with 7–0 braided polyglactin suture (i.e. Vicryl) similar to a standard hypospadias repair. In some cases, the glans tissue is reduced to create a conical-appearing glans. In roughly half of cases, the urethra lacks enough length to reach the glans. In this situation, the urethra may be matured along the ventral aspect of the penis to create a hypospadias (Figure 61.27). This can be corrected at a later date as a second-stage procedure and options for hypospadias repair are detailed in other chapters. The redundant shaft skin is maintained ventrally in these patients to assist in later penile reconstructive procedures.

Female CPRE technique

The principles and timing of repair are analogous for boys and girls (Figure 61.28). To perform this technique, the lines of initial dissection are depicted in Figure 61.29. In an effort to clearly define the bladder neck, the bladder neck dissection is tailored. The bladder neck, urethra, and vagina are mobilized as a unit.

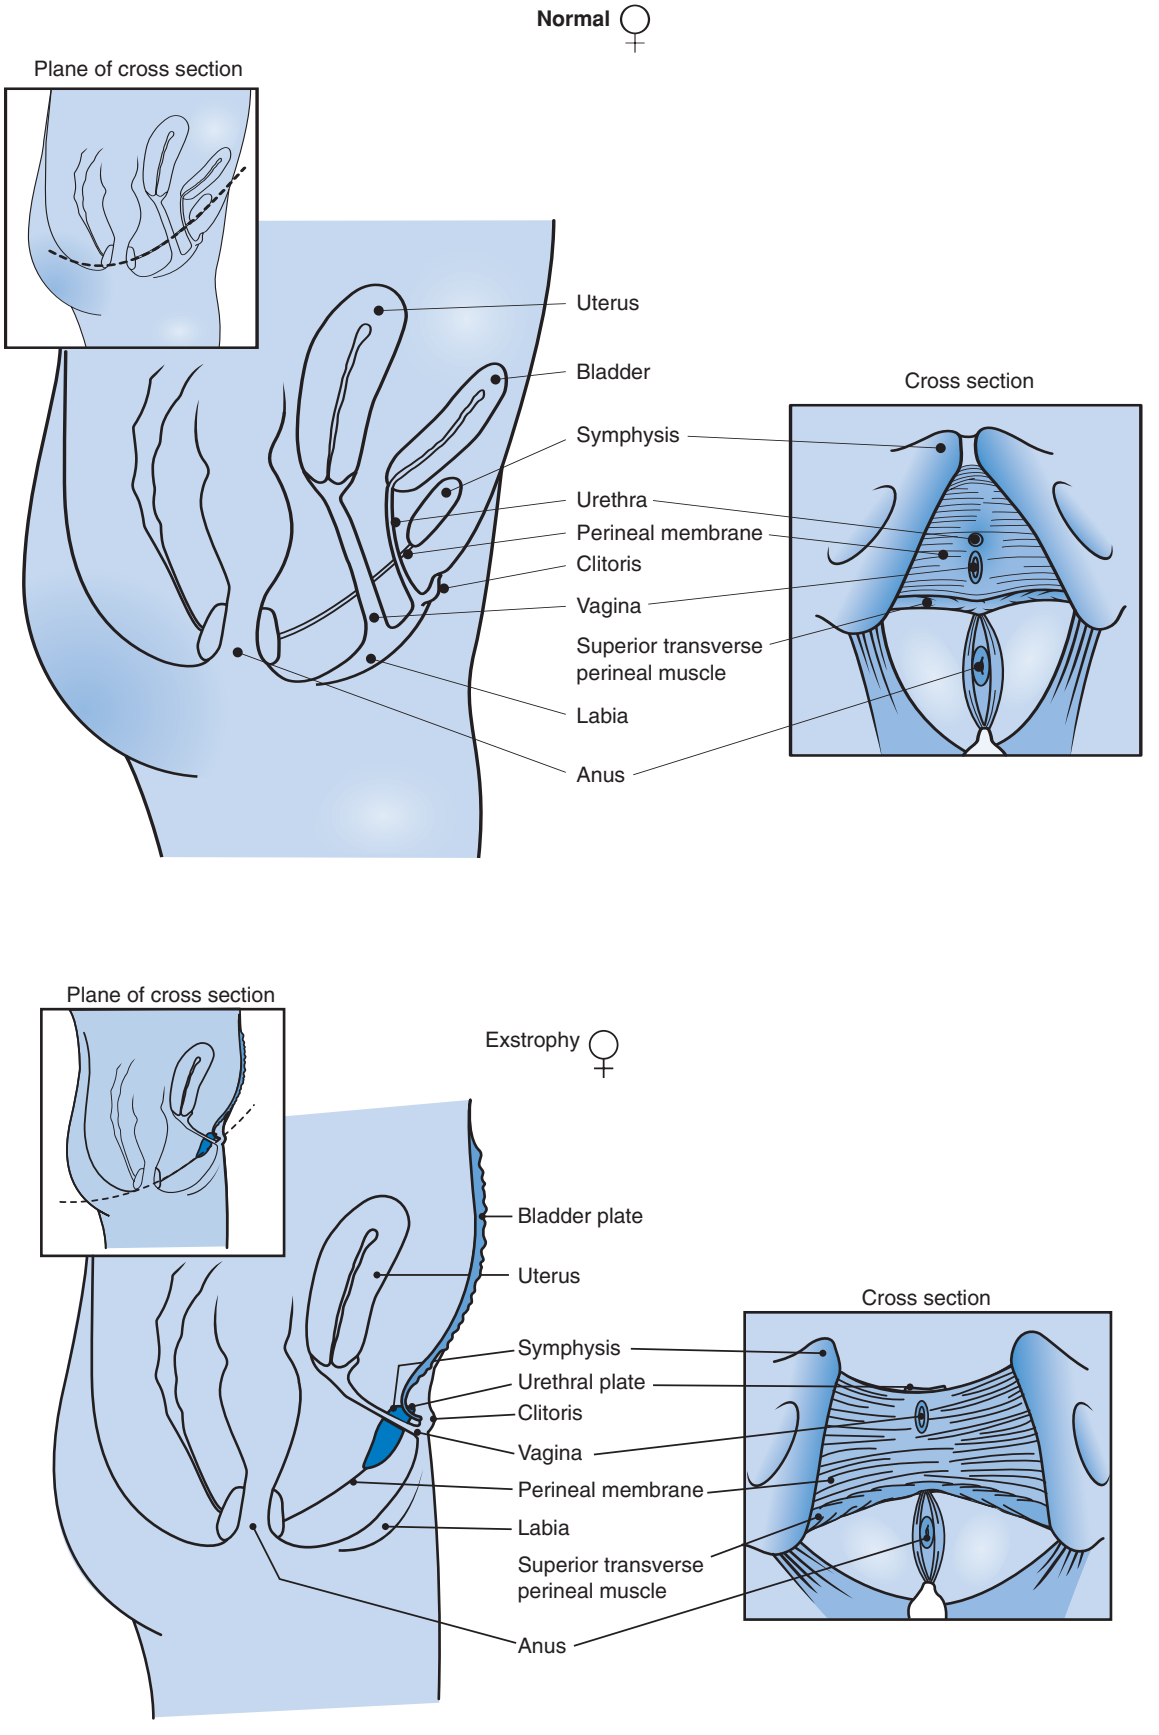

Figure 61.28 Cross section of (*a*) normal female anatomy compared with (*b*) exstrophic female anatomy.

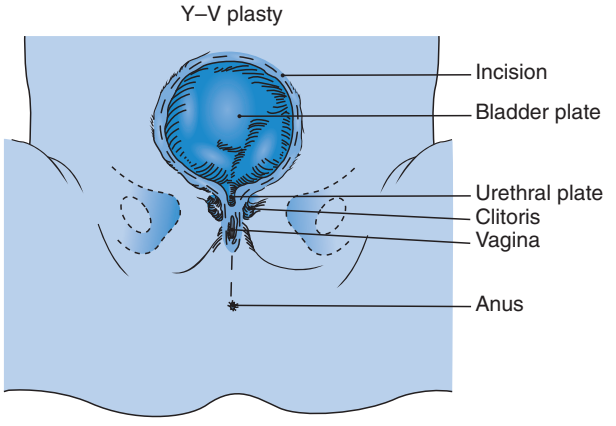

Figure 61.29 Initial lines of dissection for female complete primary exstrophy repair technique. Of note, the dissection is carried around the vaginal vault inferiorly to mobilize the vagina and urethra together.

The dissection is achieved with a tungsten-tip electrocautery (Colorado tip) to minimize tissue damage while achieving hemostasis. The appropriate plane of dissection is found anteriorly along the medial aspect of the bifid clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault (Figure 61.30). The vagina is mobilized with the urethral plate and bladder neck. The urethra and bladder neck should not be dissected from the anterior vaginal wall, as this will compromise the blood supply to the urethra.

During the posterior lateral dissection, the intersymphyseal band will be encountered and should be deeply incised to allow the vagina, urethra, and bladder neck to move posteriorly. The posterior limit of the dissection is reached when the pelvic floor musculature is exposed. The proximal urethra can be lengthened to some degree with parallel incisions in the bladder plate toward the trigone. As importantly, lateral dysplastic tissue should be excluded from this area when the bladder neck is created.

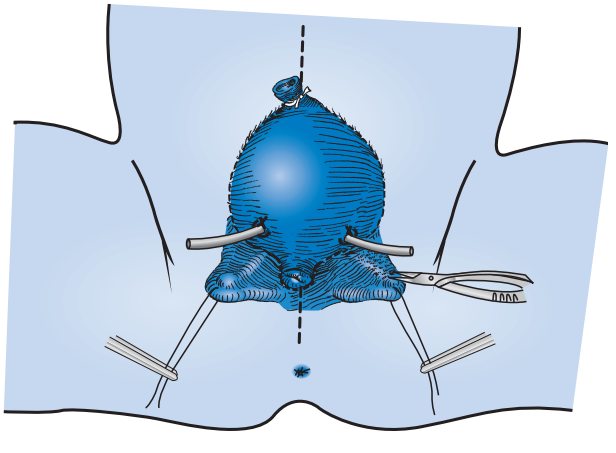

Figure 61.30 The lines of dissection are marked in this drawing of a newborn girl with classic bladder exstrophy. Please note stay sutures placed in clitoral bodies to assist with exposure.

Following adequate dissection, the vagina and urethra are moved posteriorly in the perineum with a Y–V plasty. The urethra is then tubularized using a two-layer closure of absorbable suture (Figure 61.31). Prior to the urethral closure, a suprapubic tube is routinely placed to provide postoperative urine drainage (Figure 61.32). The bladder, bladder neck, and urethra should be positioned deeply in the pelvis and traverse the pelvic diaphragm (Figure 61.33). The symphysis pubis is then reapproximated using two 0–0 PDS figure-of-eight sutures (Figure 61.34).

As in the repair in the boy, osteotomies may be necessary when a wide pubic diastasis prevents a low-tension reapproximation of the pubic symphysis. Mitchell and Grady use anterior iliac osteotomies in these situations. The rectus fascia can then be closed

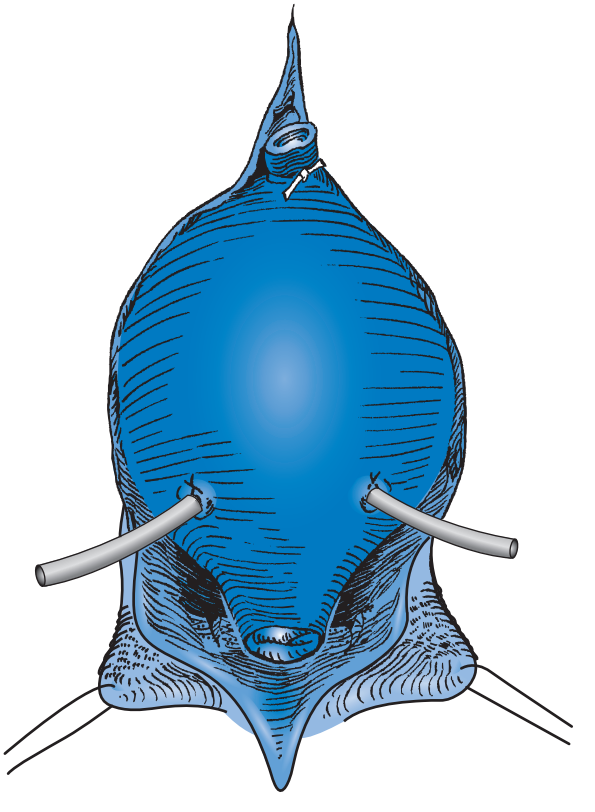

Figure 61.31 The appropriate plane of dissection is found anteriorly along the medial aspect of the bifid clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault. This allows for deep pelvic dissection to place the bladder, bladder neck, and urethra into the pelvis without tension.

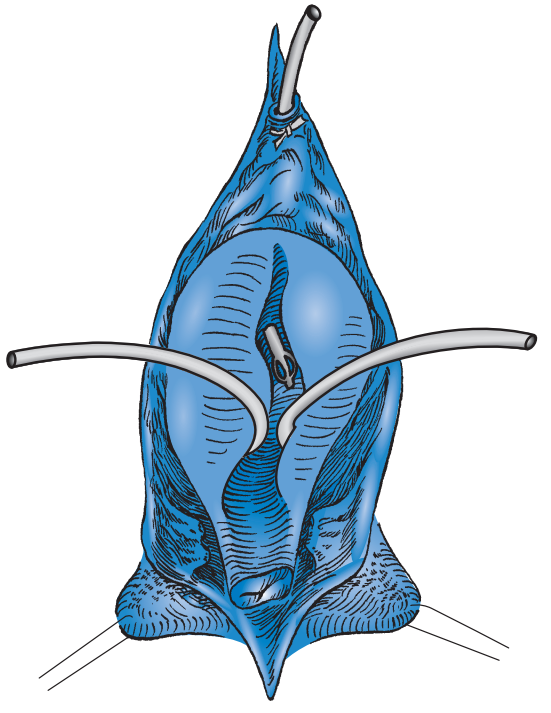

Figure 61.32 Prior to the urethral closure, we routinely place a suprapubic tube to provide postoperative urine drainage. The suprapubic tube is brought out through the umbilicus. Ureteral catheters are left in place and brought out through the urethra. All tubes are left to gravity drainage.

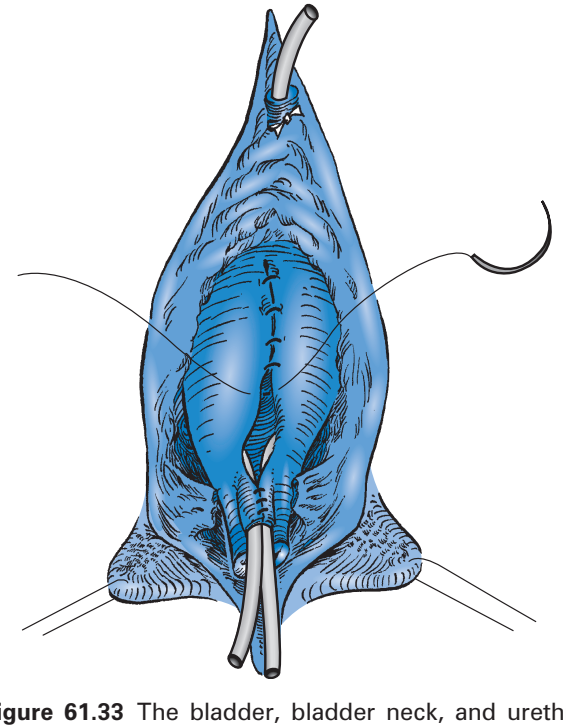

Figure 61.33 The bladder, bladder neck, and urethra should be positioned deeply in the pelvis if an adequate dissection has been performed.

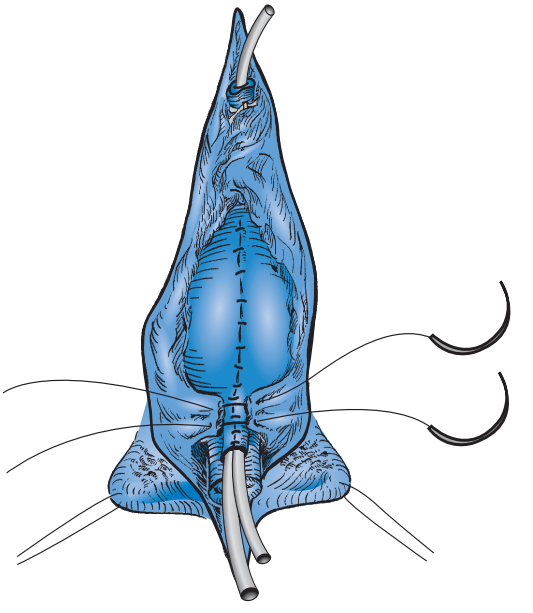

Figure 61.34 Reapproximation of symphysis pubis using interrupted sutures. Lateral dissection may be required to reapproximate the rectus fascia in the midline.

in the midline. The neourethra is matured with 5–0 Vicryl sutures and the medial sides of the bifid clitoris are united with 7–0 Maxon suture. The labia majora is advanced posteriorly to the perineum at this time to improve cosmesis of the external genitalia (Figure 61.35). A Z-plasty skin closure can be employed as well.

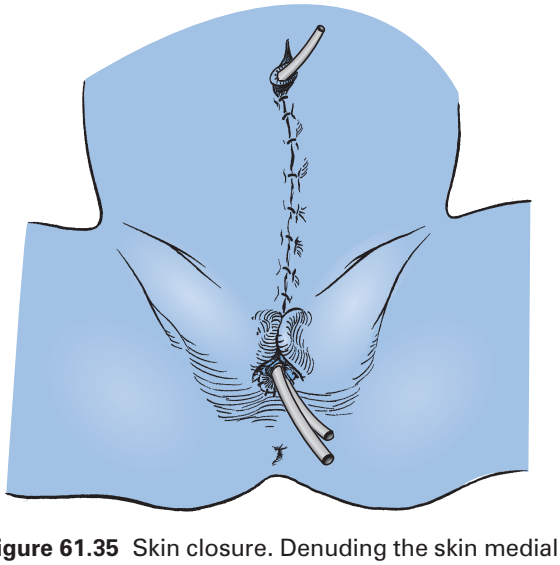

Figure 61.35 Skin closure. Denuding the skin medial to the clitoral bodies minimizes the bifid appearance of these structures postoperatively. The labia majora may also be advanced inferiorly to create a more normal cosmetic appearance.

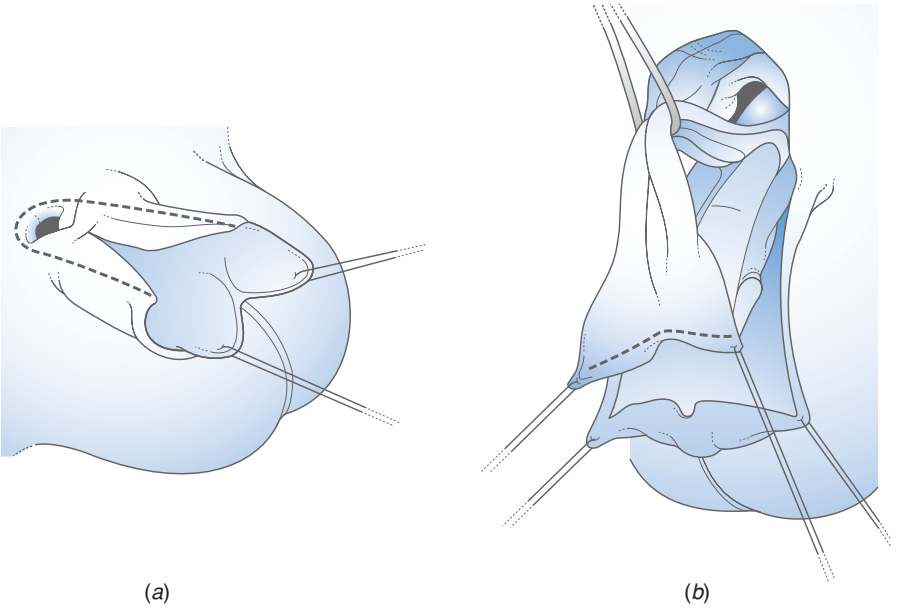
Modifications of the CPRE technique

In an effort to improve the results of the CPRE technique, several authors have reported modifications. Caione and colleagues described the use of an electrical muscle stimulator during deep pelvic dissection to preserve and reconfigure the periurethral muscle complex. Long-term results of this patient series have not yet been reported but preliminary results are promising.[127]

El-Sherbiny and Hafez have described a modification of the penile disassembly technique preserving the connection between the distal urethral wedge and the corporeal bodies to decrease the incidence of hypospadias.[128] Proposed by Emir and colleagues, one solution for intraoperatively anticipated hypospadias is to generate parameatal-based inner preputial skin flaps which do not require anastomosis to the urethral plate.[129]

Outcomes of CPRE

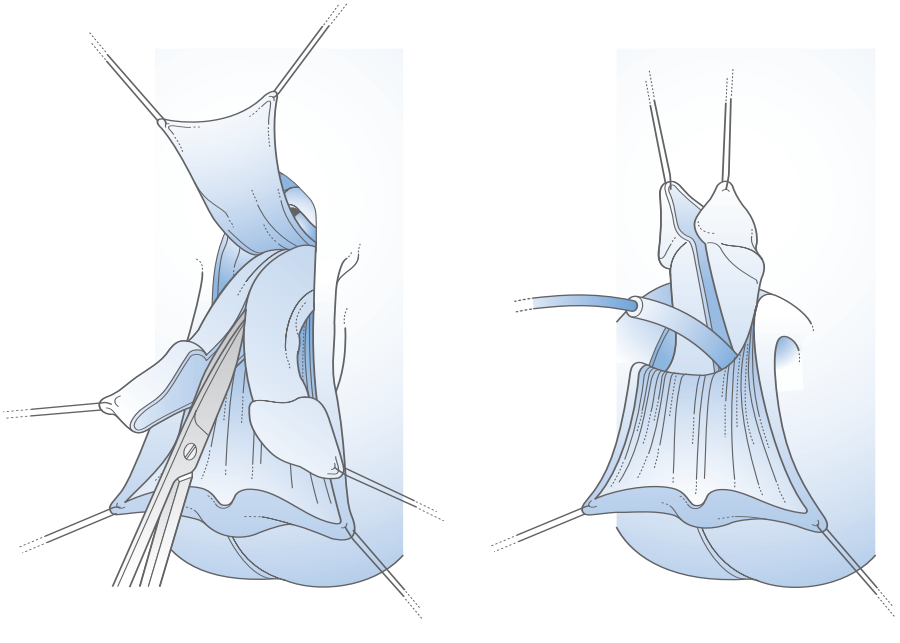


The longest series reporting outcomes of CPRE is from Children's Hospital & Regional Medical Center in Seattle, Washington, spanning 13 years: of 29 patients, 17 are >5 years of age and have 76% continence (defined as a dry interval >2 hours and spontaneous voiding without catheterization); only 3% (1 of 29) required augmentation, which compared favorably with 27% of 77 staged exstrophy closures at this institution requiring augmentation, although admittedly the latter group has been followed longer. However, this report does not mention the number of patients requiring BNR to achieve this continence rate. In 2003, preliminary outcomes from the Seattle group were presented in abstract form. In this series, bladder neck modification was performed in 72% of females and 86% of males prior to achieving continence; overall, 86% of children achieved daytime continence with volitional voiding. The majority of these bladder neck modifications were perfomed at the same time as ureteral reimplantation procedures and were performed using a Mitchell bladder neck technique.[130] A 14% complication rate and 16% moderate or severe hydronephrosis rate was also noted. Of note, in the majority of these patients the hydronephrosis remains a transient phenomenon that the authors believe represents a reaction to bladder cycling.[130] One other report from the Boston group provides an 8-year follow-up of CPRE outcomes. Borer and colleagues noted that 5 of 8 patients (63%) ≥ 4 years old had grossly inadequate bladder outlet resistance and either had or would require BNR. This same group also reported on urodynamic findings between patients who had undergone exstrophy repair using a complete primary repair technique compared with a modern stage repair technique. They found that patients undergoing a complete primary repair universally had better bladder stability and bladder compliance than those who had been repaired with a staged technique. Bladder capacity was equivalent between the two groups. Interestingly, patients repaired with a complete repair technique also had normal electromyelography (EMG) results during this study.[98]

After CPRE, hypospadias rates have ranged from 50 to 82%.[98,124,131] Borer and colleagues have decreased this rate by using interrupted urethral sutures instead of running sutures.[98] Reconstruction of the hypospadic defect can be challenging[98,132] owing to paucity of skin. Hafez and El-Sherbiny have found tubularized penile flap urethroplasty to be superior to Thiersch–Duplay urethroplasty.[132] Bladder neck fistula have been observed in as many as 41% of CPRE repairs,[133] 78% of which required fistulectomy. Partial or complete hemiglans and corporeal loss have been reported by several authors,[133,134] which is probably the most feared complication. However, this complication may not be unique to CPRE, and can be seen in any bladder exstrophy closure method.[135] Borer and colleagues reported 75% of 16 males and 29% of seven females undergoing newborn CPRE required blood transfusion.

Some surgeons have criticized the staged approach as requiring a greater number of surgical procedures than the CPRE.[135] Given the 'relative newness' of the CPRE technique, long-term studies will further delineate the number of patients who require hypospadias reconstruction and BNR to achieve urinary continence. As the male children progress through puberty, phallic growth, presence of chordee, erectile function, and ejaculatory function will be outcomes to closely monitor. Given exstrophy is a complex birth defect to reconstruct, no matter which method is chosen, complications will occur,[134,136] most of which require further surgical interventions.[98]

Complete penile disassembly for the treatment of isolated male epispadias



Mitchell performed his first complete penile disassembly or Mitchell technique for epispadias repair in 1989. Mitchell and Bagli first reported their results in 1996.[125] Complete penile disassembly offers several advantages over the modified Cantwell–Ransley tech-

(*a*) (*b*)

Figure 61.36 Complete penile disassembly technique. (*a*) Lines of initial dissection circumscribing the urethral plate and bladder neck. (Adapted from Mitchell and Bagli,[125] with permission.)

nique. The planes of dissection extend anatomically to the bladder neck. This facilitates its use with BNR. Complete mobilization of the urethral wedge from the corporeal bodies by disassembly also creates a more normal appearance of the penis by allowing ventral placement of the urethra (Figures 61.36–61.38). A detailed description of the surgical technique is included in the section on complete primary repair of

exstrophy above. Zaontz and colleagues reported on a multicenter experience using this technique and found that 16/17 boys had straight erections following repair. Three patients developed pinpoint fistulas, of which two closed spontaneously.[137] Hammouda reported on 42 repairs[138] – glans ischemia occurred in five cases, with resolution in three and loss of hemiglans in two cases. A straight phallus was achieved in 81% and one pinhole coronal urethrocutaneous fistula (2.4% of patients) was successfully closed. He suggested maintaining ventral vascular attachment of the shaft skin to the urethral wedge, the urethral mesentery, which some have suggested may decrease urethral complications. Perovic et al have described variants of this technique for epispadias that may be used in selected circumstances as well.[139] Modifications of the complete penile disassembly technique include the use of cavernotomies to assist in the correction of chordee and incomplete separation of the urethral wedge and the corporeal bodies to avoid the creation of hypospadias.

Modern staged repair of exstrophy

The staged reconstruction for exstrophy developed in response to high reported rates of renal damage from single-stage approaches in the 1970s. The initial outline for staged reconstruction as conceived by Jeffs consisted of bladder and posterior urethral closure at birth, BNR at 2–3 years of life, and epispadias repair later.[140] This paradigm was altered when bladder capacity was noted to increase with the added resistance from early epispadias repair.[141] Thus, the current MSRE, as described by the Johns Hopkins group, consists of bladder and posterior urethral closure at birth or soon thereafter (stage 1), epispadias repair at 6–12 months of life (stage 2), and BNR when the bladder capacity is adequate and the child is mentally prepared for toilet training (usually at 4–5 years of age) (stage 3).[142] In some cases, epispadias repair and BNR ± ureteral reimplantation can be combined.[143,144]

MSRE stage 1: initial early bladder exstrophy closure

At stage 1 of exstrophy reconstruction, the surgical objectives include:

- closure and repositioning of the bladder and urethra (posterior urethra in males and entire urethra in females) inside the pelvic ring
- approximation of the pelvic ring with closure of the abdominal wall.

In male patients, at the end of stage 1, this closure technique converts the classic bladder exstrophy into a male with complete epispadias, with incontinence and balanced posterior outlet resistance. This functional state stimulates bladder growth while preserving renal function.

Exstrophy closure

The initial decision as to whether a bladder template is amenable to closure is currently based on subjective data. Even a small bladder template, if distensible and contractile, can enlarge to a useful size once closed. However, if an examination under anesthesia reveals a small (<5 ml) acontractile, non-distensible bladder patch, an attempt should not be made to close this bladder.[97] Although ureterosigmoidostomy has proven useful in this group of patients,[145] it is preferred to wait and re-examine the child at 4–6 months of age under anesthesia. If at later evaluation the bladder remains inadequate, a non-refluxing colon conduit is used to divert the urine along with the abdominal wall closure and epispadias repair. This can be converted at a later age to a continent diversion or anastomosed to the rectosigmoid.

If the bladder template is amenable, early exstrophy closure is advantageous for multiple reasons. Socially, for the family, a prompt closure begins the road toward normalcy. In addition, early closure saves the bladder from prolonged exposure, which can lead to such histologic changes as acute and chronic inflammation, squamous metaplasia, cystitis glandularis and cystitis cystica, and muscular fibrosis. Functionally, it is likely that this results in a bladder with low capacity and poor compliance.[141] Electron microscopy has shown that the newborn exstrophy bladder is 'immature' when compared with control newborns,[146] having fewer small nerve fibers,[101] less smooth muscle, and a threefold increase in type III collagen content.[147] While it is unclear whether these changes are a part of the primary pathology or secondary to the lack of bladder cycling in utero, it is conceivable that prompt closure could also 'mature' the bladder by restoring bladder cycling. Similarly, clinical data from the Mayo Clinic have verified the importance of immediate postnatal exstrophy closure; infants closed before 7 days of age required fewer bladder augmentations to achieve eventual continence.[148]

Appproximation of the pelvic ring

It has become clear that approximation of the open pelvic ring eases abdominal wall closure and diminishes the rate of bladder dehiscence and abdominal wall dehiscence.[149,150] This therefore allows the construction of an intrapelvic urethra and reapproximates the pelvic floor musculature, probably contributing to long-term continence.[19,150] Additionally, in females, osteotomy may reduce the likelihood of uterine prolapse.[150] Therefore, pelvic ring reapproximation is useful at initial bladder closure as well as at later stages of reconstruction if satisfactory reapproximation was not achieved initially. Pelvic closure in the neonate younger than 48–72 hours old can be achieved without osteotomies owing to the effects of maternal relaxin; immobilization is achieved by modified Bryant's traction for 3–4 weeks (see Figure 61.15). However, beyond this age or at this time if the pelvis is not sufficiently malleable, osteotomies are performed at the time of initial closure. An interesting predicament for the surgeon is the situation of the newborn with a large bladder template. In this case with a bladder having great potential for later continence, the pubic diastasis will be wider and require osteotomy, regardless of when closure is attempted. In the MSRE with osteotomy, a combined approach of posterior vertical iliac osteotomy with anterior horizontal innominate osteotomy (see Figure 61.13) is primarily used, with good results.[102,104] Femoral nerve palsy is a possible complication that must be monitored and can be reduced with gradual tightening of the fixator. These osteotomies are secured by intrafragmentary pins, external fixation (4 weeks for newborns; 6–8 weeks for older patients), and light Buck's traction for 2–4 weeks (see Figure 61.17)

Male MSRE bladder and posterior urethral closure technique

In stage 1 of the MSRE of the male child (Figure 61.39), the bladder and posterior urethral closure technique[1,151] begins as ureteral catheters are placed and secured with 5–0 or 6–0 chromic suture. These catheters aid ureteral visualization prior to making the initial incision. A traction suture is placed in the glans penis. The posterior urethra is generated by incising a 2 cm wide strip of mucosa from the distal trigone to below the distal verumontanum. Initial dissection begins at the umbilicus and is continued circumferentially, incising around the bladder plate. The entire dissection remains extraperitoneal and is performed with a Colorado tip electrocautery. The two umbilical arteries are ligated and divided. The underlying detrusor muscle is mobilized from the rectus sheath to expose but not enter the peritoneum. The peritoneum is dissected off of the dome of the bladder plate as needed to allow movement deep into the pelvis. Extraperitoneal dissection lateral to the bladder exposes the retroperitoneal space and caudally leads the dissection in the correct plane at the level of the bladder neck. At this level, the rectus fascia meets the pubis and the urogenital diaphragm fibers meet the

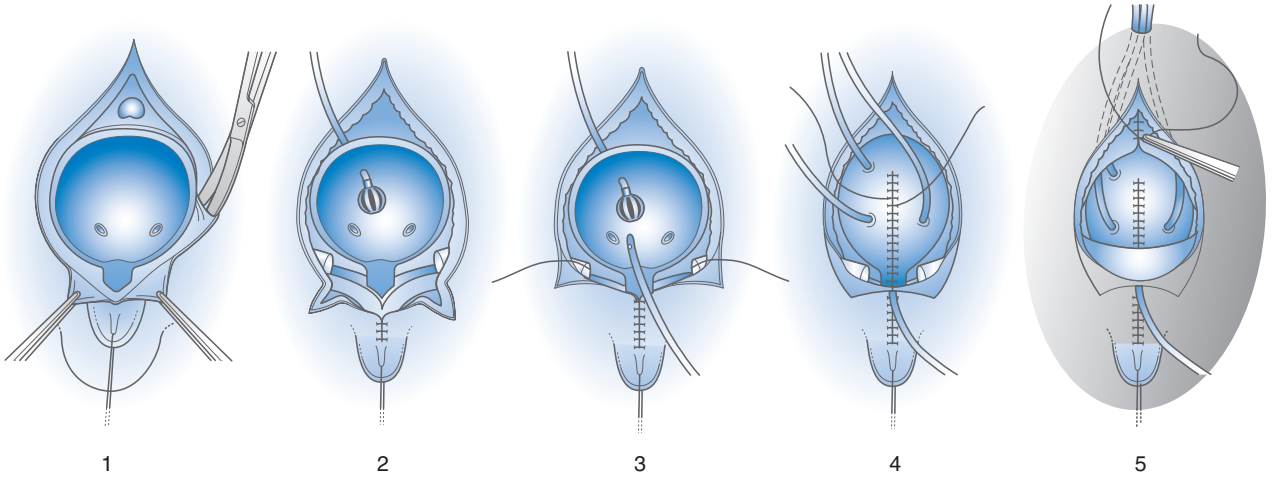

Figure 61.39 Primary bladder closure. These diagrams demonstrate the sequence of initial bladder closure in a staged repair for bladder exstrophy in the male patient. From left to right: (1) completion of dissection around the bladder and urethral plate; (2) placement of a suprapubic drainage tube after corporeal reapproximation; (3) tubularization of the urethral plate over the catheter; (4) following two-layer closure of the bladder and urethral plate, the bladder is reduced in the pelvis and fixed with sutures; (5) drainage tubes are brought out superiorly and the fascia, subcutaneous tissue, and skin are reapproximated. (Adapted from Brock and O'Neill,[2] with permission.)

posterior urethra–bladder neck. The urogenital diaphragm fibers and the intersymphyseal band must be completely taken down from the pubic subperiosteum bilaterally to the pelvic floor, or the posterior urethra and bladder will not be recessed within the deep pelvis.

At this point the posterior urethra must be assessed. If the urethral groove is adequate in length, no transverse incision is made to transect the urethral plate. If the child has severe chordee and a short urethra that inhibits attempts at penile lengthening, an incision of the urethral plate may be necessary. Management of this is best assessed after extensive mobilization of the bladder and prostatic plate from the rectus fascia, the pubic bones, and the inferior ramus of the pubis. Once radical division of the urogenital diaphragm fibers from the posterior urethra–bladder neck area is accomplished, the prostatic urethra can be displaced posteriorly into the pelvis. In some cases, division of the anterior attachments of the crura and the suspensory tissue of the penis is needed and displays the gap to be bridged between the prostatic plate and the penile plate. This lack of urethral plate length can be managed by dividing the prostatic plate distal to the verumontanum in a V-shaped fashion. After corporeal mobilization and midline reapproximation, the penile urethral plate is fashioned from a lateral rotational flap generated after a single lateral incision into the paraexstrophy skin; therefore, less tissue redundancy and dissection are necessary. Whereas this has been reconstructed after the manner of Johnston[152] or Duckett,[153] paraexstrophy skin flaps should be used with great caution. The authors have noted a 40% complication rate associated with their use and significant comorbidity.[154]

The corporeal bodies are not sewn together at this time, since this will be achieved after the urethra has been transposed beneath the corpora at the time of epispadias closure. Once the dissection appears complete, a sound on the posterior urethra can be compressed and the pelvis manually approximated to roughly assess completeness of mobilization of the posterior urethra and urogenital diaphragm.

After a silicone Malecot suprapubic tube has been placed, the umbilicus is excised and the bladder is closed in the midline in multiple layers with a running 3–0 Vicryl suture. The posterior urethra is also closed onto the base of the penis, sizing it to accept a 12–14 Fr sound. The intersymphyseal stitch is then placed but initially is not tied. A No. 2 nylon suture is recommended. It is key to perform a horizontal mattress closure, planning for the knot to be placed on the anterior surface of the pubis. This technique prevents the suture or knot from eroding into the urethra or bladder neck. Once the suture is in but not tied, three surgical personnel are needed to reapproximate the pubis symphysis. One individual applies pressure over each greater trochanter to push the pubic rami to the midline. A second individual depresses the posterior urethra and bladder neck. The third individual

ties the nylon suture. If the rectus fascia is strong, a second No. 2 nylon suture is placed just above the symphysis. The abdominal wall, subcutaneous tissues, and skin are then closed in multiple layers. A V-shaped flap of skin is fashioned in the midline for the neoumbilicus at the level of the iliac crests. The neoumbilicus is used as the site to bring the three urinary drainage catheters out to the skin. Inguinal hernias, seen in up to 82% of males, may be surgically repaired at the time of initial exstrophy closure.[21] This can be done through separate incisions or via the midline exstrophy closure incision.

Female MSRE bladder and posterior urethral closure technique

In stage 1 of the MSRE of the female child, the surgical techniques of bladder, pelvic ring, and abdominal wall closure are identical to those described for the male. However, the closure of the female differs from the male closure in that the female urethra is completely reconstructed at stage 1.[1,151] The urethral plate mucosal incision is 2 cm wide, traversing from the distal trigone to the vaginal orifice in the female. Paraexstrophy skin flaps are unnecessary in female exstrophy closures.[155] The medial aspect of each hemiclitoris is de-epithelialized to permit approximation of the two glans clitori and reconstruction of the mons. The bladder and female urethra are closed in a two-layer Vicryl closure and the pubic bones, abdominal wall, subcutaneous tissue, and skin are closed as outlined in the male. The monsplasty and genitoplasty are then performed.

Postoperative care of stage 1 MSRE

In male and female cases of initial closure, a suprapubic tube and ureteral stents are placed via the neoumbilicus, since intubation of the urethra is discouraged. Additional factors that are important to the success of the initial closure include pelvic immobilization and fixation, adequate pain control, prevention of abdominal distention, and postoperative antibiotics.[149,156] The ureteral stents are maintained for 2–3 weeks. Adequate urethral caliber and minimal postvoid residuals are assured prior to removal of the suprapubic tube at 4 weeks. The status of the upper tracts is documented by ultrasound prior to discharge and is followed by ultrasound at 3 months and every 6 months to 1 year. The successfully closed child is continued on prophylactic antibiotics, for essentially all have VUR. Increasing hydronephrosis, worsening VUR, retained urine in the bladder, and recurrent UTIs should prompt further evaluation for suture erosion or outlet obstruction. Between the ages of 1 and 3 years old, yearly cystograms under anesthesia are performed to assess the degree of reflux and, more importantly, to assess the growth of the bladder. By this age, it is hoped that the capacity will achieve 60–85 ml.

MSRE stage 2: epispadias repair

Since the initial description by Jeffs of the staged reconstructive approach to exstrophy, the timing of the epispadias repair has changed. Originally, Jeffs advocated epispadias repair as the last stage of reconstruction. However, he later recognized that earlier epispadias repair increased the success of later continence procedures by stimulating bladder growth and increasing bladder capacity.[141] In the MSRE, epispadias repair (stage 2) is now typically performed at 12–18 months of age via the modified Cantwell–Ransley technique (Figure 61.40). Epispadias repair can prove challenging. The goals of epispadias repair include a straight penis and urethra, easy urethral catheterization, normal erectile function, and a cosmetically satisfactory phallus. These goals allow the patient to stand while voiding and to have intromission during intercourse.

Preoperative considerations

In preparation for this repair, the following questions must be addressed:

1. Would preoperative stimulation of penile growth with testosterone benefit the repair?
2. Is penile straightening and lengthening required at this time?
3. Is the current posterior urethral meatus ideal, i.e. without and/or not prone to stricture?

Prior to performing the epispadias repair, several surgeons use topical or intramuscular testosterone to increase the size of the phallus and the phallic skin.[139,157,158] Intramuscular testosterone enanthate in oil (2 mg/kg) can be administered at 5 and 2 weeks prior to epispadias closure. The decision as to the need for penile lengthening can then be made after the response to testosterone has been observed. Penile lengthening can be achieved almost always at this time by division of all remnants of the suspensory ligament and scar tissue as well as further release of the crura from the inferior pubic rami. It is surprising how much of this tissue is intact at the onset of the epispadias repair. In some situations, further urethral

The dotted lines indicate the site of incision for the cavernosa – cavernosotomies; (*b*) approximation of the corpora cavernosa and performance of cavernosal anastomosis; (*c*) glans closure over urethra and skin closure. (Adapted from Brock and O'Neill,[2] with permission.)

lengthening may require free skin grafts, buccal mucosal grafts, ureteral grafts, or pedicle skin flaps. These same maneuvers can be used to repair the scarred or stenosed posterior urethra.

The modified Cantwell–Ransley technique

Cantwell first described mobilization of the urethra and moving it ventrally for epispadias repair.[159] Ransley and Woppin subsequently modified this technique and reported on their results in 1988.[160] To begin this procedure, a stay suture is placed into the glans penis (see Figure 61.40). A reverse MAGPI (meatal advancement-glanuloplasty) or IPGAM procedure at the distal urethral plate allows advancement of the urethral meatus onto the glans. Following this, skin incisions are made on the lateral edges of the urethral plate and around the epispadic meatus. This plate is dissected from the corporeal bodies up to the level of the glans distally and to the prostatic urethra proximally. Glandular wings should be developed distally as well. The corporeal bodies are then separated from each other. This allows them to be rotated medially. The urethra is then tubularized over a 6 or 8 Fr urethral catheter, using running 6–0 absorbable suture. The corporeal bodies are rotated over the urethra and reapproximated using 5–0 absorbable suture in an interrupted fashion.

Cavernocavernosotomies may be performed prior to reapproximating the corporeal bodies to help correct persistent chordee. These are performed at the point of maximal angulation. The neurovascular bundles may require mobilization to avoid injuring them if cavernosotomies are performed. The glans wings are then closed over the urethra using interrupted 5–0 absorbable suture. Penile shaft skin can be trimmed and tailored to cover the penis using interrupted 5–0 or 6–0 absorbable sutures. Z-plasties at the level of the pubis may decrease the chance of a dorsal retractile scar at the base of the penis. Postoperative care includes bladder antispasmodics, broad-spectrum antibiotics, and removal of the urethral catheter at 2 weeks.

Outcomes of this technique have revealed urethrocutaneous fistula rates ranging from 5.5 to 42%. In Lottmann and colleagues' series of 40 patients, a successful anatomic and functional result was seen in 90% of the patients at a mean follow-up period of 3 years. These authors also reported complications requiring further procedures in 45%. Complications were more common in those patients who underwent this procedure as part of an exstrophy closure vs isolated epispadias.[161] A recent review of the 10-year Johns Hopkins experience with the modified Cantwell–Ransley procedure[162] found 79 patients with classic bladder exstrophy and 14 with complete epispadias; 23% developed early urethrocutaneous fistulae, with a 19% fistula rate at 3 months postoperatively; 7.5% developed urethral stricture proximally and 83% had a straight urethra by cystoscopy or

catheterization; 93.5% had a horizontal or downward-angled penis when standing. Long-term experience with 93 patients with the modified Cantwell–Ransley repair finds a conical glans, a straight penis, and urethra below the corporeal bodies with an acceptable complication rate.[162]

MSRE stage 1+ 2: combined exstrophy and epispadias closures

In the event of a significantly delayed primary closure or an initial bladder closure failure, a simultaneous closure of the exstrophy bladder and the epispadias can be performed. The advantages to this approach include one less anesthetic exposure and increasing outlet resistance to stimulate bladder growth. Again, in this scenario, the combined horizontal innominate and the posterior vertical osteotomies are necessary for a secure bladder, abdominal wall, and posterior urethral closure and can allow transposition of the urethra to beneath the corpora with some dissection. This combined approach of simultaneous exstrophy and epispadias closures has been performed in 38 patients at Johns Hopkins Hospital with comparable results (i.e. fistula rate, BNR rate, augmentation rate, and continence rate) to age-matched patients who underwent the classic staged approach after failed initial closure.[143]

Bladder neck reconstruction

Preoperative assessment

In incontinent children after CPRE or MSRE, a continence procedure is indicated when (1) the urethra is stricture-free and capable of catheterization if necessary, (2) under anesthesia, the bladder capacity has achieved a minimum volume of 60–85 ml, and (3) the child is mature enough to participate in the postoperative voiding program.[163] This is typically around age 4–5 years. Following a careful history and physical examination, cystourethroscopy and gravity cystogram under anesthesia is performed for all patients before proceeding to open BNR. Cystoscopy and gravity cystogram provide information regarding bladder capacity and the status of any previous repairs, including correction of epispadias. Advocates of staged reconstruction emphasize the importance of achieving adequate bladder capacity prior to performing BNR. A bladder capacity of <60 ml under anesthesia or during urodynamic evaluation decreases the success of BNR.[103,135] BNR requires adequate bladder capacity because some volume is lost during construction of the bladder neck. Factors that increase the potential for the bladder to achieve adequate capacity prior to BNR include:

- avoidance of UTIs
- complete bladder emptying with institution of clean intermittent catheterization if bladder emptying is incomplete.
- epispadias repair
- avoidance of bladder prolapse.[24]

Preoperative urodynamic evaluation should be considered because it allows detection of detrusor hyperactivity or atony as well as assessment of functional bladder capacity and leak point pressures. However, the urethra of these patients may be difficult to catheterize. In these situations, a urodynamic catheter can be placed suprapubically at the time of the cystourethroscopic examination to be used later that day for the urodynamic evaluation.

Ureteroneocystostomy may be required at the time of BNR to correct VUR and to move the ureters from the lower bladder where BNR will occur. The Cohen technique is often employed. However, others have described a cephalotrigonal technique that is particularly applicable to exstrophy patients because of the angle of ureteral entry into the bladder.[164] The Marshall–Marchetti–Krantz bladder neck suspension or a bladder neck wrap using rectus muscle or fascia or gracilis may be combined with BNR as well. It is also necessary to reassess whether osteotomy might stabilize the intersymphyseal bar and improve continence at the time of BNR.

The following section describes the most commonly employed BNR techniques, including the modified Young–Dees–Leadbetter (Figures 61.41 and 61.42) and the Mitchell repairs (Figure 61.43).

MSRE stage 3: modified Young–Dees–Leadbetter bladder neck reconstruction

The modified Young–Dees–Leadbetter (YDL) bladder neck plasty[165] and the transtrigonal/cephalotrigonal bilateral ureteral reimplantation[164] are the surgical techniques employed in the MSRE stage 3. As evidenced by the name, the combined thoughts of several surgeons spanning over an 82-year period has led to the modern YDL BNR.[163] To perform a modified YDL procedure (see Figures 61.41 and 61.42),[165] the bladder neck is extensively dissected and a vertical cystotomy is made. Occasionally, a portion of the inter-

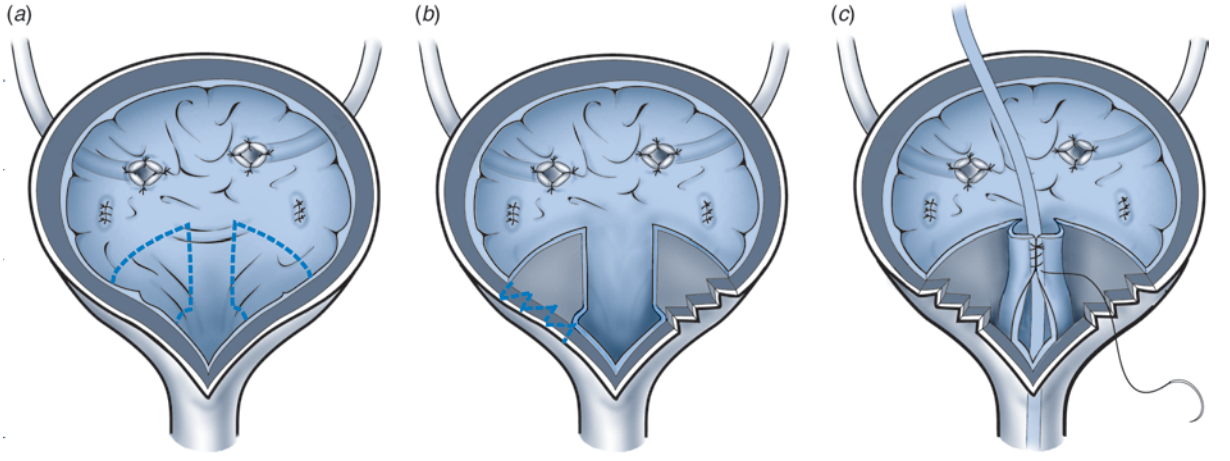

Figure 61.41 Principles of the Young–Dees–Leadbetter procedure. This is performed as the third stage of a staged reconstructive approach to exstrophy. The ureters are reimplanted as shown here to prevent vesicoureteral reflux and move them out of the area of the bladder neck reconstruction. The base of the bladder is reconstructed to lengthen the urethra and reinforce the bladder neck. (Adapted from Brock and O'Neill,[2] with permission.)

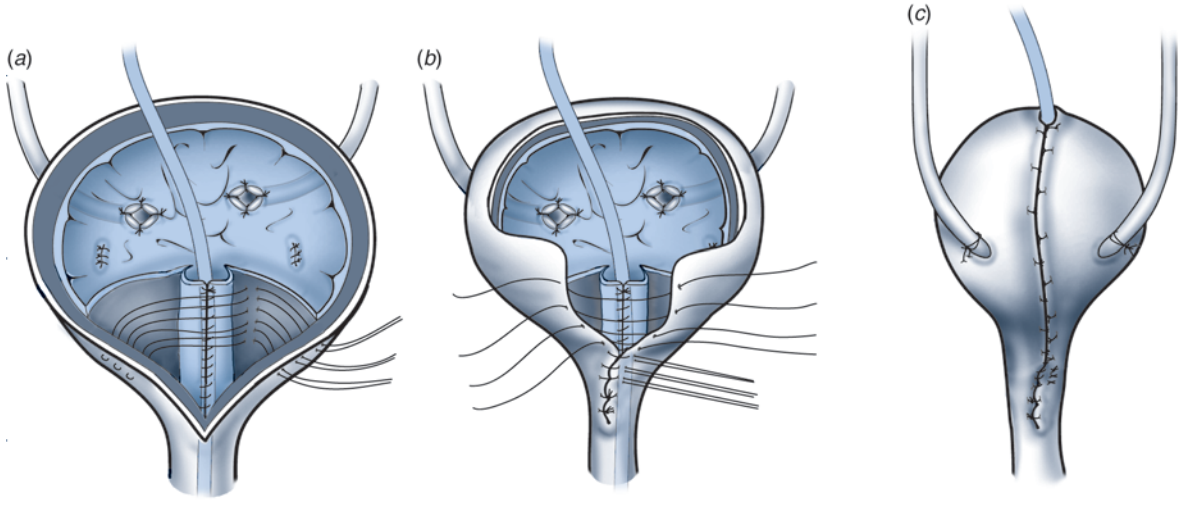

Figure 61.42 Principles of the Young–Dees–Leadbetter procedure. The bladder neck closure is reinforced with a pants-over-vest closure. Drainage catheters are brought out superiorly. (Adapted from Brock and O'Neill,[2] with permission.)

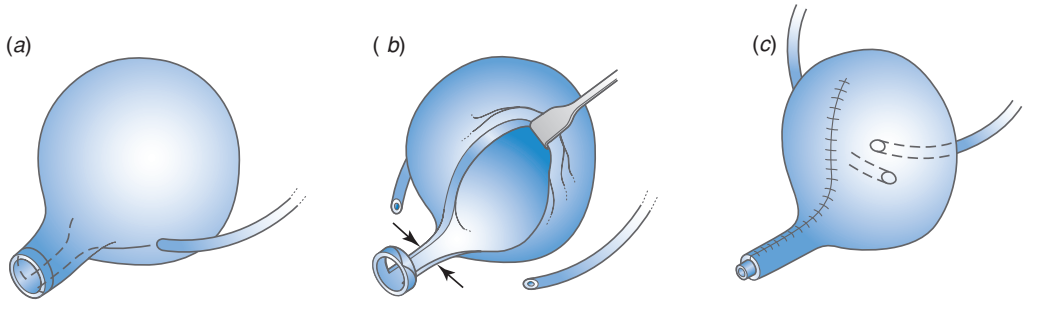

Figure 61.43 Mitchell bladder neck reconstruction. (*a*) Dotted lines represent incisions that will construct posterior bladder strip that will become urethra. (*b*) Retractor pulling inferior-most portion of the bladder superiorly, effectively enlarging bladder dome. Posterior strip (arrows) is 1.5 cm in width. Ureters detached from bladder. (*c*) Strip and bladder closed, ureters reimplanted into bladder at high level.

symphyseal bar must be resected or the pubic bar divided completely for visual access. After transtrigonal/cephalotrigonal bilateral ureteral reimplantation,[164] a strip of bladder mucosa approximately 1.5–1.8 cm wide and 3–4 cm long is generated and the lateral bladder triangles are demucosalized. Use of an epinephrine-soaked sponge during this dissection aids in hemostasis and visualization. The bladder neck may be funneled further with small vertical incisions along the cut edge of the lateral bladder walls. The neourethra is tubularized over an 8 Fr Firlit stent using interrupted or running polyglycolic acid sutures (4–0 or 5–0). The first of these sutures is a 3–0 PDS, demarcating the bladder neck. The two triangular regions of demucosalized detrusor muscle are then closed over the mucosal tube in a two-layer 'vest-over-pants' double-breasted technique using 3–0 polyglycolic acid sutures.[24] This reinforces the neobladder neck, decreases the risk of fistula, and augments the outlet resistance.[166] The sutures in the third layer are not cut, since they are used in the Marshall–Marchetti–Krantz bladder neck suspension.[163]

In the past, Gearhart et al have advocated the use of intraoperative urodynamic studies[167], but now do not routinely perform this. Retrospective studies have shown that intraoperative closure pressures of 70–100 cmH_2O will prevent urinary leakage at 50 cmH_2O intraoperatively.[164] Postoperative management is similar to that following the Mitchell repair. Some surgeons recommend avoidance of a urethral catheter in the postoperative period because of concerns that it may adversely affect later urinary continence. Urinary drainage is achieved by the use of bilateral ureteral catheters and suprapubic tube drainage.[166] Ureteral stents are removed around 2–3 weeks and voiding trials begin in the 3rd week. The urethra is calibrated with a soft 8 Fr catheter and voiding trials are begun with the suprapubic tube in place after the urine has been sterilized. If no urine is passed, cystoscopy and urethral stenting may be required for a short period of time. A bladder readjustment period may span several months before day and subsequently night continence is achieved.

Bladder neck reconstruction after CPRE – the Mitchell repair

This repair employs a modification of the Leadbetter procedure described above (see Figure 61.43).[165] In this modification, the anterior urethra is incised transversely and the incision is extended cephalad. The incision is made full thickness. After cross-trigonal ureteral reimplantation, the urethral strip is tubularized in two layers using Vicryl or Monocryl suture (4–0 or 5–0) over an 8–10 Fr urethral catheter, depending on the size of the patient. The bladder may be closed in continuity with the urethral closure. This procedure effectively narrows and lengthens the urethra. It also moves fibrotic tissue at the level of the original bladder neck away from the new bladder neck. Following the closure, dissection around the new bladder neck may be performed if a combined bladder neck wrap or sling is placed simultaneously.

Postoperatively, urine is drained through a combination of ureteral stents, a suprapubic tube, and a 6 Fr (Kendall) urethral catheter. The urethral catheter is removed 7–10 days after the operation. Ureteral stents are removed at 10–14 days after surgery. The suprapubic tube remains for 3 weeks. Voiding trials are performed with measurement of postvoid residual urine volumes to assess for urinary retention before removing the suprapubic tube. As with any BNR procedure (without augmentation), several months of adjustment will be required before the patient develops adequate bladder awareness, capacity, and control to achieve prolonged intervals of urinary continence.

Occasionally, trigonal tubularization must be combined with bladder augmentation because of small bladder capacity; most bladder neck repairs decrease bladder capacity, since bladder is used to create the continence mechanism.[168] Stomach offers the best potential to preserve spontaneous volitional voiding in this group, but places these children at risk of hematuria-dysuria syndrome which can be especially troubling in the face of persistent urinary incontinence and normal sensory innervation.[169] Other intestinal segments may also be used, according to surgeon preference. If augmentation is required, appendicovesicostomy or another form of the Mitrofanoff operation can be simultaneously performed if the urethra is difficult to negotiate because of the likelihood that patients will require intermittent catheterization to empty the bladder after BNR.

BNR results

After BNR, surgical success is defined as a dry interval >2–3 hours and spontaneous voiding without catheterization. YDL BNR and its variants have yielded surgical success, with urinary continence rates of 30–80+% for patients with bladder exstrophy.[165,170–173] Many factors influence the outcome of surgery. For instance, an initial failed bladder closure or prior failed BNR reduces the chance of achieving

subsequent urinary continence in these patients.[103] A preoperative bladder capacity of >85 ml portends a greater continence rate after YDL BNR.[174] Use of osteotomies to provide a tension-free anastomosis and patient immobilization through the use of spica casting or Bryant's traction in the postoperative period increase the success of bladder closure and subsequent continence.[143,144] Delayed bladder closure increases the likelihood of eventual need for bladder augmentation due to inadequate bladder capacity that, in turn, reduces the chance for volitional voiding.

Woodhouse and Redgrave have also reported that 8 of 13 patients with initially successful bladder closures and BNR required further surgery in their second decade of life because of poorly compliant, low-capacity bladders that caused urinary incontinence.[175] Surgeons who care for these patients must be committed to the long-term follow-up of this complex group of patients, as late complications may develop.

Outcomes of MSRE

In contrast to the high rate of renal damage reported by multiple centers employing a single-stage reconstructive effort to bladder exstrophy in the 1970s, results from a staged reconstruction approach appeared significantly better at that time. Jeffs and colleagues reviewed their results with staged reconstruction and noted normal upper urinary tracts in 87%.[176] Later series from Johns Hopkins Hospital also achieved low rates of renal damage (12% and 17%, respectively).[150,177]

Urinary continence rates with single-stage efforts in the 1960s and 1970s were also not consistently successful. Continence rates ranged from 0 to 45%, with an average of 17%. In contrast, staged efforts by Jeffs and others demonstrated continence rates of 60–88%.[122,149,171,178–182] (see Figure 61.22). These results prompted a shift from single-stage reconstruction to planned multiple-stage reconstruction for bladder exstrophy. Accumulation of the data from several series of staged reconstructions reveals that early exstrophy closure, only if in conjunction with pelvic ring approximation, results in a higher rate of continence achieved without augmentation; delayed closure, especially if without osteotomies, resulted in more bladder augmentations.[148,149] Bladder capacity under anesthesia, prior to bladder neck plasty, is the most important single predictor of eventual urinary continence.[12]

Others using the staged approach to exstrophy reconstruction have generally noted lower rates of urinary continence – as low as 9% – with the need for clean intermittent catheterization to achieve urinary continence in as many as 60% of these patients.[165,175,183] These series reflect the variable success of staged reconstruction. Conversion rates in these patients from reconstructive efforts to urinary diversion range from 7.4% to 59.4%.[175,178,184]

Exstrophy reconstructive failures

Failed initial closure

At the primary closure, failures can manifest as complete bladder dehiscence, bladder prolapse with obstruction, and stricture of the posterior urethra. Failure of the initial closure significantly decreases the chance for eventual continence with volitional voiding.[156,166,185] Gearhart and colleagues reported that only 40% of patients after a failed primary closure attempt will ultimately achieve a bladder capacity adequate for BNR.[164] If more than two closure attempts are required, chances for continence decrease to 20%.[186]

Dehiscence may be largely prevented by approximation of the pelvic ring, adequate pelvic immobilization, prevention of wound infection, abdominal distention, or urinary tube malfunction.[149,156] The child should be given a 6-month recovery period prior to a second attempt at closure. A tension-free closure, with osteotomy and immobilization, are important factors for both initial and secondary closures.[187] As noted above, the likelihood of obtaining an adequate bladder capacity for bladder neck plasty and eventual continence is markedly diminished following multiple reclosures.[187–189]

Bladder prolapse is considered a failure essentially similar to dehiscence and will require bladder reclosure/revision. Prolapse represents dehiscence of the lower end of the closure. It is a consequence of incomplete pelvic ring closure, which is why simple reclosure without osteotomy and pelvic closure is likely to be ineffective.

Bladder outlet obstruction is characterized by postvoid residuals greater than the expected bladder capacity. Outlet obstruction increases the risk of renal damage by raising storage pressures to dangerous levels; this is especially dangerous if unrecognized for several months or more.[190] Outlet obstruction also increases the risk of UTI. The bladder outlet follow-

ing initial bladder closure may be assessed with sounds or bougies 4–6 weeks after closure to detect stenosis. Ultrasonography of the bladder and upper tracts should be performed 3 months after closure to detect hydronephrosis or bladder distention that might indicate outlet obstruction. Hydronephrosis and high bladder volumes require evaluation with cystoscopy followed by urethral dilatation or the institution of intermittent catheterization as indicated. In a review of 68 patients at Toronto Sick Children's Hospital, 23% developed hydroureteronephrosis following the initial closure and all were successfully treated with dilatation of the bladder outlet or institution of clean intermittent catheterization.[190]

Neourethral stricture is often associated with the use of paraexstrophy skin flaps in the posterior urethra;[189] pubic suture reaction and erosion or urethral stents have been felt to contribute to this problem. This diagnosis may be somewhat subtle; UTIs, detectable bladder volumes on ultrasound, bladder stones, and prolonged dry periods may be indicators. Whereas nearly all closed exstrophy bladders have VUR, upper tract deterioration is always due to outlet obstruction. Management options include upper tract diversion (usually diversion into a colon conduit, which might be incorporated into augmentation or continent diversion at a later date), urethral dilatation/incision, or open urethroplasty with or without osteotomies as indicated.[191] Clearly, if renal function is compromised, the therapy must achieve reliable free drainage to allow the upper tracts and the kidneys to fully recover. No additional bladder neck or urethral reconstruction should be performed in the face of an active posterior urethral stricture.

Failed genital–urethral reconstruction

Urethrocutaneous fistula is the most common complication of Cantwell–Ransley epispadias closure, and is seen in 19% of patients at 3 months postoperatively.[162] Urethral tortuosity with difficult catheterization and strictures is uncommon with this or the Mitchell repair.

At an older age, unsightly penile scars and a short phallus may prompt further surgical intervention. Scar excision can be closed in a plastic fashion if penile skin is available; otherwise, flaps or full-thickness skin grafts can be used. Freeing all scar tissue and suspensory ligament tissue can maximize penile length. A dorsal dermal corporal graft[192] or ventral corporeal plication and rotation (Cantwell–Ransley type)[193,194] may additionally help lengthen as well as correct any chordee. However, it must be recognized that the exstrophy penis, when compared with age- and race-matched controls, is congenitally deficient in anterior corporeal tissue as assessed by MRI (see Figure 61.3). The posterior corporeal segments, attached to the inferior pubic ramus, are the same length as controls. Therefore, overly aggressive attempts at lengthening the penis may only result in corporeal denervation and devascularization without additional lengthening.[9]

Failure to gain bladder capacity

Despite a satisfactory initial closure, some bladders never attain sufficient capacity for normal function. It has become clear that multiple bladder closures, bladder prolapse, dehiscence, bladder calculi, recurrent infections, and vesicostomy have a negative impact upon the potential of the exstrophy bladder.[195] Bladder augmentation is recommended in this situation. If the bladder neck and/or urethra is problematic, a catheterizable abdominal stoma with or without bladder neck plasty or transection is performed with the augmentation.[191]

Failed bladder neck reconstruction

If urinary continence, defined as a >2–3 hour dry interval, is not achieved within 2 years of BNR, this is considered a failure. Patients who fail to achieve continence after BNR should undergo urodynamic evaluation. Some patients will demonstrate uninhibited bladder contractions resulting from increased resistance at the bladder neck after reconstruction. Treatment with anticholinergic agents such as oxybutynin can significantly improve the continence of these patients. If urodynamic evaluation reveals a bladder with adequate capacity but low leak point pressures, the YDL procedure can be performed again.

Some success has been seen in repeating a YDL repair if the bladder neck is patulous and the bladder capacity is adequate.[196] However, this is an unusual occurrence. The majority of bladder neck failures have inadequate bladder capacity and require eventual augmentation or a continent diversion.[1,154] Either the bladder neck is transected proximal to the prostate with a Mitrofanoff substitution or a continence procedure is performed, such as artificial sphincter[197,198] or collagen injection.[155]

Delayed urinary continence has been reported by Kramer and Kelalis at the onset of puberty in some males and has been attributed to prostatic growth.[194] By MRI, the prostate of exstrophy patients is clover-shaped and absent anteriorly, while its mean weight,

maximal cross-sectional area, and volume are normal.[12] Therefore, it is doubtful that growth of this abnormally configured prostate can impact upon urinary continence, although the experience of improved continence at puberty is not uncommon.

Management alternatives after failed bladder neck reconstruction

After failed BNR, several other options are available.

Artificial urinary sphincter

An artificial urinary sphincter may be used to achieve urinary continence in patients who have adequate bladder capacity and compliance but an incompetent bladder neck after BNR.[197] This device preserves the ability to volitionally void, but because of the requirements for later revision and the dexterity required to use it, it is not our first choice for younger patients. Others have described its use in combination with bladder augmentation. In one series of 11 patients who underwent sigmoid augmentation with artificial urinary sphincter placement, nine are continent. However, these patients required multiple operative revisions to achieve this degree of continence.[200] Sphincter erosion into the bladder neck or bowel segment can also occur, possibly due to prior surgeries of the urethra and bladder neck.[201]

Bladder neck wrap/sling

Bladder neck wraps and slings may also be used. However, other series reporting on the use of bladder neck wraps suggest that this procedure does not consistently maintain long-term urinary continence, especially in male patients who constitute the gender majority in exstrophy.[149,150]

Bladder neck bulking agents

Several authors have used collagen injections[155,202,203] and more recently dextranomer (Deflux)[204–206] at the bladder neck to treat patients with stress incontinence after BNR or primarily in mildly affected epispadiac patients. Ben-Chaim et al reported an improvement in continence in 53% of patients after collagen therapy, although most required multiple injections.[155] Since this injection is placed into a previously operated field, overall success rates for bladder neck bulking agents are significantly less than success rates achieved for VUR (in children without exstrophy).[207] Bulking agents can be used as an adjunctive procedure for those patients who demonstrate slight leakage due to stress incontinence after BNR.

Bladder neck closure

Bladder neck closure in conjunction with appendicovesicostomy is also an option in those patients who have failed multiple attempts at BNR. This is a last resort because it eliminates the chance to void per urethra and commits the patient to intermittent catheterization.

Urinary diversion

Proponents of urinary diversion for the treatment of exstrophy argue that the varying continence rates achieved with functional reconstruction demonstrate the unreliability of this approach.[208] The use of the native bladder will often require later bladder augmentation with intestinal segments to achieve a functional bladder storage capacity. Certainly some centers report poor rates of continence after primary reconstruction and some urodynamic studies do demonstrate low urine flow rates and poor contractility in patients following primary bladder reconstruction.[209,210]

Primary urinary diversion avoids the complications associated with functional reconstruction, including urinary retention and subsequent kidney damage, a predisposition to UTI, and later dependence on clean intermittent catheterization to empty the bladder with its own possible complications of urethral stricture formation, epididymitis, and UTI.[211] Advocates of early urinary diversion also cite a decreased risk of epididymitis and obstruction of the vas deferens by the creation of a seminal receptacle with a suprapubic window at the level of the prostatic urethra.[211] Diversion can be combined with cosmetic operative procedures for the external genitalia.

Urinary diversion is used to provide urinary continence in patients who have failed multiple attempts at functional reconstruction.[212] Some also advocate primary urinary diversion for patients with bladder plates deemed too small to close. However, because it is impossible to accurately predict which bladder plates will increase significantly in size after primary closure, we do not divert the urine primarily in exstrophy patients. Arap has described preserving the very small bladder by using it as the continence mechanism rather than a storage vessel after anastomosing the ureters to a sigmoid conduit in an antireflux manner. Final reconstruction involves attachment of the sig-

moid conduit to the neourethra and reconstruction of the abdominal wall.

Advocates of early urinary diversion argue that it achieves the primary goals of surgical intervention for bladder exstrophy with fewer operations and higher success rates than are achieved with bladder closure and urethral reconstruction. Prior to the popularization of staged reconstruction, ureterosigmoidostomy was the treatment of choice for exstrophy reconstruction. The long-term complications of ureterosigmoidostomy, including hyperchloremic metabolic acidosis, chronic pyelonephritis, and a 250–500-fold increased risk of colonic adenocarcinoma formation at the site of anastomosis, dampened enthusiasm for this procedure despite improvements in ureteroenteral anastomoses.[139,156,157] Ureterosigmoidostomy was subsequently replaced by incontinent urinary diversions such as the colonic and ileal conduits, which have the disadvantage of an external appliance. The introduction of clean intermittent catheterization allowed the development of continent urinary diversions, which are now the preferred method of urinary diversion to the abdomen in this population.

Rectal reservoirs

Various investigators have made significant improvements on the use of the rectum as a urinary reservoir, including the Mainz II pouch and the Sigma pouch.[158,161] Use of a rectal reservoir permits urinary continence without reliance on clean intermittent catheterization. Hohenfellner and Stein report a 92% rate of renal preservation in their series of children treated primarily with a urinary rectal reservoir (Mainz II pouch since 1991). Continence rates of 97% in school-age children are reported using this technique.[211] The Heitz Boyer–Hovelacque procedure involves isolation of a rectal segment for ureteral implantation followed by posterior sagittal pull-through of the sigmoid colon through the anal sphincter to achieve both urinary and fecal continence with separate anal openings for each. A small series using this procedure reported continence rates of 95% with acceptable complication rates.[213]

Complications of rectal diversion include fecal–urinary incontinence in patients with impaired anorectal sphincter control.[166] Metabolic electrolyte imbalances can be treated with complete frequent emptying of the rectal reservoir, reducing the contact time between urine and the absorptive mucosa, along with oral bicarbonate replacement. Oral bicarbonate replacement is recommended for all patients who have a base deficit of ≥2.5 mmol/L.[211] The risk of malignant degeneration still remains with use of a rectal urinary reservoir. If the increased risk of adenocarcinoma is due to conversion of urinary nitrates into carcinogenic nitrites by fecal bacteria, modifications of the rectal reservoir to prevent admixture of feces and urine may theoretically decrease the incidence.[163] Long-term results are not yet available.

Approaches to urinary diversion

Methods to construct urinary diversions include:

1 Continent diversions:
   (a) External diversions (continent urinary reservoir)
      - Indiana pouch
      - Mainz pouch
      - Penn pouch
      - Kock pouch
      - others
   (b) Internal diversions (rectal sphincter-based continence):
      - ureterosigmoidostomy
      - Sigma pouch
      - Ghoneim reservoir
      - Gersuny
      - Heitz Boyer–Hovelacque
      - rectal bladder with proximal colostomy
      - ileocecal ureterosigmoidostomy.
2 Incontinent diversions:
   - ileal conduit
   - colon conduit
   - ileocecal conduit.

Management of cloacal exstrophy

Introduction

Although cloacal exstrophy has been recognized for at least several hundred years, Spencer was the first surgeon to report the successful repair and survival of an infant with this anomaly in 1965.[164] Mortality rates of infants with cloacal exstrophy remained high for years following this initial success. In 1979, the mortality rate of a contemporary series stood at 50%.[165] Affected infants routinely died of malnutrition and sepsis. With continuing improvement in total parenteral nutrition and neonatal management, mortality rates are currently less than 10%.[214] Issues of quality of life are now paramount in this patient group.

Perioperative management

Cloacal exstrophy patients are best cared for by a team of experienced physicians, including a pediatric urologist, surgeon, orthopedist, gastroenterologist, endocrinologist, and neurosurgeon. Given many are diagnosed prenatally by ultrasound, this multiorgan system of care can often be coordinated prior to the infant's birth. Advances in neonatal care, intravenous nutrition, and the surgical management of these children have markedly reduced the mortality and morbidity of this disease. Nonetheless, the management of these children remains challenging.

In the neonatal period, the bladder and hindgut plate should be covered (Saran Wrap or Vigilon) to protect these structures. The umbilical cord should be ligated with a silk suture to prevent an umbilical clamp from abrading the bladder or hindgut plate. Antibiotic prophylaxis should be given to these patients because of the high incidence of renal abnormalities.

Preoperative studies include ultrasonography, abdominal X-ray, and karyotyping. Sonographic examination allows the evaluation of the upper urinary tracts, internal genital structures, and spinal cord. Because the genital anomalies associated with cloacal exstrophy may make it difficult to accurately identify the sex of the baby (see Figures 61.8 and 61.44), karyotyping is indicated to define the chromosomal sex in situations where the gender of the infant is unclear.

Figure 61.44 Female cloacal exstrophy. When compared with male cloacal exstrophy in Figure 61.8, each hemiclitoris is not much smaller than each hemipenis. However, closer inspection reveals labia majora instead of bilateral rugated hemiscrotum. The vaginal orifices cannot be seen in this view, but are present.

Cloacal exstrophy closure techniques

Each cloacal exstrophy patient is unique, requiring an individualized surgical plan. As indicated above, closure of a cloacal exstrophy should involve a team of pediatric specialists experienced in the care of these children. If the baby is medically stable, the initial reconstructive procedures should be performed within the first 48 hours of life, thus taking advantage of the pliable bony pelvis if closure of the entire defect is possible. However, in 29–75% of these children, spina bifida is present and may need surgical intervention, delaying the ventral abdominal wall closure. In addition, the omphalocele, seen in 88% of cloacal exstrophy patients,[215] may require immediate care to prevent rupture. The size of the omphalocele, the size of the hindgut plate and bladder plates, the extent of the pubic diastasis, and the extent of comorbidities largely dictate the timing and staging of the initial closure. A large omphalocele containing liver may preclude any attempt at complete closure.[17] If the large omphalocele is not closed because of increased abdominal pressure or tension, a silastic silo closure may be used, as a delayed closure of the abdominal hernia or an alloderm graft can be used to complete the closure.

Gastrointestinal issues are paramount. Although in the past a terminal ileostomy was routinely performed, the metabolic consequences can be significant. Currently, management decisions focus around the use of the exstrophic cecal plate and the terminal blind-ending hindgut. Options for the cecal plate include retaining it in the bladder closure as a bladder augmentation vs separating it and reconstructing it for the fecal stream. To improve bowel length and water resorption, most recommend that the cecal plate be tubularized, making the terminal ileum, cecum, and the blind-ending hindgut segment all in line for the fecal stream. The hindgut segment can be anastomosed either in an isoperistaltic or antiperistaltic fashion and brought out as the terminal colostomy. In some cases, there are hindgut duplications. No segment of bowel should be discarded unless absolutely unusable, since it could be used in reconstruction of the bowel, bladder, or vagina. Similarly, appendiceal segments should be preserved in these patients for possible use in later reconstruction

of the urinary tract. Few patients with cloacal exstrophy are candidates for an anal pull-through procedure. The best candidates are children with anal fistula and preserved innervation.

Before the dissection begins for bladder closure, ureteral catheters are placed in the ureteral orifices and secured in place with 5–0 chromic sutures. The omphalocele repair is begun, with the initial dissection beginning superiorly. The umbilical vessels are ligated and the bladder plates separated from the adjacent skin as described in the CPRE and MSRE techniques. The medial cecal hindgut plate is separated from the paired, separated bladder plates and tubularized. After the hindgut has been reconstructed, the bladder halves are reapproximated in the midline. Inguinal hernias should be repaired if detected. Primary bladder closure may be performed at this time if the intra-abdominal pressure remains low after omphalocele closure. This can be determined clinically by assessing ventilatory effort. A one-stage closure of cloacal exstrophy, including closure of the omphalocele, cecal plate tubularization and hindgut terminal colostomy, bladder and urethral closure, reconstruction of the external genitalia and osteotomies, should be performed only under optimal anatomic conditions. The decision to proceed with one-stage closure vs staged reconstruction spanning a period of months must be weighed carefully. Following forced closure, increased abdominal pressure may result in organ ischemia, excessive tension to the midline closure, or compromised lower extremity blood flow. The importance of including surgeons experienced in the care of these patients cannot be overemphasized. Thus, the reconstruction can be staged at this point by converting the cloacal exstrophy (Figures 61.8 and 61.44) into a classic bladder exstrophy (Figure 61.45). A colostomy is created with the previously described caveats in mind.

If staging was required, once the baby has recovered sufficiently to tolerate another surgical procedure, the remaining steps of reconstruction of the bladder, bladder neck, and genitalia using the CPRE technique[216,217] or MSRE technique[218] are performed as previously described. Deep pelvic diaphragm dissection with division of the intersymphyseal band is crucial to allow for appropriate posterior positioning of the bladder and urethra. After the bladder and urethra are positioned within the pelvis, reconstruction of the bladder, genitalia, abdomen, and pelvis is anatomic.

Osteotomies are almost always necessary to assist in closure and posterior positioning of the urinary tract,

Figure 61.45 Staged closure of male cloacal exstrophy. The omphalocele has been reduced. The cecal plate had been tubularized and the terminal hindgut has been brought out as an end colostomy. The hemibladders have been united in the midline but remain exstrophic.

given the pubic diastasis is usually more severe than in classic bladder exstrophy. Prior to incision, the need for osteotomies is assessed under anesthesia by watching for ischemia of the lower extremities and external genitalia during pubic reapproximation. The Johns Hopkins group recommends bilateral combined anterior innominate and vertical iliac osteotomy with gradual approximation of the bones over 1–2 weeks via the external fixture and interfragmentary pins.[20,219] The Seattle group prefers iliac osteotomies. Other authors prefer to avoid the use of osteotomies because they believe that osteotomies make the abdominal closure more difficult.[220] This has not been our experience. Fewer wound dehiscences and ventral abdominal wall hernias have been noted with osteotomies.[20]

Late procedures may be required on the urinary tract to achieve continence, including bladder neck reconstruction, bladder neck closure, bladder augmentation with stomach, ileum or hindgut, and creation of a continent catheterizable stoma.[31,221–223] Given nearly all of these children will be dependent upon clean intermittent catheterization to achieve dryness, surgical reconstruction must be individualized to meet the needs of their limitations.

Genital reconstruction and sex of rearing

Sex assignment for patients with cloacal exstrophy is currently under scrutiny both by the medical profession and by the lay public. Traditionally, male patients underwent sex conversion in infancy because

of concerns that the small, paired male hemiphalluses in these patients were inadequate for reconstruction. This approach was supported by anecdotal data of unsatisfied patients following reconstruction of the male phallus.[31] These observations, in conjunction with the prevailing notion that humans were gender neutral at birth and could undergo sex conversion safely in infancy, have recently come into question.[124,168,224] Recent evidence suggests that gender imprinting may occur during fetal development.[169] Gender identity now appears to be a much more complex issue than previously thought.

Currently males with cloacal exstrophy are routinely reconstructed as males whenever technically possible. Many gender reassigned individuals will later identify themselves in a male gender role in adolescence and adulthood.[124] Technically, however, reconstruction of external male genitalia in the cloacal exstrophy population can be quite difficult. The wide pubic diastasis and small phallic size add to the technical complexity because these findings make it more difficult to bring the two phallic halves together in the midline. In some cases, if one phallic half is diminutive, the small one can be removed and the reconstruction performed using only the larger phallic half.

Female genital reconstruction is complex as well. In genetic females, complete müllerian and vaginal duplication often leads to attempted midline reapproximation. However, if one system appears more substantial, excision of the lesser unit may be prudent. In genetic males raised female, neovaginal reconstruction is typically delayed and may require use of hindgut segment or perineal skin.

Gastrointestinal reconstruction

Short-gut syndrome is usually present in patients with cloacal exstrophy at birth, even in those with normal length of bowel. The effects of malabsorption and fluid loss from this entity appear to be clinically most significant early in life.[225] Many such children require parenteral nutritional support in early infancy.[226,227] Because of this, we share the belief that the hindgut should be constructed and placed in continuity with the intestine during initial reconstruction. This will perhaps improve nutrition and also preserve intestinal tissue that may be used in later reconstruction of the urinary tract or to form a vagina, if this is eventually needed. It is interesting that Rickham noted the importance of preservation of the hindgut in the intestine in his report of the first surviving neonate with cloacal exstrophy.[174]

Long-term concerns in exstrophy

Psychosocial concerns

Children with exstrophy face significant challenges in the development of their psychosocial identity. Reiner and co-workers have noted that 'in children with exstrophy, psychosocial and psychosexual hurdles are the rule' rather than the exception. Unfortunately, this area of development has been poorly studied but is drawing attention.[228] A preliminary study of 135 children and adolescents with bladder exstrophy revealed that a detailed sexual and social history was rarely part of the routine evaluation of these children. Other studies have shown that adolescent males with exstrophy were psychosexually delayed 2–4 years compared with their peers and delayed 4–6 years in their activity. Data on teenage girls with exstrophy are incomplete but Reiner has noted that these girls struggle with sexual self-esteem issues such as body image, genital perception, and genital appearance. Current recommendations include regular assessment of social development. These may include child psychiatric evaluation at birth with parental education about concerns. Child assessment can begin as early as 12–18 months of age and then periodically after that. Evaluation and intervention are also useful prior to operative procedures. Reiner has found that anxiety and psychosexual disorders are universal in the patients he has evaluated to date. Routine patient and parental education should be considered.[229] A recent German study found affected females to have better psychosocial and developmental outcomes than affected males.[228]

Sexual function

As exstrophy patients age, sexual function becomes a major concern, along with urinary continence and physical appearance. Libido for patients with exstrophy is characteristically present with or without surgical correction. Woodhouse noted in his series of patients with exstrophy, that many of them do develop stable partnerships. He found 33 of 43 patients married or living with a partner. However, sexual counseling in these patients is paramount because of the difficulties they face. For male patients, erectile function is usually intact.[230,231] Variable degrees of chordee can create difficulty in achieving intercourse for some patients.[231] In these situations, a female superior position provides closer apposition of the genitalia for intercourse. For female patients, sexual function is often intact.[230] In Woodhouse's

series, 14 of 23 patients had normal intercourse.[232]

Ejaculation is often present as well, despite the extensive reconstructive procedures that are done for these patients. The seminal emission may be slow and continue several hours after orgasm. Further, sperm quality and quantity are often impaired. This may be due to partial obstruction from surgery or epididymitis or recurrent UTIs. In the Johns Hopkins series, only 63% had antegrade ejaculation.[15] However, successful pregnancies have been recorded.[178] Fertility is unimpaired in female patients with exstrophy although prolapse occurs more commonly because of the lack of pelvic floor support structures. This can make bedrest necessary in the later stages of pregnancy.[233]

Conclusions

Whereas it was once deemed 'impossible to restore the bladder' (HJ Jewett, patient communication, 1957) in patients with exstrophy, modern management can successfully preserve renal function, provide urinary continence, and maintain the health of children and adults with bladder and cloacal exstrophy. The progress made over the past few decades makes us optimistic in anticipating the future of therapy for these interesting and vital patients.

This chapter is dedicated to the memory of Robert D Jeffs MD.

Unusual conditions of the bladder, including bladder trauma, urachal anomalies, and bladder diverticula

62

Marc Cendron

Introduction

Aside from the notable embryologic abnormalities of the bladder, which include bladder exstrophy and cloacal anomalies, anomalies of the bladder in children are relatively rare. In this chapter, a brief review of the embryology and function of the bladder is presented followed by a review of bladder trauma, bladder diverticula, urachal anomalies, and other bladder anomalies, including bladder agenesis and hypoplasia, bladder duplication and septation, megacystis, as well as tumors and inflammatory conditions of the bladder seen in children.

The embryology of the bladder is a complex, three-dimensional process that lasts during fetal development from the formation of the cloaca (or primitive hindgut) to the elaboration of an anteriorly located muscular reservoir connected to the ureters posteriorly and to the urethra inferiorly.[1] At about 28 days of gestation, the cloaca undergoes partitioning by ingrowth of the mesoderm from the point of confluence between the allantois and the hindgut to form the urorectal septum, which separates the genitourinary tract from the gastrointestinal tract. The urogenital sinus thus formed divides by further ingrowth of the mesoderm to form the bladder precursor anteriorly and superiorly during the 5th and 7th weeks of gestation. The bladder is connected to the allantois and to the mesonephric ducts. Growth of the anterior abdominal wall allows expansion of the bladder. The allantois, which later becomes the urachus, remains attached to the bladder dome and extends to the base of the umbilical cord. The lumen of the urachus obliterates early in human fetal development.[2]

Structural organization of the bladder occurs at 16 weeks of gestation with histologic appearance of urothelium by 20 weeks of gestation concomitant with organization of smooth muscle cells into three layers. Organization of the bladder, therefore, depends on the carefully orchestrated differentiation and growth of the mesodermal mesenchyme. Whereas the exact molecular events involved have not been clearly and precisely elucidated, functional organization of the bladder has been well identified on a histologic basis. The bladder begins to provide storage and expulsion functions as the kidneys start to produce urine at 9–10 weeks of gestation. The muscular and urothelial units are submitted to sequential stretching and contraction as documented by prenatal ultrasonography.[3] Developmental alterations in the structural organization of the bladder may allow for anomalies such as bladder diverticula to occur. In this case, normal muscular organization of the paraureteral area is altered to the extent that a muscular defect will occur, allowing for the urothelium to herniate into the perivesical space.

Bladder agenesis is seen in viable newborns exceedingly rarely – most of these female.[4,5] The exact cause of bladder agenesis has not been determined. In general the gastrointestinal tract is intact, so there is normal division of the cloaca but atrophy or failure of the bladder to develop, resulting in the incorporation of the distal ureter into the urethra, vestibule, or Gartner's duct in the female and in the prostatic urethra in the male.[6] The ureters may display distal obstruction due to their ectopic location, causing upper urinary tract dilatation, and may be associated with poorly functioning, dysplastic kidneys. Outcome for these patients depends on their renal function. Most infants born with bladder agenesis are stillborn, but survivors are usually females.[7,8] Initial urinary diversion followed by major reconstruction of the lower urinary

tract may be required should renal and pulmonary function be sufficient for survival. Other congenital anomalies are frequently seen in association with bladder agenesis.[9]

Under- or overfilling of the bladder with urine early in development may cause either underdevelopment of the bladder (hypoplasia), or overstretching (megacystis). Bladder hypoplasia occurs in disorders in which either low urine output causes the bladder not to cycle (for instance bilateral renal agenesis or severe bilateral renal dysplasia), low outlet resistance as in epispadias with incontinence, or if the bladder is bypassed altogether (bilateral ureteral ectopia). Children who have undergone bilateral nephrectomies may also experience acquired hypoplasia of the bladder, which is generally reversible with resumed bladder cycling. A pretransplant voiding cystourethrogram (VCUG) will show small bladder capacity and very often filling of the bladder will be associated with benign, self-limited extravasation of contrast[10] (Figure 62.1).

Congenital megacystis, or enlarged bladder, can be seen in association with refluxing, massively dilated ureters, known as megacystitis–megaureter syndrome[11] (Figure 62.2). The dynamics of the dilated bladder and refluxing urine cause a constant cycling or yo-yo effect between upper and lower urinary tract. Prenatal diagnosis of this rare condition has been reported.[12] Congenital enlargement of the bladder is reported in microcolon–intestinal hypoperistalsis syndrome, Ehlers–Danlos syndrome, or secondary to bladder outlet obstruction.[13,14] Initial management of patients diagnosed with megacystis is directed towards improving bladder emptying using clean intermittent catheterization and antibiotic prophylaxis in order to prevent infections. Surgical treatment of the vesicoureteral reflux should, in general, be delayed until 6 months of life. Reimplantation of the ureters may be helpful in improving bladder dynamics and emptying of the upper urinary tract, but reduction cystoplasty is not recommended.

Figure 62.2 Voiding cystourethrogram of a patient with megacystis–megaureter syndrome. Note the massive elongation and distention of the bladder with dilatation of the ureters associated with vesicoureteral reflux.

Bladder duplication and septation are also rare. In complete duplication, two functional bladders are found and are felt to possibly be the result of partial twinning.[15] Various types of bladder duplication and septation have been described (Figure 62.3).[16] In 90% of bladder duplications, two separate urethras are found. In males, duplication of the penis and in female duplications of the vagina and uterus are usually present. Management of this condition is aimed at

maintaining normal lower urinary tract function and is tailored to the individual situation.

Bladder trauma in children

Given its location early in development, the bladder is an intra-abdominal organ until 4–5 years of age, at which point, with somatic growth, the bladder becomes a pelvic organ. Trauma to the bladder is a rare occurrence in children. It is usually associated with blunt trauma to a full bladder.[17] As in adults, the most common causes of blunt trauma to the bladder are motor vehicle accidents, falls, and sport injuries.[18] Unlike adults, however, bladder injuries in children are more likely to occur in the absence of pelvic fracture, because the bladder extends above the pelvic ring in children.[19] A classification of bladder injuries has been published by Sandler et al[20] (Table 62.1).

Table 62.1 Categories of bladder trauma in children

Type 1	Bladder contusion
Type 2	Intraperitoneal rupture
Type 3	Interstitial bladder rupture
Type 4	Extraperitoneal rupture:
	(a) simple
	(b) complex
Type 5	Combined bladder injury

Bladder contusion involves damage to the bladder muscle and mucosa without disruption of the integrity of the bladder. In general, bladder contusion presents with gross hematuria. Imaging either by ultrasound or computed tomography (CT) scan will reveal a thickened, irregular bladder wall (Figure 62.4). Bladder contusion is present in one-third of all bladder injuries. Treatment of bladder contusion is usually expectant or with catheter drainage.

Rupture of the bladder can be classified as either intraperitoneal or extraperitoneal, depending on the site and mechanism of injury. Treatment is specific to the diagnosis and anatomy of the injury.

Intraperitoneal rupture is seen more commonly in children because of the anatomic location of the bladder. The mechanism of injury involves blunt trauma to the bladder, with an abrupt rise in intravesical

Figure 62.4 CT scan of a patient showing contrast extravasation in the pelvis after extraperitoneal bladder rupture due to blunt trauma.

pressure causing disruption of the bladder wall at the level of the dome, the weakest portion of the bladder wall. In general, urine will extravasate into the peritoneal cavity owing to disruption of the peritoneal lining of the bladder. Extravasation of the urine into the abdominal cavity causes urinary ascites, peritoneal signs and, in the majority of cases, abnormal serum chemistries.[21] This helps to distinguish patients with extraperitoneal rupture, who, in general, display normal serum chemistries. Patients presenting early with intraperitoneal bladder rupture display increased serum creatinine and potassium, whereas those presenting later exhibit increased serum levels of blood urea nitrogen, creatinine, and potassium, and lower levels of serum sodium. Acidosis is also occasionally observed.

Standard imaging techniques in patients suspected of having a bladder injury should include a CT scan of the abdomen and pelvis.[22] If this modality is not available, a VCUG should be obtained.[23] The diagnosis of a bladder rupture can be difficult and it must be accomplished with retrograde filling of the bladder through a urethral catheter. The contrast material should be instilled by gravity until the bladder is fully distended and postdrainage images must also be obtained. Retrograde bladder filling should be carried out during CT scan imaging because simple administration of intravenous contrast may not allow full bladder distention.[24]

Imaging of intraperitoneal bladder rupture by either CT scan or cystography will demonstrate outlining of the large and small bowel loops by contrast material and evidence of dilute contrast extending from the pelvis up into the abdominal cavity, usually along the paracolic gutter (Figure 62.5). Unless the bladder is well filled and then emptied completely, evidence of contrast material extravasation may be easily overlooked. Careful instillation (by gravity) of contrast material during the cystogram and then emptying will reveal diffuse extravasation of the contrast in the abdominal cavity with extension on the posterior aspect in the supine patient. Forceful injection of contrast into the bladder is contraindicated.

Extraperitoneal bladder rupture occurs in cases of blunt pelvic trauma usually associated with a pelvic fracture. Various mechanisms of injury have been described, and the lower half of the bladder is usually involved.[25] Sandler et al described four types of bladder injury due to blunt trauma and divided extraperitoneal rupture into simple and complex.[20] This classification is based on the appearance of contrast extravasation during the cystogram. A simple

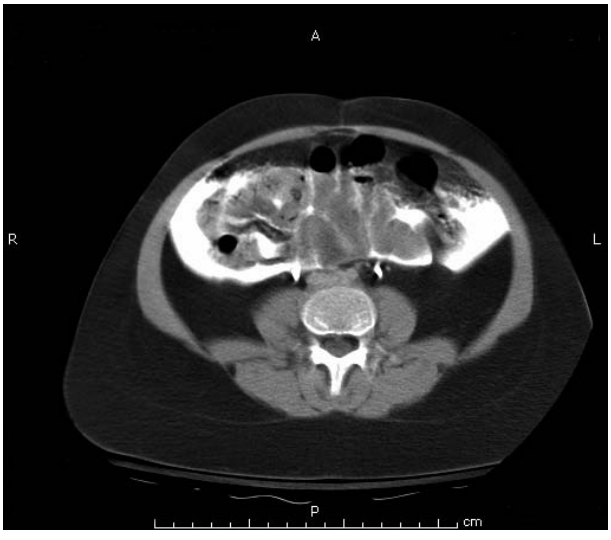

Figure 62.5 CT scan of patient with extravesical bladder rupture showing contrast extravasation extending into the abdomen along the paracolic gutters.

extraperitoneal rupture will display contrast material extravasation limited to the pelvic extraperitoneal space. Complex extraperitoneal extravasation will show contrast material outlining the muscle groups in the thigh and diffusely throughout the pelvis. It may extend into the scrotum and into the perineum. Bony spicules, which can be the result of a fractured pelvis, may also contribute to the mechanism of injury. It is important to carefully assess the bladder and the surrounding structures for fragments of bone that may contribute to further laceration of the bladder if left in place. A CT scan is the best modality for picking up bone fragments.

Management of bladder injuries is dependent on the type of injury diagnosed. In general, bladder contusion is treated with catheter drainage alone while gross hematuria is present. In general, the catheter can be removed once the urine has cleared and there is no evidence of passage of blood clots. Reimaging of the bladder is not necessary, although a pelvic ultrasound can be used to ascertain resolution of the intramural hematoma, and rule out any extravesical collections.

Standard management of intraperitoneal bladder rupture is open surgical exploration with repair of the bladder defect. This is usually carried out on an emergent or urgent basis, with concomitant exploration and irrigation of the peritoneal cavity. Once the bladder injury has been repaired, bladder drainage is accomplished by either suprapubic tube or a urethral catheter.[26] Urethral catheters appear to be as effective in draining the bladder as suprapubic catheters and

will usually ensure a shorter period of diversion.[27] Prior to removal of the drainage catheter, a cystogram should be carried out to ensure that the integrity of the bladder has been restored.

Simple extraperitoneal bladder ruptures can be treated non-operatively with urethral catheter drainage for 7–10 days. However, if a patient has experienced more complicated injuries involving the pelvis, with presence of bony spicules or fragments within the bladder, then surgical exploration can be considered to remove the fragments of bone and carry out bladder repair and drainage. Again, a follow-up cystogram is warranted to ensure that bladder healing has occurred and that there is no evidence of persistent extravasation. There are, in general, no long-term consequences of bladder injury or rupture in simple case.[28] However, in the more complicated cases involving pelvic fracture and multiorgan injuries, possibly involving a urethral disruption, the complication rate rises significantly.

Bladder diverticula

The first series of bladder diverticula in children was published by MacKellar and Stephens in 1960.[29] The advent of cystography had allowed the evaluation of children who presented with urinary tract infections. A number of these patients were found to have smooth bladder and what was then described as saccules at the ureterovesical junction. Saccules had been previously reported in trabeculated bladders secondary to bladder outlet obstruction in adults. Douglas Stephens, and subsequently John Hutch, proposed that there would be two possible etiologies to a bladder saccules or diverticula; (1) secondary to bladder outlet obstruction and (2) those that may be congenital and seen in association with a smooth bladder wall.[30] Classification of bladder diverticula in children can therefore be based on their etiology:

1 Bladder diverticula associated with bladder outlet obstruction, including posterior urethral valve, urethral strictures, large ureterocele, and neurogenic dysfunction.
2 Bladder diverticula occurring after bladder surgery, specifically after ureteral reimplantation when the hiatus is not reinforced, causing a weakening of the paraureteral detrusor layer.
3 Bladder diverticula associated with specific syndromes, such as prune belly syndrome, Menkes syndrome, Williams syndrome, and Ehlers–Danlos syndrome.
4 Bladder diverticula felt to be primary, congenital, or idiopathic diverticula with or without vesicoureteral reflux.[31,32]

Bladder diverticula in children may be single or multiple. They may be found in up to 1.7% of children evaluated by cystogram.[31]

A bladder diverticulum represents a herniation of the bladder mucosa between fibers of the detrusor muscle, resulting in an outpouching into the perivesical space. The exact etiology of congenital bladder diverticula is not known but is thought to represent an intrinsic weakness in the muscle wall of the bladder. They are most commonly seen adjacent to the ureteral orifice, as described by John Hutch in 1961.[30] This chapter confines its discussion to congenital bladder diverticula and diverticula associated with various congenital syndromes, and not diverticula associated with bladder outlet obstruction and neurogenic bladder. Congenital syndromes in which bladder diverticula are seen include Menkes syndrome, or kinky hair syndrome, a connective tissue disorder characterized by increases in tissue levels of copper and metallothionine,[33] and Ehlers–Danlos syndrome, which is characterized by joint hypermobility, skin extensibility, and tissue fragility. Ehlers–Danlos syndrome is usually inherited as an autosomal dominant condition.[34] Another condition associated with multiple bladder diverticula is cutis laxa, a syndrome characterized by decreased or absent elastic tissue. Finally, Williams syndrome is a disorder characterized by mental retardation, growth abnormalities, facial anomalies, and aortic stenosis.[35] Williams syndrome is associated with a gene deletion, possibly on chromosome 7, a gene that has a role in elastin biosynthesis. Patients with Williams syndrome have also been found to have a higher rate of renal abnormalities, suggesting the need for screening of the upper urinary tract by ultrasound.[36]

Bladder diverticula associated with chromosomal abnormalities are usually multiple and may cause bladder dysfunction. The patient has the ability to store urine but is unable to completely empty the bladder. Urinary stasis, with resultant urinary tract infections, may be the only manifestation of the bladder diverticula (Figure 62.6). Frequent, complete bladder emptying, potentially using clean intermittent catheterization, will help prevent stasis and possibly infection. Surgical excision of bladder diverticula in patients with chromosomal abnormalities must be carried out with caution since the diverticula are multiple and may recur once surgical excision of a small number of them has been carried out.

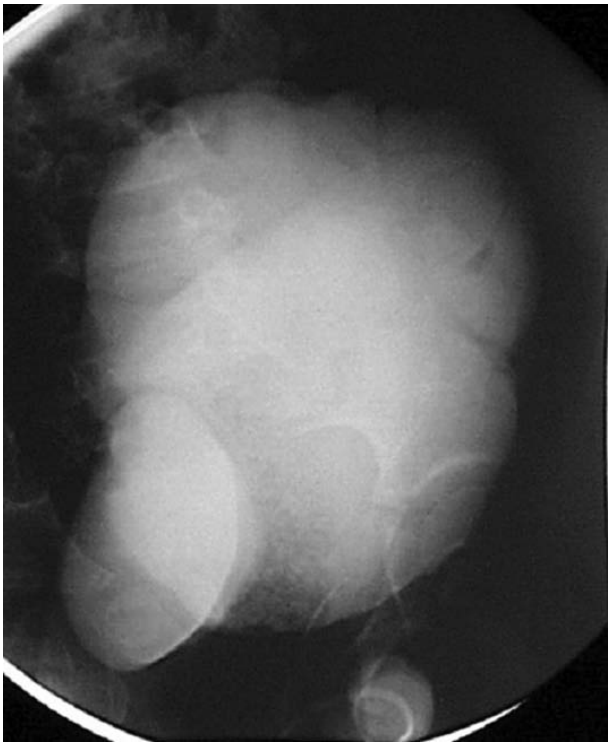

Figure 62.6 Cystogram of a 6-year-old patient who presents with recurrent urinary tract infection and incontinence. A large bladder diverticulum is seen on the right side of the bladder.

Figure 62.7 Cystogram of a bladder diverticulum associated with vesicoureteral reflux. Note, contrast in ureter, which inserts into the diverticulum.

Congenital bladder diverticula present, in general, in the course of the evaluation for urinary tract infection when a cystogram is carried out. Equal male to female distribution is noted. Bladder diverticula are usually asymptomatic, but bladder obstruction or ureterovesical junction obstruction symptoms have been reported.[37,38] Bladder outlet obstruction may be caused by an enlarging bladder diverticulum that extends inferiorly to compress the bladder neck or proximal urethra. Depending on the size and the extent of the diverticulum, the ureteral orifice may be incorporated in the diverticulum (Figure 62.7). This, in effect, will distort the normal ureterovesical junction and will prevent the ureter from having a normal intramural tunnel, thus altering the normal antireflux mechanism; therefore, vesicoureteral reflux may occur, although this diagnosis is not always easy to make.[39] Vesicoureteral reflux is associated with bladder diverticula in 5–100% of cases.[40] In addition to reflux, bladder diverticula may also be associated with distal ureteral obstruction in up to 5% of cases.[41]

More often than not, bladder diverticula are diagnosed incidentally during radiologic evaluation for a urinary tract infection. The relationship between urinary tract infection and bladder diverticula is unclear. It has been postulated that large bladder diverticula may predispose to urinary stasis, which, in turn, will provide a nidus for bacterial growth.[42,43]

Urinary tract infection in children with abnormal voiding patterns warrants close evaluation by ultrasound of the bladder and kidneys and a VCUG. These children may be found to have detrusor–sphincter dyssynergia, hyperreflexia, or hypertonia. Specifically, patients with Hinman–Allen syndrome have been reported to have associated periureteral diverticula.[44] A VCUG is the usual diagnostic modality that allows bladder diverticula to be found; however, bladder diverticula can also be noted on bladder ultrasound and CT scan of the pelvis. An intravenous urogram (IVU) will usually not facilitate the detection of bladder diverticula because the bladder will overlie the diverticulum and the diverticulum may be filled with urine, which will dilute the contrast material. Larger diverticula can also be confused with other bladder lesions such as urachal cysts, bladder ears seen in very young children, bladder herniation, ectopic ureteral insertion at the bladder neck, bladder duplication, everting ureteroceles, and ureteral stump resulting from excision of the upper part of the ureter and kidney (Table 62.2).

The relationship between bladder diverticula and voiding dysfunction has not been thoroughly clarified. Very few studies have used urodynamic evaluation to assess bladder physiology in the face of

Table 62.2 Differential diagnosis of bladder outpouching in the pediatric age group

Urachal cyst (dome of bladder)
Bladder ears (seen in young babies)
Bladder herniation (seen in large inguinal hernias)
Ectopic ureteral insertion (usually at or around the bladder neck)
Bladder duplication
Everting ureterocele
Refluxing ureteral stump

bladder diverticulum. Interestingly enough, Douglas Stephens, as early as 1960, attempted to evaluate bladder pressures in four patients of his series of 23 patients with bladder diverticula.[29] The main issue shrouding the urodynamic assessment of bladders associated with bladder diverticula is the fact that pressure recordings are difficult to interpret given the compliant nature of the bladder diverticulum. Thus, a cystometrogram may be notoriously unreliable. However, detrusor–sphincter dyssynergia, if present, may be diagnosed by performing a videourodynamic study.

The upper urinary tract may also be abnormal in the face of a bladder diverticulum. As noted, there is a variable rate of vesicoureteral reflux associated with bladder diverticulum. In addition to vesicoureteral reflux, 16–30% of patients with a bladder diverticula have renal abnormalities.[45,46] These range from focal dysplasia to multicystic dysplastic kidney. Renal lesions have also been reported in patients with vesicoureteral reflux and a history of febrile urinary tract infection. Upper tract dilatation may also be observed in cases where the bladder diverticulum causes obstruction by extrinsic compression of the distal ureter.[37] An early report from France documented seven of 43 cases of patients with bladder diverticula having evidence of renal dysplasia or multicystic dysplastic findings.[45] In a later study by Tokunaka et al out of Japan, 17 patients were evaluated, 13 of whom showed dilatation of the upper collecting system associated with renal scarring and four had small nonfunctioning kidneys.[46] The authors correlated the severity of the renal abnormalities with the position of the ureteral orifice in relationship to the diverticulum, and postulated that abnormalities in ureteral bud formation may have impacted on normal nephrogenesis. When the ureter inserted directly into the diverticulum, the likelihood of cystic dysplastic changes in the kidney increased. In light of the fact that a significant number of patients with bladder diverticula have upper tract changes, further functional evaluation of the kidney may be warranted in the form of a dimercaptosuccinic acid (DMSA) renal scan.

The management of patients with congenital bladder diverticula depends on the presentation and symptoms. As noted, most patients present with urinary tract infection. Evaluation and treatment of any bladder dysfunction should be considered prior to any attempts to treat the diverticulum surgically. It should be noted that some children with small bladder diverticula and lower grades of reflux may outgrow the reflux and have the diverticulum disappear.[40] Indication for surgical treatment of bladder diverticulum is dictated by the presence of persistent high-grade vesicoureteral reflux, and/or recurrent urinary tract infections, or documented obstruction of either the distal ureter or the bladder neck. In cases of functional bladder outlet obstruction due to a very large diverticulum extending underneath the bladder neck, excision of the diverticulum is recommended. For patients with recurrent urinary tract infection and persistent vesicoureteral reflux, diverticulectomy is recommended and should be accompanied by reimplantation of the ureter.

The surgical approach can be either intravesical or extravesical. The key surgical principle is to reinforce the muscular hiatus of the bladder to prevent reformation of the bladder diverticulum. Should the upper tract evaluation reveal a non-functioning kidney, consideration should be given to nephroureterectomy with diverticulectomy. Extravesical approaches and laparoscopic techniques can be used in these cases.[47,48]

Urachal anomalies

The urachus is an embryologic remnant derived from both the allantois and a part of the bladder.[49] Early in fetal development, the bladder descends toward the pelvis, retaining its attachment to the umbilicus through the urachus. The urachus has a lumen early in gestation that spontaneously closes, but may remain patent in cases of bladder outlet obstruction such as posterior urethral valves.[50] However, in humans, the urachus appears to close very early in gestation and rarely remains patent. Closure of the urachus is thought to occur between the 4th and the 5th months of gestation by progressive accumulation of desquamated epithelium within the lumen. Anatomically, the urachus is identified between the umbilicus and the dome of the bladder. It is 3–10 cm in length and 8–10 mm

in diameter. It is surrounded by the umbilical sheath, which extends on either side to the umbilical arteries and down to the bladder dome. The urachus is composed of three histologic layers, and a central lumen is usually hard to identify. Congenital anomalies of the urachus result from abnormal involution of the urachus; they are rare and are usually asymptomatic until adulthood. Typical presenting symptoms in children are periumbilical discharge (42%), umbilical mass (30%), abdominal or periumbilical pain (22%), and rarely dysuria (2%).[51] In another series of 26 patients, McCollum et al found that 11 patients (42%) presented with infection, seven patients (21%) with clear drainage from the umbilicus and three patients (12%) with polypoid granulation of the umbilicus, three patients (12%) with pain, one patient (4%) with recurrent urinary tract infections, and one patient (4%) with an asymptomatic sinus.[52]

Urachal anomalies can be divided into urachal sinus, urachal cyst, patent urachus, and vesicourachal diverticulum (Figure 62.8). They are isolated defects and are not associated with specific syndromes or conditions, with the exception of bladder outlet obstruction (rare) or prune belly syndrome.[54] Diagnosis of urachal

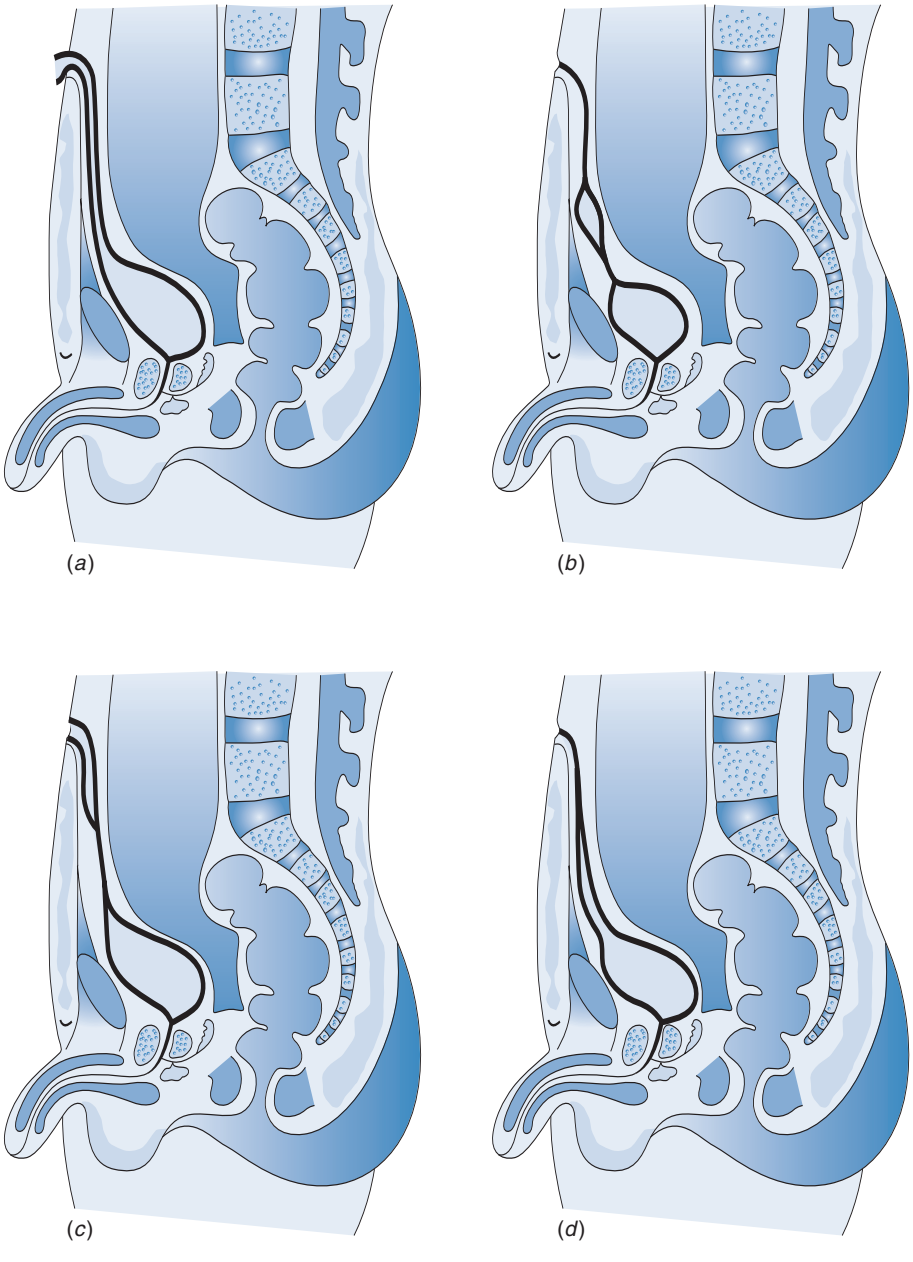

Figure 62.8 Congenital urachal anomalies: (*a*) patent urachus, (*b*) urachal cyst, (*c*) urachal sinus, and (*d*) vesicourachal diverticulum. (Reproduced from Schnyder and Candardjis,[53] with permission.)

anomalies is made either by careful physical examination or by radiographic evaluation. Children with a draining umbilicus should undergo an injection of the draining sinus with contrast.[55] Alternatively, a cystogram may reveal a patent urachus. A child presenting with a periumbilical mass should be evaluated with ultrasonography or alternatively with a CT scan.[56]

A urachal sinus occurs when the lumen of the urachus fails to completely obliterate. Children will present with intermittent or persistent drainage from the umbilicus. Occasionally, granulation tissue can be seen at the site of the lumen. A urachal sinus can become infected and inflamed, causing lower abdominal pain with fever. Very occasionally, patients will present with lower abdominal pain occurring at the end of voiding. This is due to tension on the inflamed urachal remnant. Dimpling of the umbilicus may also be reported. A sinogram is the diagnostic test of choice in this situation. Complete surgical excision of the sinus tract and resection of the omphalomesenteric duct remnant should be carried out. If an inflammatory process has been present, injury to the intraperitoneal structures is more likely as adhesions may have formed around the urachal remnant.[57]

Urachal cysts are quite rare clinically, but have been reported in up to 1 in 5000 in autopsy series.[58] They are usually found in the distal third of the urachus. Urachal cysts will present during late childhood and early adulthood, either as an asymptomatic suprapubic mass or with suprapubic pain and/or irritative voiding symptoms. Bacterial colonization and infection (usually caused by *Staphylococcus aureus*) can occur.[59,60] The infection is usually confined to the space of Retzius, but rupture of the infected cyst may cause peritoneal contamination and bowel involvement.[61,62] Severe sepsis associated with a urachal abscess has also been reported.[63]

The diagnosis of a urachal cyst is achieved either by ultrasound or CT scan. Ultrasonography allows for accurate delineation of the cystic structure and its position relative to the bladder and the peritoneum.[56] A CT scan may be helpful in cases of infected urachal cyst to determine the extent of the cyst and inflammatory process, which may be quite large and involve adjacent structures such as bowel[64] (Figure 62.9). Bladder involvement can also occur and be better defined by voiding cystourethrogram or cystoscopy.

Treatment of urachal cysts is usually tailored to the presentation. Small asymptomatic cysts may be observed. Symptomatic cysts may be excised either by open or laparoscopic techniques.[65] Infected cysts should be treated with a staged approach: first, incision and drainage with antibiotic coverage, followed by surgical excision once the inflammatory process has subsided, as documented by follow-up imaging.[66]

Figure 62.9 A CT scan of a patient with a pyourachus. Note the large inhomogeneous area anterior to the bladder, corresponding to the abscessed urachal cyst. The patient underwent percutaneous drainage and subsequent excision of the urachal cyst.

Patent urachus is a rare anomaly due to failure of obliteration of the lumen of the urachus. Such a situation may be seen in prune belly syndrome and rarely in posterior urethral valves. A patent urachus may be identified incidentally in the newborn when clear drainage is noted from the umbilicus. Symptoms can include intermittent drainage and periumbilical swelling in association with an umbilical hernia. Granulation tissue may be seen and can mimic other umbilical lesions such as healing umbilical stump, patent vitelline or omphalomesenteric duct, and infected umbilical vessel. Diagnosis of patent urachus can be made by collecting fluid and analyzing it for creatinine. Injection of the lumen with contrast or voiding cystogram will cement the diagnosis. The fistulous tract should be seen extending from the dome of the bladder to the umbilicus (Figure 62.10).

Management of a patent urachus can be expectant as a number of children will experience spontaneous closure in the first month of life.[67] In children with bladder outlet obstruction, treatment of the obstructive process will, in general, allow for spontaneous closure. Excision of the urachal tract is reserved for those patients in whom drainage persists. Surgical removal of a bladder cuff is usually recommended to ensure that all remnants of the urachus are removed.

Figure 62.10 Patent urachus in a 3-month-old boy who presented with persistent clear drainage from his umbilicus. Note the small lead ball placed at the umbilical site of drainage to help with three-dimensional localization. Contrast extends from the dome of the bladder to the base of the umbilicus, with the feeding tube in the urachus.

Vesicourachal diverticula are usually found incidentally on VCUG. Failure of closure of the lumen at the level of the bladder dome allows for the formation of a fusiform outpouching (see Figure 62.8). In general, these lesions are of little or no clinical significance. Surgical excision is required if the diverticulum does not drain well or is symptomatic.

Urachal anomalies are known to be associated with malignant degeneration in the adult population usually in the form of urachal carcinoma (adenocarcinoma). Other forms of malignancy have also been reported, such as transitional cell carcinoma, neuroblastoma, rhabdomyosarcoma, teratoma, and yolk cell sarcoma.[68,69] Whereas malignant degeneration is rare and accounts for 0.34% of all bladder cancers, management of urachal anomalies may be skewed toward surgical excision. Observation in children is certainly reasonable, using yearly ultrasound as a monitoring technique. However, parents and patients should be educated as to the malignant potential of these lesions. Yearly re-evaluation is recommended.

Inflammatory conditions of the bladder in children

Inflammatory conditions of the bladder include eosinophilic cystitis and interstitial cystitis (IC). Fewer than 25 cases of eosinophilic cystitis have been reported in children.[70] Eosinophilic cystitis may be diffuse or localized and present as an intravesical mass. Symptomatology will usually be irritative voiding symptoms with frequency/urgency, suprapubic pain, and hematuria. Ultrasound imaging of the bladder may reveal diffuse thickening of the bladder, and the diagnosis will be made by cystoscopy and biopsy of the lesion. The disorder is felt to be caused by an antigenic stimulus (infection, foreign body) that triggers an immunoglobulin E (IgE)-mediated eosinophilic invasion of the bladder wall. Degranulation of the eosinophils then promotes release of inflammatory mediators. The process is felt to be self-limited, with little or no consequences on the lower urinary tract.[71] Various therapeutic modalities have been reported to alleviate symptoms. These modalities include antibiotics, antihistamines, corticosteroids, cyclosporin A, surgical resection of the lesion, and even partial cystectomy.[72] The condition is occasionally seen in association with chronic granulomatous disease.[73]

Myofibroblastic tumor of the bladder is another rare inflammatory condition seen in children. Symptoms are similar to that of eosinophilic cystitis. A distinct mass is seen on ultrasound, and histologically these lesions are characterized by spindle cells with myofibroblastic and fibroblastic proliferation associated with a prominent inflammatory process.[72] Etiology of this condition has not been elucidated. The lesions may be fairly aggressive and may reoccur. Transurethral resection may be curative but large tumors may require more extensive open resection. These tumors are benign but should be differentiated from sarcomas or lymphomas. Immunohistochemical staining is the best way to evaluate these lesions.[72] As noted previously, eosinophilic cystitis may also present as a discreet mass, but histologically the lesion appears less invasive than myofibroblastic tumors.

IC has been reported in children and in adolescents.[74,75] However, its incidence is hard to ascertain, as it is a difficult diagnosis to make and thus may go under-reported. Held at al note that adult women with IC are 10–12 times more likely to report childhood bladder problems than a group of matched control individuals.[76] In the face of irritative voiding symptoms associated with painful bladder, cystoscopic findings and histology are needed to make the diagnosis of IC in children and adolescents. In a relatively small cohort of patients, Close et al documented IC in 16 children under 16 years old.[75] All were treated by hydrodistention, and 50% of them

responded while the rest required further therapy. Bladder compliance was reduced in only three cases.

IC should be considered as a possible diagnosis in children with severe irritative symptoms associated with painful bladder who do not respond to first-line therapy. However, the diagnosis of IC may be elusive.[76]
